The known membrane protein structures fall into three categories: a-helical, b-barrel, and monotopic membrane proteins (Table 1and Fig. 1). The majority of the structures have been determined using three-dimensional crystals and X-ray diffraction. However, the structure of a plant light-harvesting complex has been determined using electron crystallography on two-dimensional (single-layered) crystals of the protein reconstituted with lipid. The structure of bacteriorhodopsin has been solved by both methods. Electron microscopy increasingly contributes to our knowledge of membrane protein structures. Improved image processing methods and particularly the use of cryoelectron microscopy techniques (see Single Particle Reconstruction) have already resulted in a number of low-resolution structures, either in projection through the membrane or in three dimensions after merging data from tilted two-dimensional crystals. Many of these structures are likely to evolve into a higher resolution.

Figure 1. Different structural types of integral membrane proteins. (**a**) A helical membrane protein complex: the two-sut
Paracoccus denitrificans (PDB, file name 1AR1). (**b**) A b-barrel membrane protein: the OmpF porin of *E. coli* (1OPF). (

2.1. Helical Superfolds

Helical membrane proteins are characterized by having a-helices (Fig. 1a), and they appear to have superfolds characterized by the number of membrane-spanning segments and their inside/outside topology (1). In particular, there is a large family of seven-helix membrane proteins, the "7TM" superfamily, that typically act as receptors in eukaryotic organisms. Other abundant superfolds are formed by **four-helix bundles**, and some proteins have 12 predicted transmembrane helices. The latter often appear to function in **transport** of solutes or ions across membranes. A subclass of the 12-helix proteins may be formed by dimers, in which each monomer contains six a-helices.

Analysis of these superfolds may be used as a robust rule of thumb in prediction of the function of a novel integral membrane protein. It is clear, however, that no strict rules exist. For example, **membrane transport** is catalyzed by proteins that fall into different topological categories. An example is the tetrameric **potassium channels**, which can be divided into two subclasses. In one case, the monomer has two transmembrane helices, and hence the tetramer has eight, whereas the monomer of the second subclass has six membrane-spanning segments and the tetramer has 24. In both cases, only one helix of each monomer lines the ion-conducting channel (2).

The proteins in the "7TM" superfamily all have similar topologies with seven membrane-spanning a-helices and the *N*-terminus on the external side of the membrane. Many members of the family, such as rhodopsin, are G-protein-coupled receptors (see GTP-Binding Proteins and Heterotrimeric G Proteins) that mediate signaling from the outside to the cellular interior and have a sensory function in processes such as hearing, seeing, smelling, and tasting. Generally speaking, however, the 7TM proteins are functionally very diverse. It seems that the seven-helix fold is an archetype that is able to adapt to different functions by accommodating diverse ligands or **prosthetic** groups.

2.2. Beta-Barrel Membrane Proteins

In a few membrane proteins, notably the **porins** and the membrane-bound form of some toxins such as the a-hemolysin (a heptameric toxin from *Staphylococcus aureus*), the transmembrane portion comprises an b-barrel made of 8, 14, 16, 18, or 22 antiparallel **b-strands** (Figure 1b). The b-barrel is stabilized by extensive hydrogen-bonding between the b-strands. The interior of the barrel is hydrophilic, reflecting its function of facilitating diffusion of small molecules across the membrane. Because of the extended conformation of b-strands, fewer than 10 residues are needed to traverse the bilayer. Of these residues, only every second has to be hydrophobic. This complicates the prediction of transmembrane b-strands from just the primary structure. In fact, the amino acid sequences of porins and a-hemolysin are as hydrophilic as are those of soluble proteins. The monomeric a-hemolysin is a soluble protein, which rearranges to form the heptameric transmembrane pore upon interaction with lipids or detergent.

2.3. Monotopic Membrane Proteins

Prostaglandin H2 synthases (also known as cyclo-oxygenases 1 and 2) require detergents for solubilization, but their three-dimensional structures contain no transmembrane a-helices or b-strands (Fig. 1c). These enzymes appear to be examples of monotopic membrane proteins. They associate with the membrane via four short amphipathic a-helices that run approximately parallel to the membrane plane (Fig. 1). The helices are amphipathic and contain a number of aromatic side chains, which are probably exposed to the lipid headgroup region of the membrane. Most likely, the four-helix motif is only immersed into one layer of the bilayer. This means that, although prostaglandin synthases are genuine membrane proteins, they are not transmembrane proteins. It is not known how common this type of arrangement is, because sequence-based prediction algorithms for monotopic membrane anchors have not been developed. The membrane-binding domains of cyclo-oxygenases 1 (sheep) and 2 (human) are the least conserved part of the enzymes (33% identity). However, the three-dimensional structure of the membrane anchor is well-preserved.

3. Structural Stability of Membrane Proteins

In contrast to soluble proteins, membrane proteins fold in an environment from which water is largely excluded. The absence of water forces the protein to form hydrogen bonds between peptide

groups within the molecule itself, driving the formation of transmembrane helices or the transmembrane b-barrel of **porins**. The hydrogen bonds in transmembrane helices are probably much stronger than the average bonds in soluble proteins, because there is no competition to form hydrogen bonds with water. As a result, each transmembrane helix is a highly stable and rigid structure that can be thought of as an independent folding unit. In soluble proteins, the tertiary fold at least partially results from the action of the hydrophobic effect, which brings about formation of their hydrophobic core. In membrane proteins, the association of the transmembrane helices within the bilayer cannot be driven by the hydrophobic effect. Mutagenesis studies and analyses of known structures suggest that optimal van der Waals interactions are responsible for the helical packing within the bilayer. Buried residues are more conserved and more polar than those exposed to lipid, suggesting that a subtle stereochemical fit plays a key role in the formation of the tertiary structure. The interiors of soluble and membrane proteins have been concluded to have similar polarities.

A consequence of this increased stability is the resistance of membrane-spanning helices toward **denaturation** with commonly used agents, such as **SDS**, urea, and **guanidinium** chloride. In the routinely used SDS-PAGE, integral membrane proteins with multiple transmembrane helices commonly migrate faster than expected from their true molecular weight. This may be due to (a) the maintenance of secondary and/or tertiary structure under the conditions in which soluble proteins are totally denatured and/or (b) increased binding binding of the anionic detergent.

Membranes

Membranes are the anatomical boundaries of cells and their organelles (see also Endoplasmic Reticulum, Mitochondria, Nucleus, and Plasmalemma). The composition of membranes, which are principally lipid and protein, varies from 20% protein in the myelin sheath of nerve to 80% protein in bovine erythrocytes. The lipid is arranged as a planar bilayer (bimolecular layer) with an internal hydrocarbon interior shielded from the aqueous exterior and cytoplasmic interior of the cell by the polar moieties of the lipids. The distribution of phospholipids across the midplane of the bilayer is often asymmetric (1); in erythrocytes the external monolayer of the membrane bilayer contains mostly neutral phospholipids, such as phosphatidylcholine and sphingomyelin (see Lipids), while the internal monolayer contains a majority of the amino-phospholipids (phosphatidylserine, phosphatidylethanolamine) (2). This asymmetric distribution of lipids is maintained by metabolic

processes which, when suppressed, lead to a slow reversion toward a symmetric lipid distribution across the bilayer (3). The lipid composition of membranes varies widely within a cell, and from tissue to tissue.

The proteins that make up membranes represent virtually all the enzymes of the primary biochemical and physiological processes of living cells (eg, photosynthesis, oxidative phosphorylation, nerve conduction), the centers for sensory perception (vision, taste, touch, smell), and for the selective transport of ions and molecules across membranes. Membrane-associated proteins are of two classes, those that are readily dissociated from the membrane and those that require drastic treatments for removal, a process that inevitably destroys the membrane. The former are called *peripheral* or *extrinsic* membrane proteins, while the latter are called *integral* membrane proteins. Integral proteins have been visualized in electron micrographs of **freeze-fractured** membrane preparations; they contain a stretch of 21 to 26 **hydrophobic** amino acid residues coiled into an **a-helix** that is believed to facilitate the spanning of a membrane bilayer (see Amphipathic).

The apparent morphological and compositional stability of membranes belies a system that seethes with activity. Both lipid and protein components undergo continuous synthesis and degradation, without any apparent synchronization of these processes. Thus, the various lipids and protein components in the same membrane turn over at different rates relative to each other (4). Membrane assembly is believed to occur on existing membranes, which serve as templates for insertion of newly synthesized protein and lipid. The primary centers for lipid and **protein synthesis** are also located on membranes. For **eukaryotic** cells the principal locus is the endoplasmic reticulum, and for **bacteria** the locus of synthesis is the plasma membrane. Approximately 180,000 reactions per second are performed by a bacterium to synthesize the membrane lipids for a cell population that doubles in size in 20 min. Microorganisms and many animals (eg, fish, reptiles) are *poikilothermic*, and their physiological temperatures are largely a function of the environment in which they live. Wide variations of environmental temperature are accommodated by changes in the ratio of saturated to unsaturated fatty acids in the phospholipids of their cell membranes; higher temperatures generally yield increasing amounts of saturated fatty acids.

Protein insertion into membranes requires leader sequences on the protein to convey information about the location for insertion, and to initiate entry through the lipid bilayer (5) (see Topogenesis). Cell membranes also possess the facility to undergo morphological and topological transformations that allow them to fuse with other membranes. They may also undergo endocytosis, in which extracellular material is internalized by invagination of the plasma membrane, followed by formation of a pinched-off vesicle, and exocytosis, where internalized material is transported out of the cell. Proteins in membranes are distributed randomly as a mosaic and diffuse laterally within the plane of the membrane with rates that are 2 to 5 orders of magnitude lower than in aqueous solution. This process has been visualized by fusing tissue culture lines of human and mouse cells with Sendai virus. The fused cells have both mouse and human surface antigens, and the movement of both may be followed by attaching **fluorescent**-labeled antibodies. Within 40 min after the cells are fused, the parent proteins, initially separated, are almost completely mixed and uniformly distributed over the surface of the fused cells (6). Lipid components of membranes also diffuse across the surface of the cell; diffusion coefficients of the order of 10^{-8}cm^2/s have been measured (7). Exo- and endocytosis and membrane fusion may also involve processes in which specific lipids are recruited from the plasma membrane to form **vesicles** (8).

Lipid bilayer models of cell membranes (see Monolayer and Liposomes) ostensibly separate the physical and structural properties of the membranes from the biochemical processes superimposed by metabolism. The membrane bilayer is unilamellar, and within this ubiquitous biological structure integral proteins are distributed randomly, free to diffuse over the surface. These properties are embodied in the fluid-mosaic model, which assumes that the lipid bilayer is unilamellar and incorporates the concept of a viscous lipid matrix for dissolved globular proteins that diffuse laterally within the membrane. A more detailed view of the fluid membrane structure is described in the

Critical Unilamellar State Model, which proposes that the membrane bilayer is a unique state that assembles and is stable only at a critical point, the physiological temperature, T_p (9). From this perspective, the membrane bilayer assembles spontaneously from cytoplasmic lipid metabolic pools maintained by the cell at a critical composition, and it illustrates the properties that are characteristic of critical states (10). This model is supported by findings that in large unilamellar vesicles, the membrane bilayer structure forms spontaneously only at a critical temperature that depends on lipid composition and exhibits specific heats and mechanical properties that are found only at this temperature (11). For the total lipid extracts of a wide variety of cellular systems, the critical temperature for assembly of the unilamellar structure is the physiological temperature, T_p, of the cell from which the membrane lipids are removed (9, 11). Some of the cells for which this phenomenon has been observed include bacteria (T_p = 20° to 60°C), human erythrocytes (T_p = 37°C), brain tissue (squid, T_p = 16°C; rat, T_p = 39°C; human, T_p = 39° to 40°C), and hamster synaptosomes (T_p = 37°C). The concept of a membrane bilayer that assembles and is stable only at the physiological temperature has been utilized as the basis of a theory of neurodegeneration (12).

Memory Cells

Immunological memory is a basic feature of the immune system. It originates simply because when an immunogen is given for the first time, antibody production starts slowly, consisting first of

IgMthat is progressively replaced by IgG after class switching of the isotype. When the same antigen is given a second time, the antibody response is much faster, is maintained longer, and results exclusively in IgG production. Immunological memory is of course the basis for **vaccination**. This specific response indicates that some memory mechanism is operating. This phenomenon is characteristic of **T-cell**-dependent antigens, so the basis for immunological memory might be found in both the T- and **B-cell** populations. Furthermore, this recall effect has been reported for pure T-cell responses, such as delayed-type hypersensitivity, reinforcing the idea that the T-cell compartment also has memory. Are there T and B memory cells, or is immunological memory the result of a systemic organization of the immune system?

An obvious marker that might be expected from a memory cell is that it expresses a repertoire different from naive unstimulated cells. This is clearly the case for B cells that immediately produce IgG antibodies in secondary responses. Memory B cells arise in germinal centers, in the course of a primary immunization. Once stimulated B-cell clones have switched to IgG, they start to accumulate somatic hypermutations . *In situ* selection by antigen ensures emergence of clones with the highest affinities, which may evolve either to plasma cells that will produce circulating antibodies or to memory cells, which may be endowed with a long lifespan. Memory cells are $IgM^{-}IgD^{-}$ and have accumulated somatic mutations that can be identified by single-cell gene sequence determination in germinal centers. In many occasions, however, reports have claimed that memory cell survival was strictly dependent on persistence of antigen, which may be maintained as immune complexes on follicular dendritic cells in lymph nodes. Finally, it should be mentioned that the existence of separate lineages of B cells has been claimed, one of which is devoted specifically to expand as memory cells.

Identification of memory T cells is not based on a change in repertoire, because T cells do not use the class switch nor the somatic hypermutation processes. Memory T cells have nevertheless been identified, because they differ from naive T cells by an increased density of surface markers that essentially include cell adhesion molecules such as LFA-1, CD2, LFA-3, ICAM-1, and several integrins of the VLA family. Various forms of CD45, a surface phosphatase, also distinguish naive T cells (CDR5RA) from memory T cells (CD45RO). Memory cells presumably result from a clonal expansion that occurs during primary immunization. Expression of adhesion molecules in increased amounts facilitates migration of memory T cells to diverse compartments of the organism, where they may encounter **antigen presenting** cells, such as Langerhans cells in the skin, thus favoring in this case the emergence of delayed-type hypersensitivity, a pure T-cell response. Memory T cells have also been reported to have a long lifespan.

Despite the arguments supporting the existence of both B and T memory cells, one cannot exclude the possibility that immunological memory might be the result of a more complex system organization that would be inspired most from the central nervous system memory. More data will be required to clarify this issue.

Mendelian Inheritance

Mendelian inheritance patterns occur when (i) **alleles** in heterozygous **diploids** have equal chances of being transmitted to haploid gametes, thus giving rise to a 1:1 segregation, (ii) alleles of different loci combine at random in the gametes, and (iii) gametes fuse at random to form diploids.

The name *Mendelian* honors Gregor Mendel, who observed and counted carefully the phenotypes produced in many crosses of pea plants, *Pisum sativum* (1). This plant was convenient because of its relatively short generation time, easy handling, and abundant offspring. He tried other plants as well; and he found confirmatory evidence with some of them, and results that could not be understood at the time with others—for example, *Hieracium*.

Mendelian inheritance is sometimes expressed in the form of Mendel's laws, although we owe this formulation largely to later writers, such as C. Correns and H. de Vries. The first law is the law of segregation (of alleles to gametes); the second is the law of independent assortment (of alleles of different genes). The uniformity of the hybrid generation is sometimes considered a law as well.

Two underlying assumptions of Mendelian inheritance were introduced before Mendel. One is the *individuality* and *autonomy* of inherited traits: Many traits present clear alternatives that are preserved in successive generations without blending (see Genetic Marker). The other is the *combination* of separate traits with each other. These assumptions were expressed clearly by Michel Sageret (2) following his observations with melons, *Cucumis (Cucurbita) melo*. He found "marked combinations of various characters without any mixture between them" and understood that this gives, nature "the ability to vary infinitely its products and avoid monotony." The combinations of individual traits superseded the traditional holistic opinion for which every aspect of living beings had to be seen as a manifestation of a whole.

It is not generally known that Sageret came close to summarizing Molecular Biology, using in the figured sense terms from the arts of typography and casting, as our textbooks do today: "To what is due this ability of nature to reproduce in the descendants characters that belonged to their ascendants? We do not know, but we may well suppose that it depends on a type, on a primitive mold that contains the germ of all the organs, germ that sleeps and awakes, and develops or not according to the circumstances".

The rules of Mendelian inheritance provide quantitative forecasts for the frequency of different traits and their combinations in the offspring of defined genetic **crosses**. Consider a pair of genetic markers, phenotypes "A" and "a," governed by the alleles *A* and *a* of a single gene (see Genetic Marker), and two diploid parents that "breed true" [ie, are homozygous for the alleles under consideration (see Homozygote, True Breeding)]; the parental genotypes are written *AA* and *aa* to indicate the fact that diploids carry two copies of each allele (Table 1). Their gametes carry alleles *A* and *a*, respectively, and the F_1 diploids produced by their fusion will be *Aa*. The phenotype of the offspring will be uniform and will depend on the dominance or recessivity of the alleles; assuming that *A* is dominant over *a*, the offspring phenotype will be "A." The gametes of F_1 individuals will have equal chances of carrying the *A* or the *a* allele; this is conveniently represented by an algebraic sum in which each allele takes its probability as a coefficient. The fusion of gametes of F_1 individuals produce a heterogeneous F_2 segregation: The random combination of gametes is well represented by the multiplication of their respective algebraic expressions (the squaring, in this case) and yields an algebraic expression of all genotypes each with its own probability as coefficient. The offspring of other crosses—for example, a backcross—is easily predicted by similar considerations.

Table 1. Mendelian Segregation of a Monohybrid (a Dominant Allele *A* and a Recessive Allele *a*)

Generation P1:	AA	×	aa
Phenotypes:	"A"		"a"
Their gametes:	A		a
Generation F1:		Aa	
Phenotype:		"A"	
Their gametes:		$\frac{1}{2}A + \frac{1}{2}a$	
Generation F2:		$(\frac{1}{2}A + \frac{1}{2}a) \times (\frac{1}{2}A + \frac{1}{2}a) = \frac{1}{4}AA + \frac{1}{2}Aa + \frac{1}{4}aa$	
Their phenotypes:		$\frac{3}{4}$"A" + $\frac{1}{4}$"a"	
Testcross of the F1:	Aa	×	aa
Phenotypes:	"A"		"a"
Their gametes:	$\frac{1}{2}A + \frac{1}{2}a$		a
Generation R2:		$\frac{1}{2}Aa + \frac{1}{2}aa$	
Their phenotypes:		$\frac{1}{2}$"A" + $\frac{1}{2}$"a"	

This algebraic treatment can be generalized to several genes, each with their respective alleles (Table 2). Again, multiplication of polynomials expresses the random combinations of the alleles of different genes.

Table 2. Mendelian Segregation of a Multihybrid (*n* Pairs of Alleles, $A^1{}_i$ and $A^2{}_i$)

Generation P1:	$A^1{}_1A^1{}_1¼A^1{}_nA^1{}_n$		$A^2{}_1A^2{}_1¼A^2{}_nA^2{}_n$
Their gametes:	$A^1{}_1¼A^1{}_n$		$A^2{}_1¼A^2{}_n$
Generation F1:		$A^1{}_1A^2{}_1¼A^1{}_nA^2{}_n$	
Their gametes:		$\prod_{i=1}^{n}(\frac{1}{2}\mathbf{A}_i^1 + \frac{1}{2}\mathbf{A}_i^2)$	
Generation F2:		$\prod_{i=1}^{n}(\frac{1}{2}A_i^1 + \frac{1}{2}A_i^2)^2$	

Mendelian inheritance is a consequence of the phenotypic traits being governed by individual genes located on the chromosomes. It is valid for genes located in the *autosomes* (chromosomes present in two copies in a diploid nucleus) and must be modified in the cases of imperfect diploidy, such as sex linkage and aneuploidy. The random combinations of different traits apply only when the responsible genes are located on different chromosomes or at sufficient distance in the same chromosome. Genes

located sufficiently close to each other in the same chromosome tend to be transmitted to the gametes as a block.

The random segregation of alleles to the gametes does not occur in the presence of *segregation distorters*. Thus, gametes with certain changes in the structure or the number of chromosomes are formed less often than expected, particularly in the meiosis of females. Some genetic elements actively bias the segregation to their own favor. This phenomenon is called *meiotic drive*. Some meiotic-drive elements fail to impose themselves on the whole population because they are held in check by opposing selection pressures.

Independent assortment of chromosomes does not occur when there is *affinity* between some nonhomologous chromosomes, so that they tend to move together during meiosis. The result is an apparent linkage between alleles of different chromosomes.

b-Mercaptoethanol

b-Mercaptoethanol has the simple structure HO—CH_2—CH_2—SH, abbreviated here as HOEtSH, and its thiol group is of typical reactivity and ionizes with a pK_a of about 9.6. It is one of the most extensively used reagents for protecting biological materials, especially proteins, from oxidation. It has the advantage of being a stable, colorless liquid that is readily miscible with water. Its thiol group will react with oxidants and heavy metals, thereby protecting biological materials, and it can also be used to keep the thiol groups of proteins and other macromolecules in the reduced form. It is frequently used to reduce disulfide bonds in biological materials, especially in preparation for SDS-PAGE.

Mercaptoethanol has limitations in this respect that should be recognized. Its thiol group is not a very potent reductant, very similar to that of glutathione. The equilibrium constant for **thiol-disulfide exchange** between these two molecules,

$$2\text{HOEtSH} + \text{GSSG} \leftrightarrow \text{HOEtSH} + \text{HOEtS-SG} + \text{GSH} \leftrightarrow \text{HOEtS-SEtOH} + 2\text{GSH} \qquad (1)$$

is approximately unity. The equilibrium constant for the reduction of stable disulfide bonds in folded proteins,

$$P_S^S + 2HOEtSH \leftrightarrow P_{SH}^{SSG} + HOEtSH \leftrightarrow P_{SH}^{SH} + HOEtS\text{-}SEtOH \quad (2)$$

$$K_{eq} = \frac{[P_{SH}^{SH}]\,[HOEtS\text{-}SEtOH]}{[P_S^S]\,[HOEtSH]^2} \quad (3)$$

has been measured with glutathione and will be about the same for mercaptoethanol; values in the region of less than 5×10^{-3} have been measured for the overall reaction of Eq. 3 (1). Therefore, a large excess of mercaptoethanol will be required to reduce stable protein disulfide bonds.

A further problem is that mercaptoethanol becomes air-oxidized readily, especially at alkaline pH values, and the disulfide form is a potent oxidant (Eq. 2 and 3). If only 1% of a 10 mM solution of mercaptoethanol becomes oxidized, it will be unable to reduce stable disulfide bonds like those previously described. In the presence of significant amounts of the disulfide form of mercaptoethanol, mixed disulfides of the mercaptoethanol with protein thiol groups will be significant. The reagents **dithiothreitol** and **dithioerythritol** are much more powerful in reducing disulfide bonds because they form a stable, intramolecular disulfide bond; the disulfide bond of HOEtSSEtOH can be considered to be intermolecular because two molecules are produced when the disulfide bond is reduced. A solution in which 99% of dithiothreitol has become oxidized will be no less potent at reducing protein disulfide bonds than the above solution of mercaptoethanol that was only 1% oxidized.

Mercurials

The medicinal use of mercurials can be traced back over 3000 years, although their modern therapeutic applications began with the discovery of the diuretic action of mercurous chloride in 1849. When Zeise discovered C_2H_5SH in 1834, he called it “mercaptan” (corpus mercurium captans) because the formation of mercury derivatives was a striking characteristic (1). The aryl mercurials, such as *p*-mercuribenzoate, were introduced as enzyme inhibitors in 1937, and the alkyl mercurials, such as methylmercuric chloride, in 1950. Organomercuric ions of the type $R–Hg^+$ comprise a useful family of reagents that react specifically with thiol groups and can be used as titrants, reactivity probes, or reporter groups, depending upon the characteristics of group R. Such organomercuric ions are monovalent and react with a single thiol group:

$$X\text{-}SH + R - Hg^+ \leftrightarrow X - S - Hg - R + H^+ \quad (1)$$

In contrast, mercuric ion, Hg^{2+}, tends to react with two thiol groups and to cross-link them. The reaction with either is reversible, but the binding is tight, so that the equilibrium generally lies far to the right, unless an excess of another thiol reagent or of cyanide is added, when the original thiol group can be regenerated. A slight complication is that mercuric ions exist in a variety of loose complexes with components of the aqueous solution, such as hydroxide and chloride ions (2).

The classical organomercurial reagent was *p*-mercuribenzoate (3):

(2)

which is often called *p*-chloromercuribenzoate, although the chloride component is simply a counterion, and it makes little difference what salt is used. It has useful spectroscopic properties, and its absorbance increases at 250 nm upon reaction with a thiol group. Many variants have been prepared and used subsequently. Nevertheless, such reagents are not widely used now, in part because the adduct is not irreversible, and the original reagents are always present in significant quantities, due to the reverse of Eq. (1). Such mercurial reagents can always react with any other constituents subsequently added. Ions such as hydroxyl and chloride, especially if present at high concentration, can also compete with thiol groups for the mercurial. Furthermore, the C—Hg bond is relatively weak, so Hg^{2+} can exchange rapidly with the alkyl mercurial, and inorganic mercury can be split off rather readily.

Such reactions of cysteine thiol groups with mercurials are the most obvious, and one of the more useful, ways to make heavy-atom derivatives for X-ray crystallography determination of protein structure (see Isomorphous Replacement).

Meroblastic Cleavage

Meroblastic cleavage is the incomplete cellular division found in embryos with large amounts of yolk (1). In embryos with little yolk, the early cleavage furrows can completely separate the daughter cells, or blastomeres. In many vertebrate embryos, the large amounts of yolk prevent the cleavage furrows from completely separating the daughter blastomeres. In these embryos, the cytoplasm is usually segregated to one end of the embryo and sits on top of the yolk. The cleavage furrows begin in the cytoplasm, but only proceeds part of the way through the yolk. The nuclei and associated cytoplasm are separated on one surface, but remain connected to the yolk (and to each other) at the interior. Later divisions tangential to the original cleavage furrows completely separate the cells in the dorsal and middle portions of the cytoplasmic region, while the cells more ventral and lateral continue to be connected cytoplasmically to the yolk and each other. Eventually, a disc of blastomere cells is formed that sits on top of the yolk, with the nearest cells still connected to the yolk. Meroblastic cleavage is common among birds (eg, the domestic chicken embryos that have been used extensively for embryological studies), reptiles, bony fishes, and amphibians.

Merodiploids

A merodiploid is an essentially haploid organism that carries a second copy of a part of its genome . The term is derived from the Greek, meros = part, and was originally used to describe both unstable partial diploidy, such as that which occurs briefly in recipients after mating with an Hfr strain (1), and the stable state, exemplified by F-prime strains (see Hfr'S And F-Primes). Over time, usage has tended to confine the term to descriptions of stable genetic states.

The inability of bacteria to maintain more than a single copy of their chromosome makes it easier to isolate mutations. Most of the mutations useful to a geneticist are recessive, and their effects would be hidden if a second unmutated gene copy were present to provide wild-type function, as in eukaryotes. Because bacteria are haploid, mutations are expressed directly as mutant **phenotypes**, and mutants are readily isolated by straightforward selection and screening procedures, vastly expanding the range of genes attainable by classical genetic methods. Beyond this point, however, the haploid state is inconvenient, because analyzing the function of a gene identified by a mutation usually involves determining how the mutated function interacts with the wild-type one or with related mutants, for which diploidy is needed. Merodiploidy provides a solution to this problem.

The discovery of natural merodiploidy arrived happily at a moment when it would make one of its most notable contributions. Hfr strains in which the integrated F factor, or F plasmid, is situated near the *lac* genes were found to give rise to $F'^{-}lac^{+}$ **plasmids**, by excision of the *lac* region along with the F DNA (2, 3). When an F′*lac* transferred itself into a new cell, it rendered the *lac* gene region of the chromosome diploid. At this time, François Jacob and his colleagues had proposed that *lac* gene expression is regulated by the action of a repressor at a control locus, the **operator**, situated next to the *lac* genes. Seeking evidence for the operator, they used an F′*lac*/lac^{+} strain to isolate mutants that expressed the *lac* genes even in the presence of the repressor. The mutations caused unregulated expression only of the *lac* genes to which they were linked (***cis*- acting**) and not of *lac* genes in ***trans***, just the property expected of the hypothetical *cis*-acting control locus (4).

The advantages offered by merodiploidy were well-illustrated by an analysis of *E. coli* mutants unable to make flagella (5). The *fla* mutants were first mapped to three clusters by complementation with F-primes carrying defined regions of the chromosome. The mutations were then crossed onto the F-primes by recombination, and the resulting F-primes transferred into each mutant to determine which pairs of mutations complemented to allow synthesis of flagella. These tests provided an estimate of the minimum number of *fla* genes in each region. The literature of bacterial genetics is replete with similar examples.

The uses of merodiploidy are limited to neither *E. coli* nor plasmids. The genes for catechol metabolism in *Pseudomonas aeruginosa* were mapped by first allowing recombinational transfer of transposon insertion mutations from R-prime plasmids to the chromosome and then carrying out complementation analysis using overlapping **cosmid** clones (essentially, smaller prime plasmids) (6). Potassium transport mutants of *E. coli* were analyzed by infection with lambda phage for **transduction** and plating on potassium-deficient media: Formation of turbid plaques containing lysogens occurred only for complementing mutants (7).

The existence of natural stable merodiploid states is one reason for raising the question, Why are bacteria haploid? There are others. Partial diploidy of the F-prime type is usually well-tolerated, suggesting that doubling the gene dosage is not generally deleterious. In several bacteria, the genome is distributed over more than one DNA molecule, implying the ability to coordinate replication and gene expression of physically distinct chromosomes. Bacteria have no trouble maintaining oligo- and multicopy plasmids in a polyploid state and, when growing fast, maintain their chromosomes in a state of pseudopolyploidy owing to the formation of multiforked chromosomes. J.-P. Bouché and his colleagues (8) produced a conditionally diploid *E. coli* by reducing synthesis of the essential cell division protein FtsZ, therby moving the replication cycle forward relative to division.

Nevertheless, haploidy is the invariable ground state. Could it be that the advantage that haploidy confers on the bacterium is the same as that offered to the geneticist? Whereas multicellular eukaryotes require the phenotypic stability of diploidy on which to build a developmental program and to prevent unregulated growth, bacteria have a different imperative: to adapt rapidly to diverse environmental and chemical challenges by generating from within their enormous populations mutations that are expressed immediately.

Messenger RNA

Messenger RNA (mRNA) is a fully processed RNA containing a particular open reading frame (see

Gene Structure) that is **translated** by the ribosome into a specific polypeptide chain. In **eukaryotes**, all mRNAs carry a cap (1), and most are **polyadenylated** (2); both of these modifications can contribute to the translational efficiency of the mRNA. Normally, mRNA have the general structure from 5′ to 3′: 5′ cap and 5′ untranslated region [5′UTR], open reading frame [ORF], 3′UTR, and poly A tail. The mRNA are synthesized from the DNA sequence of the gene as a precursor, pre-mRNA, by DNA-dependent **RNA polymerase** II, which must be processed in order to generate the mature mRNA. This processing usually involves the removal of noncoding **introns**, which are specifically removed in the spliceosome (3) (see Gene Splicing), and most mRNAs are polyadenylated cotranscriptionally (2) (see Polyadenylation). Translation of the ORF initiates normally at an AUG codon, which encodes the initiating methionine residue (see Initiation Codon and Translation). Translation of the ORF is then terminated when the ribosome encounters a stop codon.

Metacentric Chromosome

A *metacentric* chromosome has its centromere in or near its middle. Robertsonian translocations occur when two acrocentric chromosomes fuse to form a single metacentric (see Fig. 1 of Acrocentric Chromosome). Dissociation occurs when a metacentric chromosome breaks at the centromere to form two acrocentrics. This type of chromosome fusion and breakage is a major source of variation in chromosome numbers within various taxa. Species with high numbers of metacentric chromosomes tend to have fewer chromosomes than those with high numbers of acrocentrics. Metacentric and submetacentric chromosomes (where the centromere is near the middle) have two arms and appear as V- or J-shaped structures in metaphase preparations. The shorter arm of a submetacentric is called the ‘p’ arm, and the longer arm is the ‘q’ arm (Figure 1).

Figure 1. The basic organization of a mammalian chromosome, indicating p and q arms, telomeres, and centromeres.

Metalloproteinase Inhibitors, Protein

The classical vertebrate digestive enzymes carboxypeptidases A and B are Zn^{++} -dependent metalloproteinases. Along with many other proteinases, they are inhibited by their propeptides. In addition, carboxypeptidase A inhibitors from potatoes and from the roundworm *Ascaris lumbricoides* were intensively studied. The potato inhibitor is a single polypeptide chain of 39 residues crosslinked by three disulfide bridges. The disulfides bond pattern corresponds to that in the 30 residue squash inhibitors of serine proteinases. A small number of recombinant changes endowed the same protein molecule with trypsin inhibitory activity, located near the inhibitor's NH_2 terminus and with carboxypeptidase inhibitory activity located near the COOH terminus. The three-dimensional structure of the carboxypeptidase A–potato inhibitor complex reveals that, among others, the P_3, P_2 and P_1 residues make strong contacts with the enzyme. The original COOH terminal residue (P_1'), which is a Gly, is hydrolyzed off but not fully released. It remains attached to the complex.

A 102-residue inhibitor of metalloproteinases was isolated from *Streptomyces nigrescens*. It appears to inhibit thermolysin and related endoproteinases according to the standard mechanism employed by most protein inhibitors of serine proteinases.

A large number of metalloendoproteinases, the matrix metalloproteinases, or MMPs, are known. They are involved in remodeling of tissues and invasion of cells both in normal and in pathological processes. Such enzymes are synthesized as inactive zymogens that require the release of the propeptide for activity. This release is frequently but not always autocatalytic. The activity is also controlled by a number of closely related protein inhibitors. The most studied of these are called tissue inhibitors of metalloproteinases, or TIMPs. At the time of this writing, TIMPs 1,2,3, and 4 have been described. They differ from one another by being specific for different members of the large MMP set. A striking feature of TIMPs is that they form complexes that block the actual or potential activity of both the MMP enzymes and zymogens. The inhibited zymogens are no longer capable of autoactivation. Aside from the four TIMPs, a number of other protein inhibitors of MMPs have been reported.

Recently, a three-dimensional structure of a complex of matrix metalloproteinase, MMP3, or human stromelysin and TIMP-1 was reported. The NH_2 terminal Cys^1, which also forms the Cys^1-Cys^{70} intramolecular disulfide serves as the P_1 residue in TIMP. This residue is placed just above the catalytic Zn^{++} of MMP3. It forms two close (2.0Å) contacts with Zn^{++} involving its N and O atoms. The Thr^2 residue that serves as P_1' is embedded in a large hydrophobic S_1' pocket of the enzyme. There is strong reason to suppose that this mode of interaction occurs in all or most MMP - TIMP complexes.

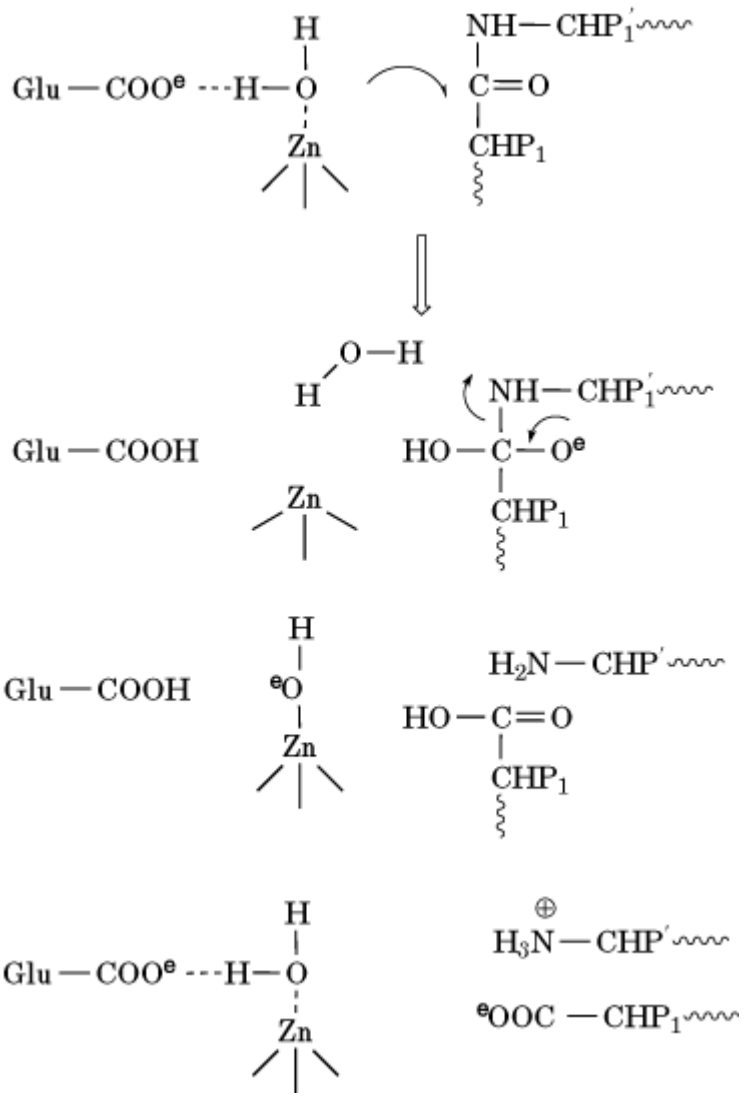
Metalloproteinases

In addition to the **carboxyl**, **thiol**, and serine proteinases, there is another large group of protein-degrading enzymes that use a zinc hydroxide ion to help catalyze the hydrolysis of peptide bonds. The Enzyme Commission of the International Union of Biochemistry and Molecular Biology has assigned them the classification E.C. 3.4.24. The zinc ion is bound to the protein by interaction with three amino acid side chains, and the fourth coordination site on the zinc is occupied by a water molecule (1). As the amino acid sequences and three-dimensional structures of increasing numbers of zinc metalloproteinases became available, certain patterns of metal binding emerged. The first to be recognized was the sequence -His-Glu-X-X-His- (where X is any amino acid other than histidine or glutamic acid). The two His residues, along with a third residue—typically a glutamic acid separated from the second His by from 21 to 61 intervening residues—constitute the metal binding site (2). Later another group of metalloproteinases was found in which the third residue is another His separated from the second His by only five intervening residues (3). At least three other modes of metal binding have now been identified (4). In those enzymes where a glutamic acid residue is adjacent to the first metal-binding histidine, as in thermolysin, the glutamic acid carboxyl group is thought to activate the metal-bound water molecule by removing a proton and allowing the hydroxide to attack the carbonyl group of the peptide bond that is to be hydrolyzed (Fig. 1). Similar mechanisms may pertain to other zinc metalloproteinases.

Figure 1. Schematic representation of the mechanism of action of zinc metalloproteinases. The carboxylate group of the active-site glutamic acid residue potentiates the attack of a zinc-coordinated water molecule on the carbonyl group of the substrate. In a substrate with more than one peptide bond, the particular peptide attacked is determined by the ability of the enzyme to recognize P_1 and P'_1, which are the principal specificity-determining side chains. The tetrahedral intermediate rearranges to form products, which dissociate, and the active site is ready to act on another substrate.



An important subgroup of these enzymes includes the matrix metalloproteinases. Among them are the enzymes that degrade collagen (collagenases) and other constituents of the extracellular matrix, hence their collective name. It is noteworthy that these enzymes bind two zinc atoms, one at the active site and a second that may have a structural role. Two zinc ions are also found in lens aminopeptidase, but in this case they are close together, apparently bridged by the carboxyl side chain of a glutamic acid residue. This would seem to be an example of a co-catalytic site (5), with one metal being important for catalysis and the other for substrate binding (6).

Metalloproteinases play an important role in tissue remodeling, in degenerative diseases such as rheumatoid arthritis, and in cancer. Several snake venom toxins are metalloproteinases, and a key enzyme in blood pressure regulation, angiotensin converting enzyme, is a metalloproteinase. Classically, these enzymes are recognized by their susceptibility to inhibition by metal-binding agents (chelating agents), such as ethylenediaminetetraacetic acid (**EDTA**) or 1,10-phenanthroline. They are not inhibited by reagents that are specific for carboxyl (ie, pepstatin), thiol (leupeptin), or serine (PMSF) proteinases. A number of metal-binding substrate analogues have been found in nature (eg, phosphoramidon); and others, synthesized in the laboratory, are important pharmaceuticals.

Metalloproteins

Many proteins bind metal ions, permanently as **prosthetic groups** or more transiently as **ligands**. These metal ions play a variety of roles in metalloproteins: **electron transfer**, maintaining the protein structure, **oxygen binding**, forming coordinated hydroxide radicals, substrate binding, and electrophilic catalysis (see Metal-Requiring Enzymes and Metalloproteinases).

During the past 15 years, it has become apparent that metalloproteins also play important roles in regulating the expression of genetic information. Such proteins take up stoichiometric quantities of trace metal ions and then undergo conformational changes that produce marked differences in their abilities to bind to specific sites on the **genomic** DNA or RNA of a given organism. The physiological effects of the binding of metalloproteins to, or release from, **nucleic acids** include increased resistance to heavy metals, control of iron uptake and storage pathways, recognition of packaging signals within the RNAs of retroviruses, control of vertebrate development events, and recognition of steroid hormones. Minerals present in high concentrations, such as Na^+, K^+, and Mg^{2+}, can play important roles in stabilizing nucleic acid structures, but they are unlikely to be widely used in gene regulation. The remaining essential metals are normally trace elements. Hence, it is not surprising that zinc, iron, and copper are prominent metalloregulators (see also Calcium-Binding Proteins, Zinc-Binding Proteins, and Iron-Binding Proteins). The incorporation of a particular trace metal ion into an apoprotein is influenced by its ionic radius, thermodynamic stability, ligand-substitution kinetics, and charge (Table 1). Three to four ligands, usually the side chains of cysteine and histidine residues, typically complete the coordination sphere about a bound metal ion.

Table 1. Coordination Environments Preferred by Common Metal Ions Found in Proteins

Metal Ion	Coordination Number	Geometry	Ligands
Zn^{2+}	4	Tetrahedral	His, Cys
Fe^{2+}	4	Tetrahedral	His, Cys, Glu, Asp
Cu^{+}	4	Tetrahedral	Cys
Cd^{2+}	4	Tetrahedral	Cys

Hg^{2+}	3	Trigonal	Cys

Because of their intrinsic biological functions, regulatory metalloproteins are not normally present in large quantities in cell and tissue homogenates, and most are colorless or only weakly colored. Nonetheless, the study of regulatory metalloproteins has become the fastest growth area of inorganic biochemistry. The term "metalloregulation" refers to regulating the transfer of genetic information by metal ions.

Regulatory metal-binding proteins are generally specific for a particular trace metal ion. For example, a synthetic **zinc finger** analogue (1) displays a strong preference for Zn^{2+} over Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, and Cd^{2+}.

1. Characterization

As with any metalloprotein, the metal stoichiometry is of paramount importance. It is usually determined by titration or atomic absorption spectrometry. Several thousand putative metalloregulatory proteins have been reported in the literature, usually on the basis of limited sequence patterns alone. In the absence any physical characterization, however, such reports must be viewed as speculative because they offer no real evidence regarding the metal element involved.

The nature of the metal coordination sphere can be probed by electronic absorption spectroscopy in cases involving iron or copper coordination. Zn^{2+} presents a challenge because it is colorless, but the Zn^{2+} can be replaced with Co^{2+}, a chromophoric probe that possesses a comparable ionic radius, is kinetically labile, and prefers similar coordination environments.

X-ray absorption spectroscopy is particularly useful for investigating the local environment (<~5) of the metals in these proteins (2). When X rays are absorbed by metal atoms, they liberate electrons that are backscattered from neighboring (ie, ligand) atoms. This interference phenomenon provides a very precise measurement of the distance to neighboring atoms. The edge region of the spectrum provides information about the valence state and coordination geometry of the metal and the identity of neighboring atoms. The extended X-ray absorption fine structure (**EXAFS**) region of the spectrum contains information about the number and average distances of neighboring atoms and about their relative disorder (see **EXAFS**).

The structural methods do not address key issues regarding the way a regulatory protein acts as an information transducer. Electrophoresisexperiments, including hydroxyl-radical footprinting and **mobility shift assays**, can indicate what region of the DNA or RNA is recognized and whether protein binding induces a structural change in the nucleic acid. More precise structural information relating to the nature of the protein–nucleic acid contacts requires their cocrystallization and **X-ray crystallographic** structural determination. Solution nuclear magnetic resonance (NMR) is also used in structural determination of small metalloproteins, but it has not yet been used to study complexes with DNA or RNA. Approximately 50 structures of metalloproteins have been deposited to date in the Brookhaven Protein Data Bank (see Structure Databases).

2. Regulatory Metalloproteins

The major regulatory metalloproteins are described in Zinc-binding proteins, **Zinc fingers**, Iron-binding proteins, Iron-response elements, and **Metal-response elements**. In addition, organisms must frequently cope with toxic elements in the environment. Bacteria are especially rich sources of metalloregulators and encode resistance systems (3) for many toxic metal ions, including Hg^{2+}, Tl^{+},

Ag^{+}, AsO^{-}_{2}, Cd^{2+}, and Cu^{2+}. Heavy-metal resistance is achieved in various ways, including sequestration in proteins, such as **metallothioneins**, efflux "pumping," and reduction to volatile metal atoms (eg, Hg^{0}).

3. Concluding Remarks

In contrast to the surging interest in structural studies on metalloproteins, the metabolic effects of dietary metal supply on the availability of metalloregulatory proteins have not received nearly as much attention as is warranted. Sorting out these effects is complicated by the presence of trace metal ions in structural proteins and enzymes. For example, zinc is found in **RNA polymerase** and in zinc fingers.

The sensing of small molecules by metalloproteins is only beginning to be understood. How are gases of physiological relevance (eg, O_2, CO, NO, CO_2) recognized by proteins other than the heme-containing oxygen-binding proteins and cytochrome oxidases, and what are the regulatory consequences at the genetic level? For example, the requirement for CO_2 as an environmental determinant of gene expression involved in many bacterial capsule and toxin biosyntheses has long been recognized by microbiologists but is not understood. Curiously, heme proteins (4), rather than the nonheme iron-responsive proteins discussed in Iron-response elements, have been implicated in most of what is presently known about the molecular mechanisms of gas sensing in biology.

The initial reports of mutant metal-binding proteins have naturally led to their consideration for use in the biotechnology industry. The development of artificial regulators of eukaryotic gene expression is a much sought after goal. Can metalloprotein-based drugs be produced that block the expression of genes whose products are important in the developing animal and plant diseases? Alternatively, could such types of regulatory proteins be used to produce large **transgenic** animals and plants? Novel zinc-finger proteins designed to function as specific transcriptional switches have been reported (5, 6). Other potential applications for engineered metal-binding proteins include highly sensitive metal-ion biosensors.

Metallothionein

In 1957, Vallee and co-workers (1) discovered a small, **cysteine**-rich protein, which they termed metallothionein (MT). Metallothioneins have been found in most higher eukaryotes, fungi, and cyanobacteria. These proteins are produced in response to heavy-metal uptake, and they sequester these ions in protein-bound metal clusters. Cysteine is the sole amino acid residue that binds to metals in metallothioneins.

Regulation of metallothioneins is necessary because high metallothionein levels indiscriminately attenuate the levels of trace metals inside the cell. Metallothionein regulation is currently being studied in fungi and cyanobacteria as model metalloregulatory systems (2), where Cu^{1+} or Zn^{2+} function as the effector metal ions. Table 1lists the key transcription factors, all of which dissociate from their DNA **metal-response elements** upon metal-ion binding. The **X-ray crystallographic** structure (3) of the cyanobacterial metallothionein repressor, SmtB, shows a classic **helix-turn-helix** motif, in common with many other DNA-binding proteins. The binding of DNA by SmtB, unlike other zinc metalloregulators (see Zinc-Binding Proteins), is inhibited by the metal. Two other transcription factors, ACE1 and AMT1 (see Table 1), are both activated by Cu^{1+}. Four copper ions congregate in an all-or-nothing manner to form a tetracopper-thiolate cluster in the N-terminus of each protein (4). The C-termini contain the **transactivation** domains. Cu- and S-**EXAFS** show that Cu-Cu distances of 2.7 Å and Cu-S distances of 2.26 Å characterize the clusters of both proteins and the copper-thiolate cluster in copper-loaded metallothionein. These observations point to an interesting similarity between Cu^{1+}-bound ACE1 (AMT1) and the gene product they regulate.

Metal-Requiring Enzymes

Enzymes that require metal ions for their catalytic activity fall into two classes. They are the metal-activated enzymes and the metalloenzymes. The latter contain tightly bound metals that do not dissociate during isolation or dialysis of the enzyme under conditions where activity is retained. However, such metal ions can be removed under more drastic conditions, such as low pH. Bound metal ions can be involved with the maintenance of the structural integrity of enzymes, and they can participate in electrophilic catalysis.

Metal ions that are found in metalloenzymes include those of the first transition series of elements in the periodic table: Mn^{2+},Fe^{2+},Co^{2+},$Ni^{2+}$and Cu^{2+}, as well as Zn^{2+},$Mo^{2+}$and Ca^{2+}. Examples of enzymes that contain metal ions are listed in Table 1. Metal ions involved with enzymes that participate in electron transport undergo **redox reactions**. Thus, the ionic forms of iron, copper, cobalt, and molybdenum can be Fe^{2+}/Fe^{3+},Cu^{+}/Cu^{2+},Co^{2+}/Co^{3+},and $Mo^{2+}$to Mo^{6+}, respectively. For convenience, these metal ions will be listed simply as bivalent ions. Fe^{2+} is most commonly found as a heme complex in redox enzymes such as catalase and **peroxidases** (see Iron-Binding Proteins). It also occurs as a component of **iron–sulfur** clusters in enzymes that are involved in one-electron transfer processes; NADH dehydrogenase and succinate dehydrogenase belong to this group and are flavoprotein enzymes. Like Fe^{2+},Cu^{2+} has multivalent oxidation states, and many Cu^{2+} enzymes are either oxidases or **hydrolases** that utilize molecular oxygen. Co^{2+} enzymes, such as methylmalonyl-CoA mutase and ribonucleotide reductase, have the cobalt atom bound within a corrin ring. Ni^{2+} is rarely found as a component of metalloenzymes, but urease from jack bean is an exception. The occurrence of Mn^{2+} and Ca^{2+} in metalloenzymes is also somewhat rare (see Calcium-Binding Proteins). Mg^{2+}, the alkaline earth metal that is found so commonly in biological systems, does not play a role in the functioning of metalloenzymes, but is important in metal-activated enzymes (see below). By contrast, Zn^{2+} is an important and widely utilized metal for electrophilic catalysis (see Zinc-Binding Proteins). Not all enzymes that catalyze a particular reaction have the same requirement for a metal. Thus, fructose bisphosphate aldolase from yeast and bacteria utilize Zn ions, whereas the same enzyme from muscle uses a Schiff Base intermediate to activate the substrate (1).

Table 1. Selected Examples of Metalloenzymes

Metal Ion	Enzyme

Ca^{2+}	amylase, galactosyltransferase, thermolysin
Co^{2+}	dioldehydrase, glycerol dehydratase, methylmalonyl-CoAmutase, ribonucleotide reductase
Cu^{2+}	cytochrome c oxidase, dopamine-b-hydroxylase,superoxide dismutase
Fe^{2+}	catalase, NADH dehydrogenase, nitrogenase, peroxidase, succinate dehydrogenase, xanthine oxidase
Mn^{2+}	arginase, histidine-ammonia lyase, pyruvate carboxylase
Mo^{2+}	nitrogenase, xanthine oxidase
Ni^{2+}	urease, Ni–Fe hydrogenase
Zn^{2+}	alcohol dehydrogenase, carbonic anhydrase, carboxypeptidase, superoxide dismutase, thermolysin

---

The largest group of metal-activated enzymes contains the **phosphotransferases** that catalyze the transfer of the terminal phosphoryl group of ATP to an acceptor molecule that can be an alcohol, carboxylic acid, nitrogenous compound, or a phosphorylated compound (see Kinase). Their essential requirement for a bivalent metal ion is always satisfied by Mg^{2+} or Mn^{2+}. However, other bivalent metal ions have been shown to activate some phosphotransferases (2). The role of bivalent metal ions in the activation of phosphotransferases is to form a $MgATP^{2}$ complex that then acts as the true substrate for the reaction. Thus, the binary complex formed by the interaction of the enzyme and its nucleotide substrate is an enzyme–nucleotide–metal complex. Some phosphotransferases involve a second metal ion that is liganded by the enzyme as well as the substrate. Examples are pyruvate kinase and the biotin-containing enzymes that form carboxybiotin by the initial phosphorylation of bicarbonate to carboxy-phosphate (1). Pyruvate kinase also differs from most other phosphotransferases in its requirement for K^{+} and its inhibition, rather than activation, by Ca^{2+}.

Metal Response Element

The metal response element is present in multiple copies in **genes**, such as the metallothionein genes, whose transcription is increased in response to treatment of cells with metals like zinc, copper, cadmium, and lead (1, 2). The metallothionein proteins are **cysteine** -rich metal-binding proteins that play a critical role in protecting cells from metal toxicity. Hence, increased levels of potentially toxic metals lead to enhanced transcription of the metallothionein genes. Inspection of the regulatory regions of the metallothionein genes reveals that they contain multiple copies of a 13- to 15-bp element with the **consensus sequence**

CTCTGCRCNCGGCCC

where R = purine and N = any base. The core sequence of this motif (underlined above) is essential for the ability of the metallothionein gene to respond to metals. Thus mutagenesis of this sequence destroys the metal responsiveness of the metallothionein gene (3), while individual elements of this sequence can confer metal responsiveness upon a gene that is not normally induced in response to this treatment (4).

This element is thus a metal response element (MRE), which allows the transcription of specific genes to be activated in response to metals (see Response Element).

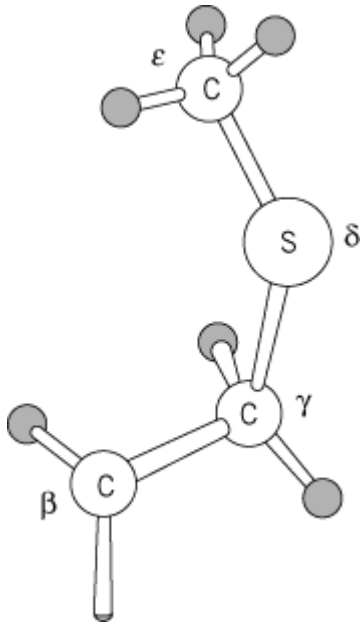
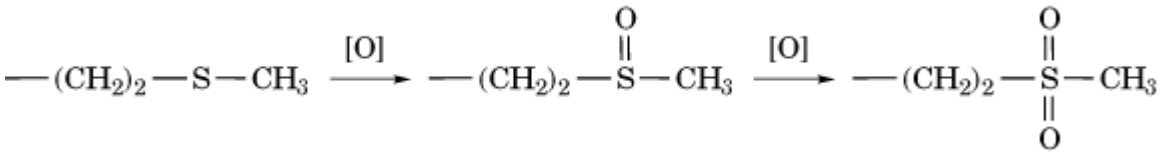
Methionine (Met, M)

The amino acid methionine is incorporated into the nascent polypeptide chain during **protein biosynthesis** in response to only one **codon**—AUG—and represents approximately 2.4% of the residues of the proteins that have been characterized. It is usually the initiating residue in translation and occurs at the *N*-terminus of the initial gene product. In **prokaryotes**, the amino group of this residue is formylated, but this group is normally removed post-translationally by a formylase enzyme. Frequently, the initiating methionyl residue is removed by a **ribosome**-associated Met-aminopeptidase enzyme. An internal methionyl residue has a mass of 131.19 Da, a **van der Waals volume** of 124 $Å^3$, and an accessible surface area of 204 $Å^2$. Met residues are changed only moderately frequently during divergent evolution; they are interchanged in **homologous** proteins most frequently with leucine residues.

The long side chain of Met residues is nonpolar and relatively unreactive chemically:



It is the only unbranched nonpolar side chain of all the natural amino acids. The sulfur atom is somewhat nucleophilic, but unlike other nucleophiles in proteins, it cannot be protonated. Consequently, it is the most potent nucleophile in proteins at acidic pH. Its reaction with **cyanogen bromide** under such conditions causes the polypeptide chain to be cleaved after Met residues, which are converted to homoserine residues; this is the most useful chemical method for cleaving polypeptide chains. The Met sulfur atom can be selectively modified under acidic conditions, readily forming sulfonium salts with alkylating agents, such as methyl iodide. This reaction can be reversed by thiol groups, and the methyl group removed is equally likely to be the original one or that introduced by the methyl iodide, so this reaction offers the possibility of introducing a radioisotope label in 50% of the residues by using labeled methyl iodide. The sulfur atom of Met residues is also susceptible to oxidation by air or by more potent oxidants, such as peroxides. The sulfoxide is formed first, followed by the sulfone:



The first step, but not the second, can be reversed by sulfides and by thiol groups. Either oxidation state makes the Met residue unreactive with alkylating reagents.

In folded proteins, about 40% of the Met residues are totally buried. The Met residue favors the a-helix conformation in model peptides and occurs most frequently in that type of **secondary structure** in folded protein structures, although it also occurs frequently in *beta* **-sheets**. In some cytochromes, the Met sulfur atom is one ligand to the iron atom of the heme group.

Methionine Regulon

In addition to its role as an amino acid constituent of proteins, *methionine* participates in initiating **protein biosynthesis** (as *N*-formylmethionine), as a universal methylating agent (as S-adenosylmethionine, AdoMet;), and as a precursor of **spermidine** through AdoMet. Consequently, controlling the growth rate by regulating the availability of methionine is a very effective strategy in microorganisms.

Methionine is synthesized only in **microorganisms** and **plants**, and its biosynthetic pathway is complex. The carbon skeleton derives from aspartic acid, the sulfur atom from cysteine, and the methyl group from the b-carbon of serine (1). In *Escherichia coli*, the genes involved in methionine biosynthesis are scattered throughout the chromosome . Table 1summarizes the names of the genes, of the protein they encode, their position on the circular chromosome, and the product of the catalyzed reaction. The conversion of aspartate to homoserine has been treated elsewhere (see Multifunctional Proteins; Enzymes and Isofunctional Proteins).

Table 1. Genes and Enzymes in *Escherichia coli* for Biosynthesizing Methionine from Homoserine

Genes	Gene Product	Position (min)	Reaction Product
metA	Homoserine transsuccinylase	90.7	*O*-Succinylhomoserine
metB	Cystathionine-g-synthase	88.9	Cystathionine
metC	b-Cystathionase	67.8	Homocysteine
metE	Methionine synthase (cobalamin-independent)	86.4	Methionine
metH	Methionine synthase (cobalamin-dependent)	90.9	Methionine

The methyl group of methionine originates from the b carbon of serine, via methylenetetrahydrolate, in a series of enzymatic reactions listed in Table 2.

Table 2. Biosynthesis of the Methyl Group of Methionine Used by the Cobalamin-Independent or Cobalamin-Dependent Methionine Synthases

Genes	Gene Product	Position (min)	Reaction Product(s)

glyA	Serine hydroxymethyl transferase	57.6	Glycine + methylenetetrahydrofolate
metF	Methylenetetrahydrofolate[a] reductase	89	Methylenetetrahydrofolate

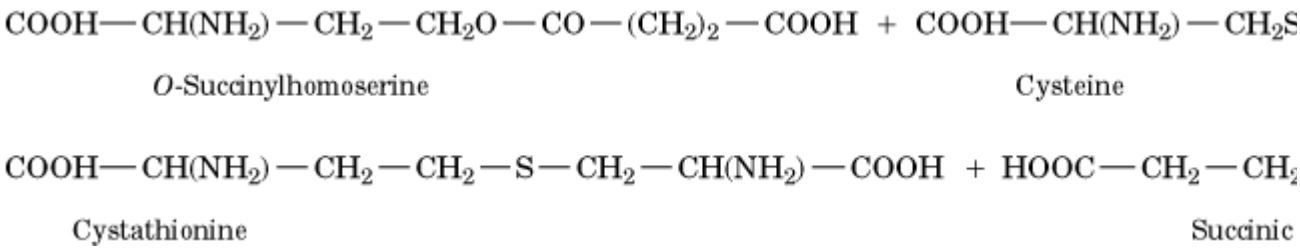
[a] Methylenetetrahydrofolate is the direct methyl donor to homocysteine.

The first step of methionine biosynthesis is the succinylation of homoserine, catalyzed by *homoserine succinyltransferase*, the product of the *metA* gene (2):

In yeast, acetylCoA and acetyl- *O*-homoserine replace the succinylated products.

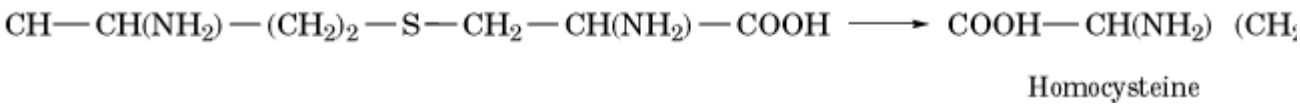
The *metA* gene codes for a polypeptide of molecular weight 35,673 (3), and the enzyme is a homodimer. It has unusual temperature sensitivity in many *Enterobacteriaceae*, which limits growth at elevated temperature (4). The enzyme appears to be a **heat shock** protein and is involved in other **stress responses**. In this respect, note that one of the genes (of unknown biochemical function) involved in methionine biosynthesis in **Saccharomyces** *cerevisiae* is identical to a gene responsible for high salt tolerance. Furthermore, supplementing the growth medium with methionine increases the tolerance of **yeast** to NaCl.

O-succinylhomoserine is transformed to cystathionine, a seven-carbon diaminoacid, in the presence of cysteine (5):



This reaction is catalyzed by cystathionine-g-synthase, encoded by the *metB* gene, and uses pyridoxal phosphate as a **cofactor**. The reaction mechanism of the enzyme is thought to proceed via a pyridoxamine derivative of vinylglyoxylate. The enzymes from *Salmonella typhimurium* and *E. coli* are homotetramers of a 40-kDa subunit, each containing one pyridoxal phosphate molecule. The *metB* gene of *E. coli* codes for 386 amino acid residues (6).

Cystathionine is cleaved to give homocysteine, ammonia, and pyruvate in a reaction catalyzed by cystathionase (cystathionine-b-lyase), the product of the *metC* gene (7).



This is also a pyridoxal phosphate-containing enzyme that has been only partially characterized. 3,3,3-Trifluoroalanine binds covalently to the enzyme and inhibits it irreversibly. The protein was first reported to be a hexamer, each subunit binding a molecule of pyridoxal phosphate, but further studies suggest that it is a homotetramer (8). Its sequence of 395 residues is strongly homologous with that of cystathionine-g-synthase, indicating a common ancestor of the two proteins (9).

A mutation in the gene *metQ* (39.5 min) allows *metC* mutants to catalyze the formation of homocysteine directly from homoserine, bypassing the normal cystathionine intermediate (10).

The last step in methionine biosynthesis involves methylation of homocysteine:

$$\mathrm{COOH{-}CH(NH_2){-}(CH_2)_2{-}SH} + \mathbf{R}{-}\mathrm{CH_3} \;,\; \mathrm{COOH{-}CH(NH_2){-}(CH_2)_2{-}CH{-}S{-}}$$

The methyl donor **R** is ^{5}N-methyl tetrahydropteroylglutamate, a member of the folate family (see Aminopterin, Methotrexate, Trimethoprim, and Folic Acid), which is derived from ^{5}N, ^{10}N-methylene tetrahydrofolate (generated by the conversion of serine to glycine catalyzed by serine hydroxymethyltransferase) by a reductase specified by the *met F* gene. This reaction produces the methyl group specific for methionine biosynthesis. Two enzymes catalyze this reaction (11):

1. a transmethylase (product of the *metH* gene) dependent on the presence of vitamin **B12** that can use either the mono- or polyglutamate forms of ^{5}N-methyl tetrahydropteroylglutamate as a methyl donor;
2. a vitamin B_{12}-independent transmethylase (product of *metE*) that uses only the polyglutamate forms of ^{5}N-methyl tetrahydropteroylglutamate (N > 3).

The gene *metE* encodes a polypeptide chain of 84654 Da (12), and *metH* codes for an exceptionally long polypeptide of 132,628 Da showing no similarity to the *metE* product (13). *E. coli* possesses both enzymes, whereas most microorganisms possess only one. It does not synthesize vitamin B_{12} and uses one or the other transmethylase according to the availability of vitamin B_{12} in the medium. Strains with a mutation in *metE* require either methionine or vitamin B_{12} for their growth. However, vitamin B_{12} can be synthesized anaerobically. The vitamin B_{12}-independent enzyme, coded by *metE*, is a rather inefficient enzyme.

The mechanism of the B_{12}-dependent enzyme involves methylation of the vitamin's cobalt atom. Catalytic amounts of AdoMet are required for this priming step. After the methyl group is transferred to homocysteine, subsequent methyl groups come from ^{5}N-methylenetetrahydrofolate. In addition to AdoMet, methyl B_{12}, and the folate derivative, the enzyme requires reduced **FAD** for activity.

The B_{12}-independent transmethylase involves neither a methylated coenzyme nor the other requirements of the vitamin-dependent enzyme, such as AdoMet or a reducing agent. Alkylation of Cys726 of the enzyme results in complete loss of activity. This thiol might function as an intermediate methyl acceptor in catalysis, analogous to the role of cobalamin in the reaction catalyzed by the B_{12}-dependent enzyme.

Table 3refers to the genes responsible for synthesizing proteins involved in regulating methionine biosynthesis (see Methionine Repressor) and in synthesizing AdoMet, the corepressor of many of these proteins.

Table 3. Genes Involved in Regulating Methionine Biosynthesis

Genes	Gene product	Position (min)	Reaction product
metK	Methionine adenosyl	66.4	*S*-Adenosylmethionine (AdoMet)

	transferase		
metJ	Methionine repressor	88.9	Methionine repressor
metR	Positive regulatory gene	86.4	Protein regulating *metE* and *metH* expression

Methionine Repressor

1. Regulation of Methionine Biosynthesis by Gene Expression

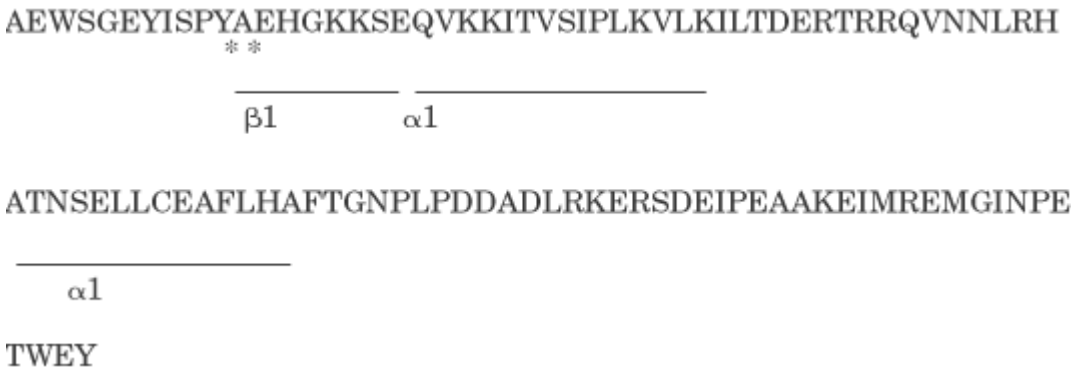
The *metA* gene codes for the first step in the methionine biosynthetic pathway, starting from homoserine (see Methionine Regulon). It has two starting sites for transcription located 74 nucleotides apart. Both **promoters** are used *in vivo*, but only one is regulated by intracellular methionine levels. The *metB*, *metC*, and *metF* genes, coding respectively for cystathionine synthase, cystathionase, and 5,10-methylene tetrahydrofolate reductase, each have a single promoter. The *metA*, *metB*, *metC*, *metE*, and *metF* genes are all **repressed** when excess methionine is added to the minimal growth medium, albeit to different degrees. The level of the enzyme varies 300-fold for homoserine transsuccinylase, 40-fold for cystathionine synthetase, 6- to 12-fold for cystathionase, 20-fold for the methylene tetrahydrofolate reductase, and 60-fold for the vitamin **B12**-independent transmethylase. Thus there is no coordinate repression, reflecting the fact that the *met* genes do not form a single operon, but are scattered through the bacterial chromosome.

There is a notable exception: *metB* and *metL*, coding for cystathionine synthetase and aspartate kinase II-homoserine dehydrogenase II, constitute an operon and belong to a gene cluster, **metJBLF**, located around 89 min. on the chromosome (see Methionine Regulon). Methionine also regulates the

synthesis of aspartokinase II-homoserine dehydrogenase II (*metL*) and **S-adenosylmethionine** (AdoMet) synthetase (*metK*). Although methionine affects the level of the B_{12}-dependent transmethylase, coded by *metH*, this effect appears to be the indirect result of repression of the synthesis of an activator protein (MetR, see below). Expression of the *metE* gene is repressed by vitamin B_{12}.

The *E. coli metJ* gene is 312 bp long and codes for the Met repressor, a molecule of 104 amino acid residues that exists as a homodimer (Fig. 1). *metJ* is transcribed divergently from *metB*. Consequently a complex 276-bp regulatory region is found between them. There is a single promoter for *metB*, whereas *metJ* is transcribed from three separate points. Only two of the three *metJ* promoters are regulated by methionine. The repressor regulates its own synthesis.

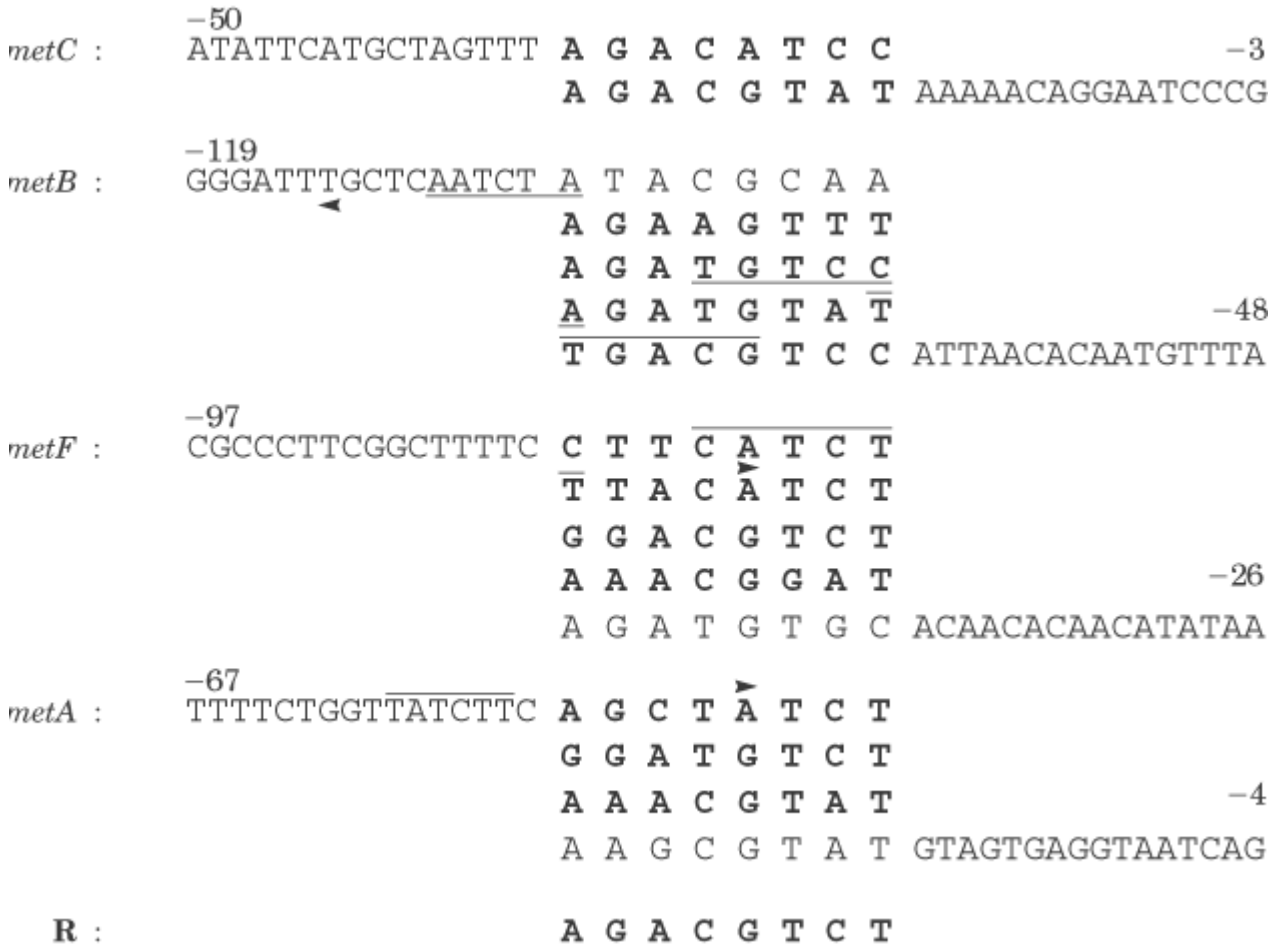
Figure 1. Sequence of the *E.coli* methionine repressor. The * sign indicates the amino acid residues making contacts with DNA, inferred from the structure of the repressor/DNA complex. The underlined sections indicate the b-strand and two of the a-helices of the protein (1).



The effect of the repressor on the synthesis of the methionine biosynthetic enzymes has been assessed by measuring **Beta-galactosidase** synthesis in a cell-free system where the synthesis of this enzyme is under the control of *metF* (*metF–lacZ* fusion). Methionine had to be present in these experiments as a necessary building block for protein synthesis. Expression of b-galactosidase was progressively repressed by increasing concentrations of the aporepressor. Complete repression was attained at 600 nM. At a constant concentration of aporepressor, AdoMet enhances the repression in a concentration-dependent manner. Half-maximum inhibition is reached at 10 mM AdoMet and complete repression at 100 mM. Similar *in vitro* assay systems demonstrated that the aporepressor and AdoMet have the same effect on the expression of the *metB* and *metL* genes and on that of the *metJ* gene itself.

Equilibrium Dialysis demonstrates that the methionine repressor binds two molecules of S-AdoMet per dimer. The corresponding Scatchard Plot is linear, showing that there is no **cooperativity**. Methionine does not bind to the aporepressor. Because the repressor binding sites should be similar for all of the genes regulated by methionine, comparison of the four 5′ regions of the *metC*, *metB*, *metA*, and *metF* genes reveals a repetitive unit (R) eight nucleotides long, named the “Met box.” In the alignment presented in Figure 2 of 128 positions, 89 matches, and 21 transitions are found when the repetitive units are compared to the **consensus sequence** R. This consensus sequence is a perfect palindrome, AGACGTCT, which is present in an altered form two to five times in the Met boxes. The *metB* and *metJ* genes are transcribed divergently and share the same Met box.

Figure 2. Comparison of the upstream regions of the *metC*, *metB*, *metF*, and *metA* genes. The sequences 5′ to the structural *metC*, *metB*, *metF*, and *metA* genes are presented discontinuously and have been aligned in order to focus on the presence of the underlying repetitive palindromic repetitive unit. Nucleotides matching the consensus sequence presented in line **R** are in boldface. Numbers indicate positions relative to the adenine of the respective start codon taken as +1. The –10 promoter sequences are overlined and arrowheads indicate the transcription start signals. In the case of *metB*, the overlined hexamer is the –35 box: the two underlined promoter sequences represent the –35 and –10 boxes of the first promoter of *metJ* (2).



The *metE* and *metR* genes also possess these repetitive units (3 for *metE* and 4 for *metR*). The two exceptions are *metK* and *metH* which, although regulated by methionine, do not possess the consensus sequence. The differences in the number and/or sequences of the Met boxes may be related to the different extents of repression elicited by the Met repressor. A **filter-binding assay** using nitrocellulose and **radioactive** oligodeoxynucleotides has shown that DNA fragments containing two consecutive consensus Met boxes are tightly bound by repressor in the presence of saturating AdoMet, whereas nucleotide sequences containing only one Met box are not bound. Binding is **cooperative** with respect to repressor concentration. The repressor protects the operator against nuclease digestion (see Footprinting), and the results strongly indicate the binding of an array of repressor dimers centered on the 16-bp operator site but extending into the neighboring DNA. The same was found for a fragment containing the *metF* regulatory region, where five boxes are protected. These observations are consistent with the following *in vivo* data: the level of repression of defined mutants of the *metC* operator, the smallest one known (having two Met boxes), is increased when the sequence becomes closer to the consensus sequence. Similar results were obtained with the five Met boxes of *metF*. Furthermore, the arrangement of all five boxes in tandem repeats is important for effective repression, since some point insertions within the operators lower repression 100-fold.

2. Three-Dimensional Structure of the Methionine Repressor of its Binary Complex with AdoMet and of its Ternary Complex with AdoMet and DNA

As in the case of the Trp repressor, (see TRP Operon) the two subunits of the Met repressor are strongly intertwined to form the dimer. AdoMet binds to the dimer at two independent but symmetrical sites, one on each monomer. The purine nucleus of AdoMet inserts into a **hydrophobic** pocket, normally occupied in the aporepressor by the side-chain of Phe65, whereas the methionine moiety lies at the protein surface. This explains why methionine itself does not bind to the aporepressor, whereas S-adenosylhomocysteine binds with about half the affinity of AdoMet. The positively charged trivalent sulfur atom lies at the C-terminus of helix B. In contrast to the Trp repressor, there is no major conformational change associated with corepressor binding. The apo and holo structures are indistinguishable, except for the absence or presence of AdoMet and small conformational changes at the N-terminus and Phe65. AdoMet does not contact DNA in the repressor-operator complex (see below), and how it regulates binding remains unclear. One possibility is a long-range electrostatic effect based on the positive charge on the sulfur atom.

Each monomer of the Met repressor is composed of three a-helices and one b-strand, accounting for about 50% of the sequence (see Fig. 1). In the protein dimer, the b-strands pair to form an antiparallel Beta-sheet, whereas the a-helical regions pack against the sheet and against each other to stabilize the dimer. The molecule lacks a helix-turn-helix motif which makes it different from many other repressors and from the **cyclic AMP receptor protein**.

By X-ray crystallography it was found that a 19-bp oligonucleotide containing two adjacent 8-bp Met boxes binds two dimeric Met repressor molecules. One dimer binds to each half-site, each of which contains a twofold axis of symmetry that coincides with the twofold axis of the protein b-sheet. The a-helix 1 on one dimer interacts with the same a-helix 1 on the adjacent dimer to form a tetrameric protein structure. Sequence specificity is achieved by inserting the double-stranded, antiparallel, protein b-sheet into the major groove of B-form DNA. Direct hydrogen-bonding occurs between amino acid side-chains on the exposed face of the sheet and the base pairs. Lys23 from each b-strand contacts a guanine base, and the neighboring Thr-25 on each strand contacts an adenine. Residues from the N-terminus of a-helix 2 make backbone contacts. The repressor also recognizes sequence-dependent distortion or flexibility of the operator phosphate backbone and confers specificity even for inaccessible base pairs.

3. The *metR* Gene and its Product

Surprisingly it was found that some mutants with normal *metF*, *metE* and *metH* genes express the two transmethylases from the *metE* and *metH* genes at very low levels, resulting in a growth requirement for methionine. This **auxotrophy** was overcome in strains carrying **multicopy plasmids** with either the *metE* or the *metH* gene. This implied that the methionine auxotrophy was caused by independent mutations resulting in an inability to synthesize enough homocysteine transmethylase enzyme to permit growth. It was found that these mutations are linked to *metE* but lie outside the *metE* structural gene. Their locus was called *metR*. The *metR* gene from *E. coli* encodes a 35,628-Da polypeptide 317 amino acid residues long. The native protein is a homodimer and is believed to contain a leucine zipper, a motif characteristic of many eukaryotic DNA binding proteins (and of the *E. coli* Lac repressor).

Expression of *metR* is repressed by the Met repressor, as the 5′ flanking region of *metR* contains four Met boxes, and by the product of *metR* itself. Conversely, the MetR protein plays no role in regulating the *metJ* gene for the Met repressor. MetR activates the expression of both *metE* and *metH*. Homocysteine, the substrate of both transmethylases, is the coactivator for *metE* but not *metH*. This positive regulatory mechanism may apply when vitamin B_{12} is absent, ie, when there is no B_{12}-dependent transmethylase activity (catalyzed by the *metH* product). The resulting methionine

starvation would then cause derepression of the biosynthetic enzymes and accumulation of homocysteine. The latter could then act as a signal to activate the synthesis of the vitamin B_{12}-independent transmethylase, coded by *metE*.

In *S. typhimurium*, the MetR protein activates *metA*, the gene for homoserine succinyltransferase, but homocysteine inhibits this activation. This result explains why expression of the *metE* gene is repressed by vitamin B_{12}. It is primarily caused by a loss of MetR-mediated activation through depletion of the coactivator homocysteine, rather than a direct repression by the metH-B_{12} holoenzyme.

Methylation, DNA

Enzymatic DNA methylation consists of the covalent attachment of a methyl group to a cytosine or adenosine residue in a defined sequence of double-strand DNA by a DNA **methyltransferases** (also called a *methylase*). DNA methyltransferases use ***S*-adenosyl-L-methionine** (AdoMet or SAM) as the methyl-donating cofactor and are separated into two major classes (see Methyltransferase, DNA). The first class methylates the C5 carbon of cytosine to form 5-methylcytosine (5mC). The second class methylates exocyclic amino nitrogen atoms to form either *N*-6-methyladenine (N6mA) or *N*-4-methylcytosine (N4mC). **Eukaryotic** DNA contains 5mC and **prokaryotic** DNA contains all three methylated bases: 5mC, N6mA, and N4mC. These methyl substituents are located in the major groove of DNA and disrupt interactions with some DNA-binding proteins and enzymes by perturbing binding or catalysis (1). These methyl-induced disturbances may be due to direct steric clashes combined with longer-range conformational changes produced in the DNA–protein interface (2).

1. Prokaryotic Methylation

DNA methylation plays diverse roles in biology. For instance, methylation by the *N*-6-methyladenine DNA methyltransferase (Dam), found in *Escherichia coli* "marks" a DNA strand for

repair by the methyl-directed mismatch repair system. In this repair system, a newly synthesized DNA strand, which lacks methyl groups, is scanned for mispairing of its bases with the original parental DNA strand that had been methylated by Dam MTase prior to replication. The parental strand serves as a template to direct the replacement of erroneously incorporated nucleotides. Shortly after proofreading and repair, Dam methylase modifies the new daughter strand to yield fully methylated DNA. In addition, Dam methylase plays an important role in DNA replication. High-efficiency *E. coli* chromosomal replication is dependent on eleven fully methylated Dam (GmATC) sites located at the *ori*C (the ***ori*gin of replication**). Although not lethal, loss of Dam methylation leads to increased spontaneous mutation rates and asynchronous DNA replication (3). Another prokaryotic N6mA methylase (CcrM) from *Caulobacter crescentus* is cell cycle–regulated and essential for viability. CcrM methylation at GATNC sites of daughter strands is temporally regulated at late stages of chromosomal replication and functions before **cell division**. Cells constitutively expressing CcrM throughout the cell cycle have abnormalities in their DNA replication and cell division. These findings indicate that the state of chromosomal DNA methylation regulates the progression of the cell cycle in this organism (4).

Prokaryotic methyltransferases, as part of restriction–modification systems, methylate host DNA sequences for protection against cleavage by the partner restriction enzyme. Methylation by enzymes like Dam that is involved in the normal functioning of host genomes may have been the evolutionary progenitors of restriction endonucleases and restriction–modification systems (5).

2. Eukaryotic Methylation

In eukaryotes, methylation functions in **gene expression** and regulation and cell division and development. Eukaryotic methylation is accomplished by DNA methyltransferases (DNA MTases) to form 5-methylcytosine residues at CG sites (6). Mutations that reduce cytosine methylation in **fungi** and plants result in abnormal chromosomal segregation and stability. Methylation may also serve to compartmentalize structurally large eukaryotic genomes (such as those of plants and vertebrates) into inactive, compact, methylated regions and unmethylated regions accessible to gene transcription and regulatory factors. In vertebrate genomes, 5-methylcytosine represents 1% of bases (7). Vertebrate methylation is developmentally and tissue-specific and leads to defined, heritable patterns because of the preference of DNA MTase for hemimethylated DNA, specifically, DNA methylated on only one strand at a given methylation site (8). Li et al. (8) found that transfected mice embryos that were homozygous for a MTase mutation had 30% the normal amount of DNA methylation, major developmental abnormalities, and a recessive lethal phenotype. Methylation patterns have a role in **genomic imprinting**, where paternal and maternal **alleles** of a gene are differentially expressed. For instance, human and mouse insulin-like growth factor genes (*Igf* 2) are selectively expressed from the paternal gene, which, unlike the maternal allele, contains a methylated region upstream of the *Igf* 2 promoter. This finding suggests that the methylated region may interfere with the binding of a transcriptional repressor (9). Abnormal methylation of **promoters** of tumor suppressor genes promotes tumorigenesis (10). Interestingly, the spontaneous hydrolytic deamination of 5-methylcytosine residues in DNA produces thymidine; on replication, a transition mutation occurs that is responsible for one-third of human mutations (7).

3. Molecular Basis of Effects of Methylation

An understanding of the effects of methylation on local DNA structure, DNA-protein interactions, and catalysis provides insight into the multiple roles of methylation. For example, thermodynamic melting experiments using GATC-containing and methylated GmATC-containing decameric oligodeoxyribonucleotide duplexes show that the T_m value (the **melting temperature** at which half of the duplex population has dissociated into single strands) was 10° lower for the methylated oligomer, indicating that methylation had a destabilizing effect on the DNA (11). Studies were also conducted with *Eco*RI endonuclease using fully methylated oligomeric duplexes methylated at the second adenine containing the canonical sequence (GAmATTC) (the biologically relevant

methylation site for *Eco*RI). Methylation destabilized the conformation of the DNA–protein interface, interrupting the precise structural geometry needed at the transition state for optimal catalysis and thereby prevented cleavage. Also, the cleavage rate constants for each strand on doubly methylated duplex were reduced ~600,000-fold compared to the unmethylated sequence. This rate reduction, combined with the lowered binding association rate caused by the methyl groups, explains why methylation effectively prevents *Eco*RI endonuclease cleavage (2).

DNA methylation is a ubiquitous, essential biological phenomenon in prokaryotes and eukaryotes. It is relevant to many areas of biology, molecular biology, biochemistry, and medicine. Examining DNA methylation at the molecular level also helps provide an understanding of the dynamic structure of DNA, protein–DNA interactions, and catalysis. Several uses for methylation of DNA in molecular cloning are discussed under Methyltransferase, DNA and Staggered Cut.

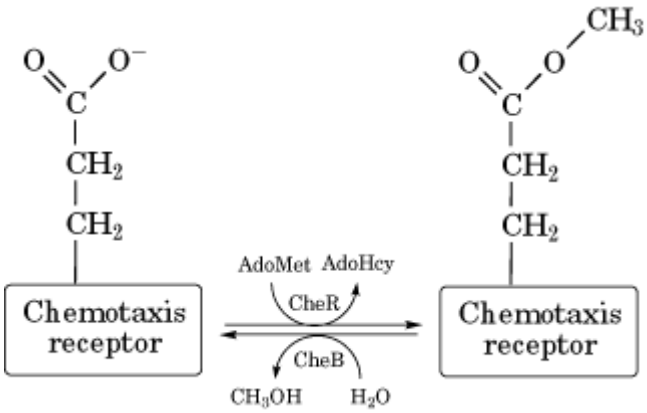
Methylation, Protein

A number of amino acid residues are subject to methylation, catalyzed by **methyltransferases** using *S*-**adenosylmethionine** as the methyl donor (1). In carboxyl methylation of glutamate, aspartate, or carboxyl-terminal residues, the methylation is reversible. In methylation of sulfur or nitrogen atoms, it is probably not reversed during normal metabolism. In the former, the methylation may play a role in signal transduction, or it may be connected with protein rejuvenation. In the latter, methylation is probably related to specific structures of proteins that enable them to function better (2, 3). Four distinct types of carboxyl methylation are known.

1. Glutamate Residues

The first is that of specific glutamate side-chains on chemoreceptors mediating chemotaxis in bacteria (Fig. 1). Increased methylation increases the activity of the CheA kinase that governs the behavior. The purpose of the receptors is to regulate the CheA kinase. For example, in *E. coli*, reduction of CheA activity caused by addition of attractant is compensated for by receptor methylation so that the stimulus is only short-lived (4) (see Chemotaxis).

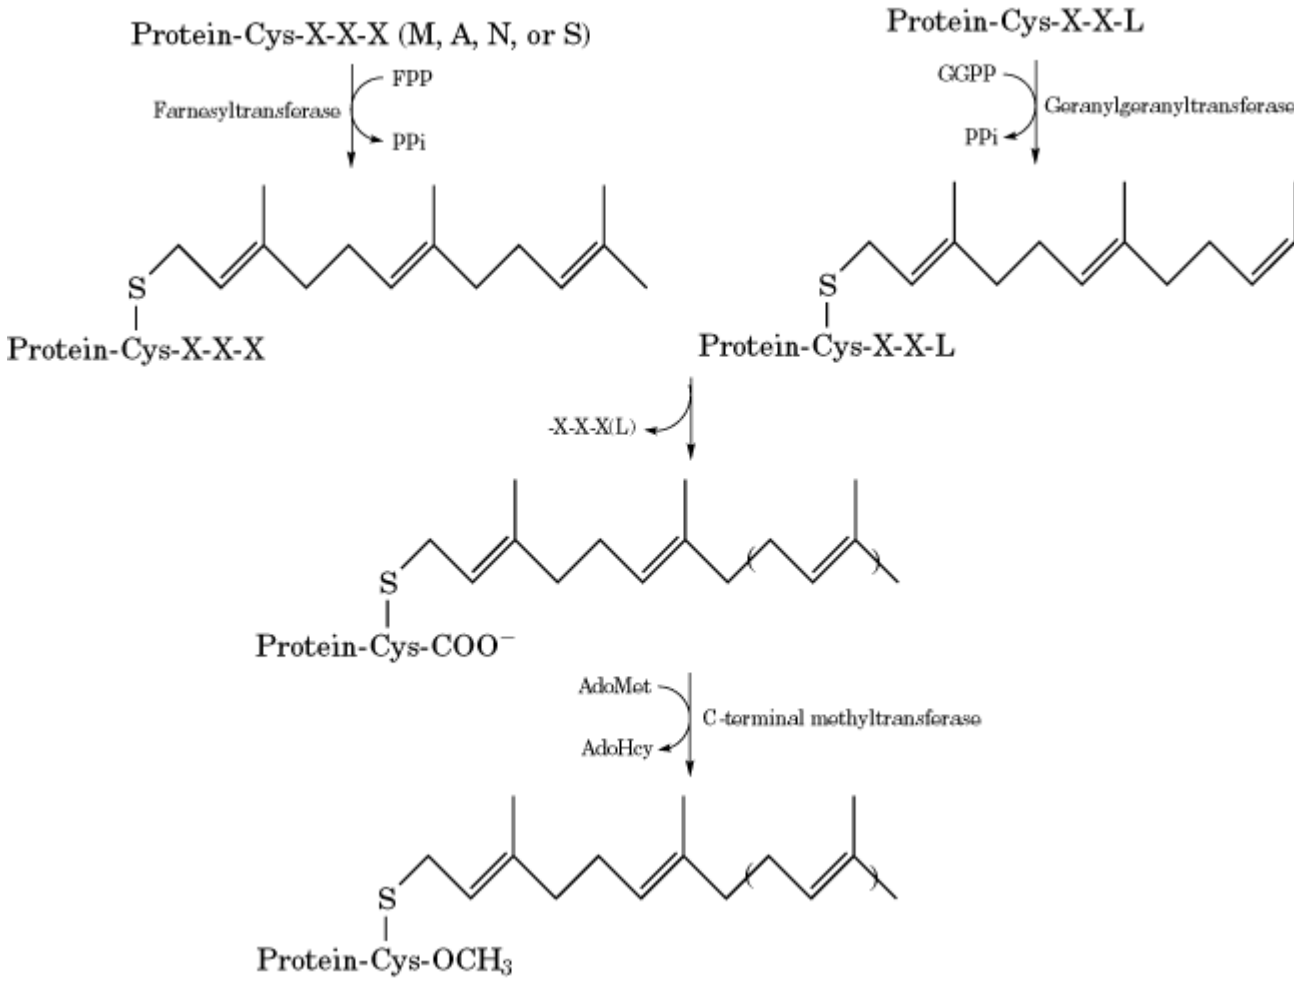
Figure 1. Methylation reactions on glutamate residues within the chemotaxis receptors in bacteria. The methylation reaction is catalyzed by CheR, and demethylation by CheB. Upon loss of its methyl group, the *S*-adenyosyl methionine (AdoMet) is converted to *S*-adenosyl homocysteine (AdoHcy).



2. C-Terminal Residues

The second type involves methylesterification in eukaryotic cells of C-terminal residues, specifically leucine and isoprenylcysteine. Protein **phosphatase** 2A dephosphorylates a number of phosphorylated, regulated enzymes, and it is regulated by methylation of its C-terminal leucine residue. Following the addition of a C_{15}-farnesyl or a C_{20}-geranylgeranyl group to the side-chain and usually the cleavage of the three terminal amino acids (see Prenylation), certain cysteine residues now become candidates for carboxyl methylation (Fig. 2). Certain fungal **mating type** factors, **ras proteins**, analogous small **G proteins**, and the g-subunits of large G-proteins are some of the proteins regulated by methylation. The assembly and disassembly of nuclear lamins may be regulated by methylation Even eukaryotic chemotaxis and platelet aggregation may involve reversible protein methylation (3).

Figure 2. Reactions involved in the process of C-terminal methylation of cysteine residues in eukaryotic cells. The C-ter
the target protein are shown at the top in the one-letter code. FPP is farnesyl diphosphate, and GGPP is geranylgeranyl d
transfer to the protein releases pyrophosphate (PP_i). The methyl donor is *S*-adenosylmethionine (AdoMet), which is relea
adenosylhomocysteine (AdoHcy).



3. Basic Residues

Protein methylation also facilitates "permanent" structural changes in proteins to allow them to function even better. Methylation of lysine residues to mono-, di-, or trimethyl-lysine is common in bacteria and eukaryotic cells. Examples include bacterial **flagellins**, **ribosomal** proteins, histones, rhodopsin and calmodulin. Calmodulin plays a role in controlling many enzymes, and transgenic **plants** that have unmethylated calmodulin produce poor seed. Trimethyl-lysine has a fixed positive charge and remains charged even in a **hydrophobic** environment.

Arginine residues can be mono- or dimethylated. Examples include myelin basic proteins, **myosin**, **heat shock** proteins, and proteins of the nucleus and ribosomes. It is common to find these among RNA-binding proteins, possibly because arginine methylation might disrupt certain hydrogen bonds that would occur between the protein and the nucleic acid (2).

Histidine, also a basic residue, is methylated in actin, myosin, histones, and rhodopsin, but beyond the possibility of furthering interactions with particular proteins, the purpose has not been discerned in any of the cases. One related example is the further metabolism of a particular histidine residue in ribosomal elongation factor EF-2 that is subject to ADP-ribosylation by diphtheria toxin. This histidine residue is metabolized to diphthamide in a process involving trimethylation of the a-amino group. Yeast unable by mutation to make this change grow more slowly. Finally, a particular amide nitrogen on an asparagine residue in certain phycocyanins and phycoerythrins, involved in photosynthesis in **cyanobacteria** and red **algae**, may be methylated, possibly to enhance efficiency of energy transfer to the light-harvesting complex (2).

4. Isomerized Aspartate Residues

As proteins "age," L-aspartyl residues become **isomerized** to L-isoaspartyl residues or **racemized** to D-aspartyl residues. Then these residues may become methylated, and their spontaneous demethylation sometimes restores the original L-isomer. Repeated cycles eventually restore the native protein (Fig. 3) (2).

Figure 3. Isomerization of an aspartate residue and its reversal using methylation. The succinimide intermediate can be generated by deamidation of an asparagine residue.

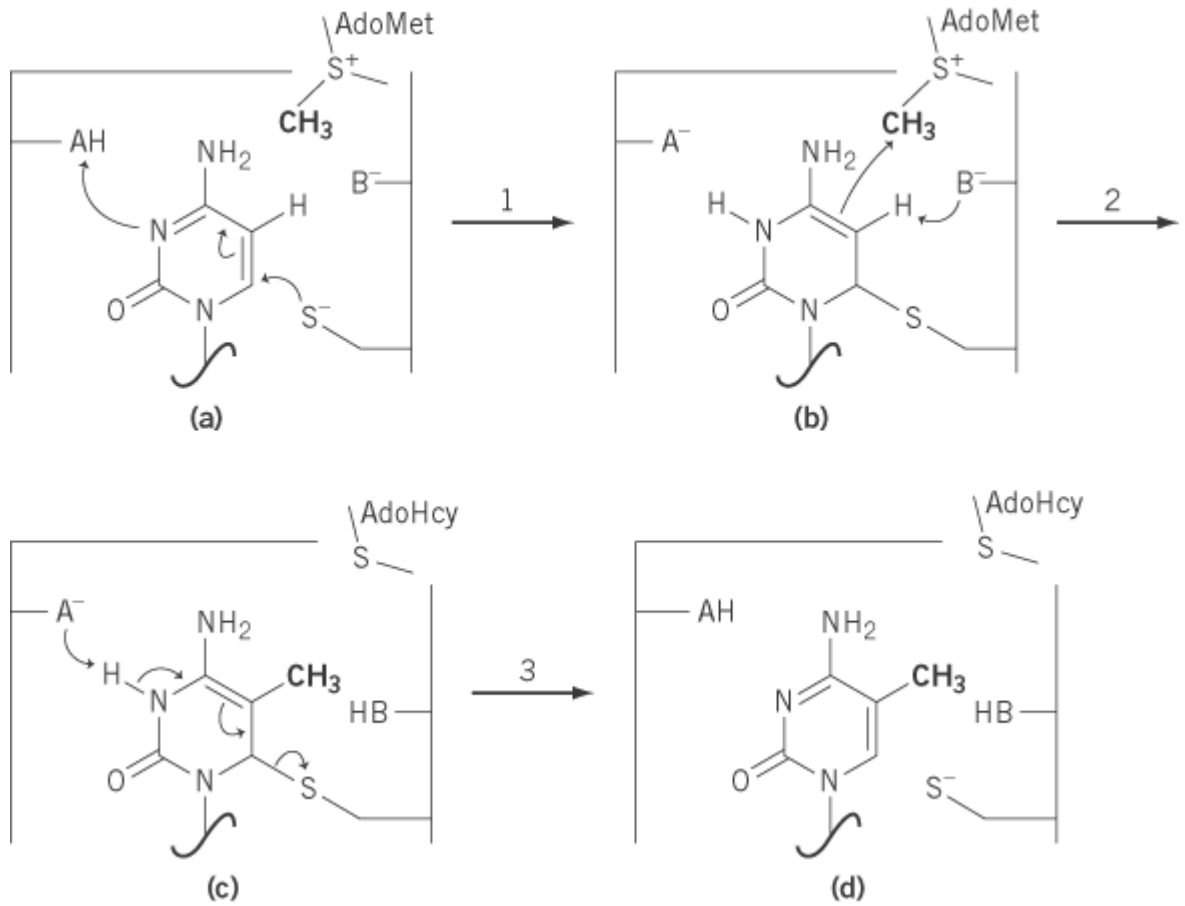
5-Methylcytosine

Cytosine bases in DNA can be modified to 5-methylcytosine (5mC) by DNA **methyltransferases**

(MTases, methylases). DNA methyltransferases are monomeric enzymes that catalyze the transfer and covalent attachment of a methyl group from the cofactor ***S*-adenosylmethionine** (AdoMet) to DNA with the release of *S*-adenosylhomocysteine (AdoHcy). Thus, methylation occurs at cytosine or adenine bases and forms C5-methylcytosine (5mC), *N*-4-methylcytosine (N4mC) or *N*-6-methyladenine (N6mA) (see Methyltransferase, DNA for structures). DNA methylation is involved in biological phenomena ranging from prokaryotic DNA replication and host DNA protection (as part of restriction–modification systems) to eukaryotic **gene regulation** and embryonic development (see Methylation, DNA). The X-ray crystallography structures of two prokaryotic 5mC MTases, M•*Hha*I (1) and M•*Hae*III (2), have increased our understanding of the structural and mechanistic basis of 5mC methylation. The structure of M•*Hha* I (GmCGC), where mC indicates the methylated cytosine in the GCGC DNA recognition sequence, was determined in a complex with AdoMet and in a ternary complex with the cofactor and a 13-bp DNA duplex containing a **suicide substrate**, base analogue, 5-fluorocytosine (5FC). M•*Hae*III (GGmCC) was solved as a binary complex with an 18-bp DNA duplex, also containing 5FC. These complexes are consistent with a catalytic mechanism for 5mC MTases that involves a covalent DNA–protein intermediate. In a mechanism first described by Wu and Santi (3) and later modified by Erlanson, et al. (4), methylation of a cytosine base occurs in three steps (Fig. 1). The second step is prevented when 5FC is the substrate; the electronegative fluorine in place of the hydrogen at C5 cannot be eliminated, and the enzyme is locked in a dead-end, covalent complex with the DNA (5, 6). In contrast, less direct evidence for the mechanism for the amino-methylating, N4mC-forming and N6mA-forming MTases exists. Interestingly, structural comparison of the enzymes M•*Taq*I (a N6mA MTase), and M•*Pvu*II (a N4mC MTase), both crystallized without DNA, with M•*Hha*I, revealed a basic similarity in active-site architecture that allowed the identification and assignment of catalytic residues involved in a proposed catalytic mechanism for the exocylic amino-methylating MTases (7). The proposed mechanism involves a direct transfer of the methyl group from AdoMet to the amino group, rather than through a covalent intermediate. The crystal structures of M•*Hha*I and M•*Hae*III have provided snapshots of the mechanism for both the 5mC and the exocyclic amino group methyltransferases.

Figure 1. Mechanism of 5mC methylation. (**a**) Nucleophilic attack on C6 carbon by thiol group of cysteine residue of MTase; (**b**) abstraction of methyl group from AdoMet and removal of hydrogen at C5; (**c**) regeneration of thiol group; (**d**) 5-methylcytosine (indicates bond attaching cytosine to the DNA, and the long straight lines indicate the active site of the protein).



Both M•*Hha*I and M• *Hae*III are two-**domain** proteins, with the larger domain containing catalytic and cofactor binding sites and the smaller domain involved in DNA recognition. The AdoMet binding regions of M•*Hha*I and M•*Hae*III contain Rossman folds for nucleotide binding analogous to the structures of other AdoMet-binding proteins, such as M•*Taq*I and catechol *O*-methyltransferase (2, 6), and a comparison of Ca positions of the M• *Hha*I and M•*Hae*III DNA MTases shows structural similarity throughout the large domain and bridging region. In contrast, the smaller DNA-binding domains have little structural similarity, except for a small conserved region that serves as a scaffold for the amino acids that interact with the DNA (2). The most remarkable feature in both crystal structures containing DNA is the extrahelical cytosine base, which is flipped out of the DNA duplex and positioned in an active-site pocket in the MTases. For M•*Hha* I, the cytosine is located near AdoHcy in the AdoMet binding pocket. How does the DNA duplex compensate structurally for the cavity created by the flipped base? M•*Hha*I shows significant distortion of the phosphate backbone of the strand in which the extrahelical cytosine is located, along with interdigitation of two amino acid residues from the recognition domain into the cavity opposite the orphaned guanine base. These residues **hydrogen-bond** to the unpaired guanine residue (6). With M•*Hae*III, on the other hand, flipping out of the base is accompanied by a reorganization of base pairs such that the lone guanine residue hydrogen bonds with a neighboring (3′) cytosine base on the opposite strand. This produces another unpaired 3′ guanine that hydrogen-bonds to an arginine residue, but leaves a large unfilled pocket in the DNA duplex (2). The overall structural similarity of C5-cytosine methyltransferases suggests that base flipping may be a common mechanism for this family of enzymes.

The base-flipping mechanism was first found with M• *Hha*I, but several lines of evidence suggest that the extrusion of a base from duplex DNA (or RNA) may be a prevalent occurrence among enzymes that must perform chemistry on bases. Studies using X-ray crystallography on short,

double-stranded DNA containing unpaired bases have shown that the unpaired bases can have both intra and extrahelical positions stabilized by crystal packing (2, 8). NMR studies of imino proton exchange in short, double-stranded DNA have shown the standard **free-energy** change for the base-pair opening to be 7–9 kcal/mol, comparable to protein-induced DNA distortion energies provided by the contacts made at the DNA–protein interface (8). Several DNA-binding enzymes crystallized without DNA, such as T4 b-glycosyltransferase, M• *Taq*I, and M•*Pvu*II have been proposed to contain active-site pockets that would accommodate extrahelical bases (9, 10). The crystal structure of a DNA repair enzyme involved in pyrimidine dimer excision, T4 endonuclease V, complexed with duplex DNA containing a thymine dimer, has been found to have an extrahelical adenine base. The expelled adenine base, which is complementary to one of the bases in the thymine dimer, is trapped in a pocket on the surface of the enzyme (11). Although the expelled base in this structure is opposite the strand in which the thymine dimer resides, its exit from the helix renders the damaged bases accessible to the repair enzyme. The detailed mechanism of how the cytosine or adenine bases are extruded remains speculative.

Determination of the mechanism of 5mC methylation and of the crystal structures of M•*Hha*I and M•*Hae*III provides insight into the structure–function relationships of these proteins. These findings also raise intriguing questions about the DNA dynamics resulting from DNA–enzyme interactions. Aberrant methylation patterns in mammals promote tumorigenesis and lead to developmental abnormalities (12, 13). Since eukaryotic C5-methylcytosine methyltransferases have amino acid sequence similarities to their prokaryotic relatives, the results from studies of the bacterial enzymes will likely contribute to understanding their eukaryotic counterparts.

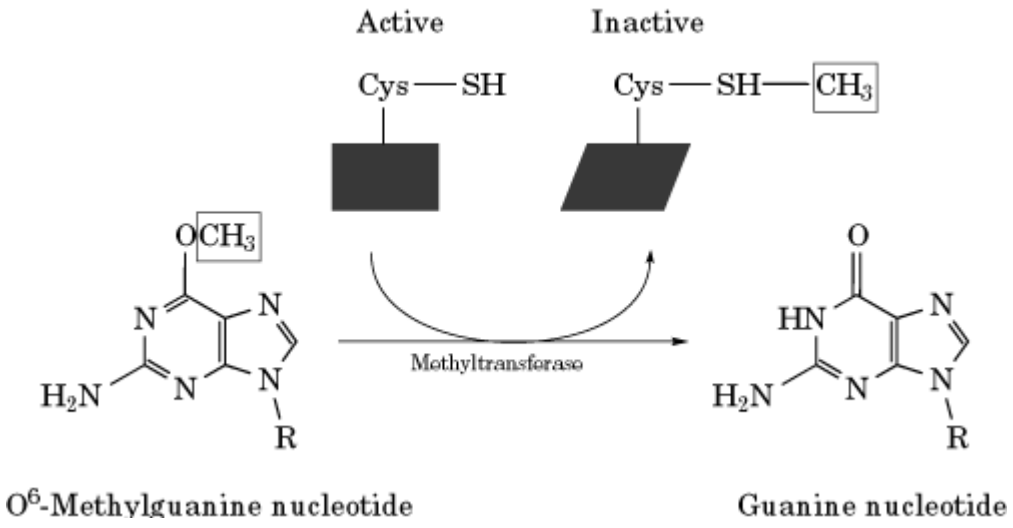
O^6-Methylguanine-DNA Methyltransferase (MGMT)

MGMT is an important enzyme of DNA repair. It carries out direct repair of alkylated DNA by transferring the alkyl group from oxygen atoms within the DNA molecule to a cysteine residue on the enzyme. This reaction is irreversible, and thus the MGMT is said to be a “suicide” enzyme

(Figure 1). The three lesions repaired by MGMT are O^6-methylguanine, O^4-methylthymine, and methylphosphotriesters induced by methylating agents such as *N*-methyl- *N*′-nitro-*N*-nitrosoguanidine (MNNG). The enzyme also repairs other alkyl guanines, however, such as O^6-ethylguanine and O^6-butyl-guanine, albeit at a much lower efficiency.

Figure 1. The "suicide mechanism" reaction catalyzed by MGMT. The enzyme transfers a methyl group from the O6 position of guanine to the active-site cysteine residue of the MGMT polypeptide chain to restore the normal base and form the stable *S*-methylcysteine adduct, which inactivates the enzyme.



MGMT has been found in all free-living species tested. Enzymes from these sources exhibit considerable sequence homology and contain the active-site cysteine residue within the –Pro–Cys–His–Arg–Val–signature sequence. *Escherichia coli* contains two MGMTs: Ada and Ogt. The Ada protein was the first MGMT discovered, and it mediates the "adaptation" response in this organism (1): Exposure to subtoxic doses of an alkylating agent such as MNNG renders cells resistant to subsequent toxic doses of the same or related alkylating agents. Ada is a protein of 39 kDa, and it has two well-defined, and easily separable, NH_2- and COOH-terminal domains. It performs three functions (2): (i) positive transcriptional regulator, (ii) phosphotriester methyltransferase, and (iii) O^6-methylguanine methyl transferase. The active-site residue Cys69 in the NH_2-terminal domain accepts methyl residues from the phosphodiester backbone, to form *S*-methyl-cysteine. Methylation of Cys69 causes a conformational change in Ada and enables it to activate the **promoters** of *ada, alkA* (methyladenine DNA glycosylase), *alkB*, and *aidB* genes and thus to increase cellular resistance to alkylating agents. The COOH-terminal domain contains the active-site Cys321, which carries out direct repair by accepting methyl groups from O^6-MeGua and O^4-MeThy, to form *S*-methyl-cysteine and to restore the normal bases. In addition to Ada, *E. coli* contains another MGMT called Ogt (3). This enzyme is structurally and functionally homologous to the COOH-terminal domain of Ada; it is expressed constitutively and is not part of the adaptive response.

Like *E. coli*, most other bacteria tested exhibit the adaptive response, although the mechanistic details might vary (see DNA Damage, Inducible Responses To). In *Bacillus subtilis*, AdaA has methylphosphotriester methyltransferase and transcriptional activator activities, in a manner analogous to the NH_2-terminal domain of Ada of *E. coli* (4). The AdaB of *B. subtilis*, similarly carries out the MGMT function performed by the COOH-terminal domain of the *E. coli* Ada protein. In *B. subtilis* there is also a noninducible MGMT (Ada C) comparable to the *E. coli* Ogt protein (4).

The eukaryotic MGMTs (including the human enzyme) are structural and functional homologues of Ogt-type methyltransferases (M_r ~20kDa); that is, they are suicide enzymes that repair O^6-methylguanine and O^4-methylthymine (5). They have no transcriptional regulatory function, nor is there evidence that these enzymes are induced by DNA damage specifically. In humans, increased resistance to anticancer alkylating agents occurs when there is a loss of MGMT activity by gene **silencing**, accompanied by a mismatch-repair defect arising from a mutation in a mismatch-repair gene.

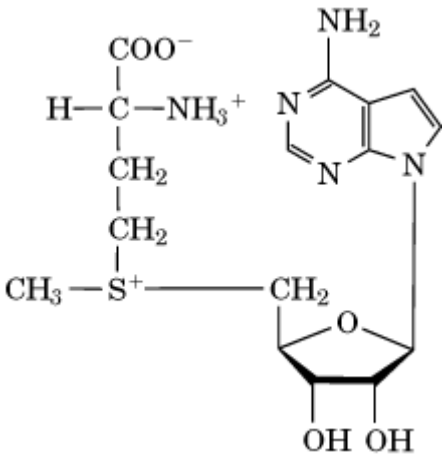
Methyltransferase

Methyltransferases use ***S*-adenosylmethionine** (AdoMet) as a methyl donor to catalyze methylation of functional groups on amino acids, usually on their side chains (1). Many different amino acids in proteins are methylated by a host of specific enzymes (see Methylation, Protein). Several instances of these are described in this article. The methyl group donated from AdoMet is on a sulfonium ion (trivalent sulfur atom having a "formal" positive charge) (Fig. 1) and is readily and irreversibly transferred to other atoms (1). AdoMet is an "expensive" molecule because it is synthesized from methionine and ATP with production of inorganic phosphate, P_i, and pyrophosphate, PP_i; the latter is rapidly cleaved to 2 P_i by pyrophosphatases. The net cost is three "high-energy" bonds (see Adenylate Charge), which signifies that maintaining AdoMet levels is a high priority for cells generally, apparently to methylate proteins and DNA (1).

Figure 1. Structure of *S*-adenosylmethionine.



Perhaps the most well characterized methyltransferases are the CheR methyltransferases in bacteria involved in Chemotaxis. These enzymes catalyze the methylesterification of a glutamate *(E)* residue within the protein **consensus sequence** (A/S)XXE*EX*(A/T/S)A(A/T/S) (2). These residues are located on two a-helical coiled coils within the cytoplasmic region of the **receptors,** known as methyl-accepting chemotaxis proteins (2). These methylated residues are located in different places in the receptors of ***Bacillus*** *subtilis* and ***Escherichia*** *coli* (3). In *E. coli* the effect of methylation is to increase kinase activity. In *B. subtilis,* the position of the site of methylation governs whether CheA kinase activity is increased or decreased. Interestingly, in some instances the glutamate residue is produced from a genetically encoded glutamine (see Genetic Code) by the CheB methylesterase acting as a deamidase. This enzyme also hydrolyzes the methyl esters produced by the action of CheR (2) (Fig. 2).

$$\text{MCP-glutamine} + H_2O \xrightarrow{\text{CheB}} \text{MCP-glutamate} + NH_3$$

$$\text{MCP-glutamate} + \text{AdoMet} \xrightarrow{\text{CheR}} \text{MCP-glutamyl-}CH_3 + \text{AdoHey}$$

$$\text{MCP-glutamyl-}CH_3 + H_2O \xrightarrow{\text{CheB}} \text{MCP-glutamate} + CH_3OH$$

In contrast with CheR, the CheB methylesterase of both *E. coli* and *B. subtilis* is activated by phosphoryl transfer from phosphorylated CheA and, hence, becomes stimulated when CheA is activated (2, 4). After autophosphorylation, the CheA kinase leads to increases in the concentrations of the phosphorylated forms of CheY and CheB. The former enhances tumbling in *E. coli* and smooth swimming in *B. subtilis,* whereas the latter causes demethylation of the receptors to reduce the activity of the CheA kinase (4). In other words, upon activation, CheA *simultaneously* causes an excitatory event (due to phosphorylated CheY) and sets in motion the adaptation process (due to the action of phosphorylated CheB). Moreover, in *B. subtilis,* both CheR and CheB are much more active immediately after the addition or removal of attractant rather than later, probably due to slow conformational changes in the receptors exposing the sites of methylation.

Other methyltransferases catalyzing methylesterifications have been identified and characterized. These include the enzyme that catalyzes the metabolically labile methylation of the carboxyl-terminal leucine residue of protein **phosphatase** 2A, an enzyme important in regulating cell

metabolism (7). The methylation and demethylation represent a novel device for regulating the phosphatase itself. The membrane-bound methyltransferase that catalyzes methylation of carboxylterminal isoprenylcysteine residues, which in yeast is the product of the *STE14* gene, has also been characterized, and strains lacking it have been studied (see Prenylation). Among other consequences, the a-**mating type** factor activity is much reduced (7).

In bacteria, the methyltransferase that catalyzes methylation of isoaspartate residues, an isomer of aspartate that occurs when proteins age, has been identified and the gene disrupted. This enzyme helps with reisomerizing isoaspartate back to aspartate, restoring the original protein. Bacteria mutant in this gene are sensitive to **heat shock** and survive poorly in a stationary phase, results that imply the importance of this type of protein repair (7).

Arginine methylation in eukaryotes is performed by a specific subfamily of methyltransferases. This family of methyltransferases contains AdoMet binding motif similar to small molecule and nucleic acid methyltransferases (8). Many of the methyltransferases also include a C-terminal domain involved in arginine substrate recognition. The typical recognition motif for the methyltransferase is RGG, RXR, and RG, which can be methylated in three ways: N^G-monomethylarginine (MMA), N^GN^G (asymmetric) dimethylarginine (aDMA), and N^GN^G (symetric) dimethylarginine (sDMA). Methylation of these conserved sites is also selective. RGG recognition sites have only been isolated as MMA and aDMA and no sDMA, while RXR and RG motifs have been isolated as aDMA-methylated but not MMA or sDMA. SmD1 and SmD3, spliceosomal small nuclear RNA binding proteins, have been isolated with sDMA methylation on the site GRG leading to the possibility that more recognition motifs exist and provide specificity as well as control of extent of methylation by the arginine methyltransferase.

Histone methylation at specific N-terminal lysine residues is believed to be associated with the epigenic inheritance of heterochromatin (transcritionally silent DNA), and transcriptional regulation (9). This modification is catalyzed by histone methyltransferases (HMT) on K4, K9, K27, and K36 of histone H3 and K20 of histone H4 in many organisms, although the pattern may be species-specific (9). Like all methyltransferases, HMT contains an AdoMet-binding motif, and, as arginine's guanidino group is multiply methylated, a single lysine can be mono, di, and tri-substituted. Little information is available concerning HMT regulation, although, in developing rat neuron HMT, activity is enhanced, and adult rat neuronal HMT activity is reduced (9).

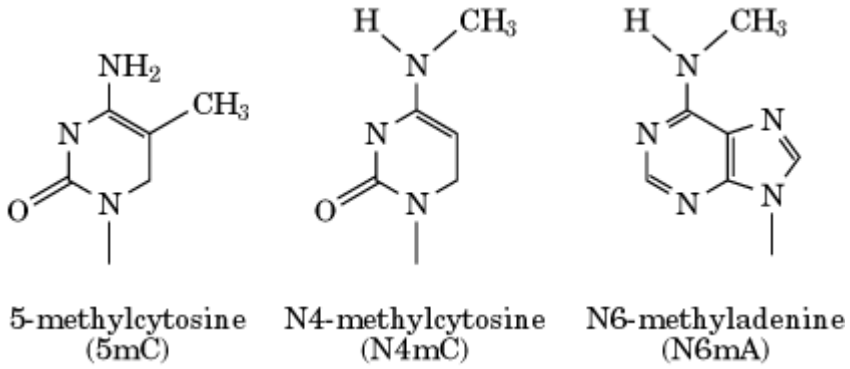
Methyltransferase, DNA

DNA methyltransferases [MTases, methylases] recognize specific duplex DNA sequences and catalyze the transfer of a methyl group from ***S*-adenosylmethionine** (AdoMet) to recipient adenine or cytosine bases within these sequences, with the release of *S*-adenosylhomocysteine (AdoHcy or SAH). DNA MTases are widespread in nature and serve several physiological roles (see Methylation, DNA). Prokaryotic DNA MTases function in mismatch repair and DNA replication and as part of restriction–modification systems. Eukaryotic DNA MTases are involved in **gene regulation**, development, and genome compartmentalization. MTases are classified according to the base they methylate (Fig. 1). The first class methylates the C5 position of cytosine to form 5-methylcytosine (5mC). The second class methylates exocyclic nitrogen atoms of adenine or cytosine to form *N*6-methyladenine (N6mA) or *N*4-methylcytosine (N4mC). The second class is further divided into different groups, a, b, or g on the basis of amino acid sequence differences and structural analysis (1, 2). Over 100 MTase genes have been **cloned** and sequenced. Analysis of several 5mC MTase amino acid sequences reveal a linear arrangement of 10 conserved motifs. One motif, a glycine-rich segment, is also found in other AdoMet-dependent MTases and is involved in **cofactor** binding (3). Another conserved segment, PC, is unique to the 5mC MTases and is a part of the active site . Analysis of the primary sequences of N6mA and N4mC MTases reveals two motifs, where the arrangement and distance between the motifs defines the subgroup classifications (2). The first motif is the glycine-rich segment analogous to those in 5mC MTases and the second a tetrapeptide sequence, (Asp/Asn/Ser)–Pro–Pro–(Tyr/Phe), which has been implicated as part of the active site.

Figure 1. Types of methylated bases in DNA.



Discussion here will be limited to prokaryotic type II methyltransferases. For type I, IIs, III, and eukaryotic methyltransferases see Restriction–Modification Systems or **DNA methylation**.

1. Crystal Structures and Sequence Comparison

The crystal structures of four prokaryotic type II MTases have been determined. Two 5mC MTases, M•*Hha*I (4) with AdoMet and M•*Hae*III (5), without AdoMet, have been solved in association with their target duplex DNAs. One N4mC MTase, M• *Pvu*II, and one N6mA MTase, M•*Taq*I, have both been solved in complexes with AdoMet (6, 7). Comparison of the crystal structures of the four enzymes, as well as the results of a **proteolysis** study using M•*Eco*RI (8), reveal that all these monomeric enzymes have a two-**domain** organization, having the cofactor-binding and catalytic site and DNA recognition region associated with different domains. The structures indicate similar patterns of folding and organization at the cofactor binding and active sites (5, 9). In fact, the active site and cofactor-binding regions of M• *Hha*I, M•*Pvu*II, and M• *Taq*I are found to be very similar when the central **b-sheets** of their structures are superimposed on each other (3, 6). On the other

hand, the DNA recognition domains of M• *Hha*I and M•*Hae*III have very dissimilar structures, except for two regions of amino acids that provide a scaffold for residues contacting the DNA (5). The common catalytic domain structures led Malone, et al. (1) to do a structure-assisted amino acid sequence analysis of 42 N6mA and N4mC MTases. This analysis revealed nine variably conserved motifs analogous to those found in 5mC MTases (I–VIII and X.) (1). Motifs I–III and X were hypothesized to be responsible for forming a cofactor-binding pocket and interacting with AdoMet. Motifs IV, VI, and VIII (the conserved PC motif in 5mC MTases and (Asp/Asn/Ser)–Pro–Pro–(Tyr/Phe) in N6mA and N4mC MTases) were proposed to participate in catalysis. Motifs V and VII were postulated to provide a structural framework for the catalytic region. Motif IX may provide a structural framework for the DNA recognition region in 5mC MTases, but no analogous motif was found in the exocyclic amino-methylating MTases (1, 3). Furthermore, the N6mA MTases analyzed by Malone et al. fell into three groups, a, b, or g depending on the order of the motifs from the *N* to *C* terminus of the protein, supporting the earlier sequence analysis by Wilson (2). For Dam MTase, a representative $N6mA_a$ MTase, motifs involved in binding AdoMet are first, followed by sequences involved in DNA recognition, and finally by catalytic-site motifs. Group b, which contains most of the N4mC MTases (including M•*Pvu*II), has an arrangement where catalytic-site motifs are first, followed by the DNA recognition region, and then the cofactor-binding motifs. Finally, group g, including M•*Taq*I, has an arrangement of cofactor-binding motifs, followed by the catalytic site motifs, and terminating with the DNA recognition region. In general, the solved structures support the proposals of Malone et al. (1).

2. DNA Recognition

MTases are monomeric enzymes that transfer one methyl group to a recipient base of one strand at the recognition sequence per binding event. Most MTases show no preference for hemimethylated or unmethylated DNA and will methylate either molecule at the same rate. MTases appear to search for their canonical recognition sites by facilitated diffusion, or sliding, along the DNA until the recognition sequence is located (10). Kinetic studies of MTases, including M.• *Hha*I (a C5 MTase) (11), M•*Eco*RI, and *Escherichia coli* Dam MTase (N6mA MTases) (12, 13), show that bound cofactor is necessary for specific sequence recognition. X-ray crystallography of M•*Hha*I (14) and footprinting analysis of M•*Eco*RV (15), M•*SssI*, and M• *Hha*I (16) indicate a majority of the interactions with DNA occur with bases and phosphates in the major groove. Studies of M•*Eco*RI (17) and M•*Eco*RV (18) with base analogues indicate that some interactions may also occur in the minor groove. For some *N*6-methyladenine methylases, site-specific recognition may be facilitated by DNA bending. Whereas the crystal structures of M•*Hha*I and M•*Hae*III show little bending of the DNA helix, gel-shift-mobility assays and scanning force microscopy techniques have shown that M•*Eco*RI (19) and M•*Eco*RV (20) bend DNA about 52° and 60°, respectively. A striking feature, which may be a recognition mechanism as well as a catalytic property of all MTases, was found in the X-ray crystal structures of the 5mC MTases M•*Hha*I and M•*Hae* III. The substrate cytosine base is extrahelical and flipped from the helix into a pocket in the enzyme, where it is subsequently methylated and released. This extrahelical base flipping is considered in greater detail in 5-methylcytosine. Others have used fluorescence-based assays of M• *Eco*RI (21) or modified base interference studies with M•*Eco*RV (22) to provide evidence for a base-flipping mechanism for N6mA MTases. The structures of both M• *Taq*I and M•*Pvu*II, although lacking DNA, have a "pocket" into which the target base could be flipped (6, 7). The N4mC MTases have sequence similarities to the N6mA MTases. All the DNA MTases likely require AdoMet binding and utilize phosphate and base interactions in combination with base flipping and possibly DNA bending to accomplish sequence-specific recognition.

3. Catalytic Properties

The steady-state kinetic analyses performed on MTases are consistent in that methylation by MTases follows an ordered bi–bi steady-state scheme, where AdoMet binding is a prerequisite to canonical DNA sequence recognition and methylation (11, 12, 23): (*1*) the MTase binds to nonspecific DNA

randomly, with or without AdoMet bound; and (*2*) in the presence of AdoMet, which confers recognition specificity, the target sequence is located and the recipient base of one strand is methylated. The product ternary complex is MTase-methylated DNA-AdoHcy. AdoHcy then dissociates, and depending on the processivity of the MTase (a measure of the ability to scan base pairs), the enzyme will dissociate from the DNA or move to the next site on the same DNA molecule (24). The overall reaction of DNA MTases is slow, with turnover rates (k_{cat}) generally less than $0.1 s^{-1}$ (12). The average K_M values for AdoMet and substrate canonical DNA are in the nanomolar range. MTases are extremely efficient catalysts, with k_{cat}/K_M values reaching **diffusion-controlled** limits (10^8–10^9 $M^{-1}s^{-1}$). The rate-limiting step for MTase catalysis occurs after the methylation step, since k_{cat} is slower than the rate of methyl group deposition, k_{meth} (11, 12, 23). The mechanism of the 5mC MTases has been elucidated and involves a covalent enzyme intermediate (see 5-Methylcytosine for a detailed description of the mechanism). The mechanism of N4mC and N6mA MTases likely involves the direct methylation without a covalent enzyme intermediate (6, 25). The structure of M•*Pvu*II, an N4mC-forming MTase, revealed the structural similarity of its active site to those of M•*Hha*I and M• *Taq*I, which form 5mC and N6mA, respectively (6). The similar locations of amino acids in the active sites of these three MTases that form all three kinds of methylated base allowed the assignment of specific residues to a catalytic mechanism for M•*Pvu*II. This mechanism, which probably does not involve a covalent enzyme–DNA complex, can likely be extended to enzymes like M•*Taq*I that form N6mA as well as to other N4mC-forming MTases.

4. Applications

Methyltransferases, or modification enzymes, can be used to modulate cleavage by restriction endonucleases (see Restriction Enzymes). Methylation of the DNA within or outside a specific restriction endonuclease recognition site prevents or inhibits cleavage by interfering with endonuclease binding or catalysis. For instance, MTases can be used decrease the number of possible restriction sites on a long DNA molecule. For example, R•*Ban*II cleaves at the degenerate sequences (GAGCTC) or (GGGCCC). Premethylation of DNA with M•*Hae*III, which is specific for (GG5mCC), reduces subsequent R•*Ban*II cleavage to the single sequence, (GAGCTC), because the other sequence is rendered refractory. Also, particular restriction sites can be protected from methylation by masking the restriction site with the use of DNA-binding proteins or oligonucleotides (that form triplex DNA regions). These proteins or oligonucleotides can subsequently be removed to unmask the chosen restriction site. In another technique, methylase-limited partial digestion, larger fragments of DNA can be generated by a restriction endonuclease through prior partial methylation with the cognate MTase (26).

In summary, DNA MTases are ubiquitous and simple in composition and cofactor requirements. Thus, MTases are useful for the study of DNA–protein interactions, enzyme mechanism and kinetics, and protein–cofactor interactions. They are also useful tools for the molecular biologist.

Michaelis–Menten Kinetics

Reactions catalyzed by non**allosteric**, classical enzymes E on substrate A to convert it to product P occur by the general mechanism

$$\mathrm{E} + \mathrm{A} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \mathrm{EA} \xrightarrow{k_3} \mathrm{P}$$

and are described by the general steady-state rate equation

$$v = \frac{VA}{K_a + A} \qquad (1)$$

where v and V represent initial and maximum velocities, respectively; K_a is the Km (Michaelis constant) for substrate A, which is present at concentration A. This equation will apply to multisubstrate reactions, provided that only a single substrate is varied and all others are held at fixed concentrations. Reactions described by the equation are considered to obey Michaelis–Menten kinetics.

It is important to recognize that for steady-state conditions to apply, the concentration of substrate must be sufficiently greater than that of the enzyme, by at least about an order of magnitude, so that formation of the enzyme–substrate complex does not significantly reduce the concentration of free

substrate. Under these conditions, the concentration of free substrate can be equated to the total substrate concentration, and the concentration of the enzyme–substrate complex will remain essentially constant during the time over which the initial velocity of the reaction is measured.

1. Characteristics of the Michaelis-Menten Equation

The Michaelis–Menten equation is a saturation function identical to that which would be obtained for the interaction of an antigen with an antibody or of a **ligand** with a **receptor**. Thus, a plot of velocity as a function of substrate concentration yields a rectangular hyperbola. There are two fundamental parameters associated with the equation:

1. When A tends to infinity, v = V and the reaction is zero-order with respect to A. V, the maximum velocity of the reaction, will be dependent on the concentration of enzyme E_t and the first-order rate constant k_3. This constant is equal to V/E_t and is the turnover number for the enzyme, which gives a measure of the number of moles of product produced per mole of enzyme (or subunit) per second. The magnitude of turnover numbers varies considerably as illustrated in Table 1.
2. When A is very small and tends to zero, $v = (V/K_a)A$. In this case, the initial velocity of the reaction is first-order with respect to A, and V/K_a represents an apparent first-order rate constant for the interaction of substrate with enzyme. This apparent rate constant has units of $M^{-1}s^{-1}$ and can be expressed simply in terms of rate constants as

$$\frac{V}{K_a E_t} = \frac{k_1 k_3}{k_2 + k_3} = \frac{k_1}{1 + k_2/k_3} \qquad (2)$$

It is only when $k_3 >> k_2$ that a true value for the bimolecular rate constant k_1 would be observed. The rates for the formation of enzyme–substrate complexes vary considerably and can approach the diffusion rate, which is in the vicinity of $250 mM^{-1}s^{-1}$ (Table 1) (see Diffusion-Controlled Reactions).

Table 1. Values of Kinetic Parameters for Selected Enzymes

Enzyme	Substrate	K_a (mM)	V (s^{-1})	V/K_a (mM^{-1} s^{-1})
Chymotrypsin	acetyl-L-tryptophanamide	5000	100	0.02
Lysozyme, hen	hexa-*N*-acetylglucosamine	6	0.5	0.08
Chorismate mutase	chorismate	100	47	0.5
Prephenate dehydrogenase	prephenate	65	95	1.5
Dihydrofolate reductase	dihydrofolate	1	20	20
Beta-Lactamase	benzylpenicillin	50	2000	40
Fumarase	fumarate	5	800	160

The Michaelis constant is the ratio of the two fundamental parameters V and (V/K_a), so it is not a fundamental parameter, but it is nevertheless an important parameter for the reasons outlined in Km (Michaelis constant).

Microfilament

Microfilaments are the helical polymers found in eukaryotic cells that are formed from actin. These filaments may contain only actin, or actin and associated proteins. In vertebrate striated muscle such filaments also contain tropomyosin, troponin, and nebulin (see Thin Filament). The term microfilament is largely an historical artifact, as it was used to denote the perceived morphological difference between these filaments, intermediate filaments, and the thick filaments of striated muscle that are formed from myosin. While the actin-based filaments were seen by various forms of electron microscopy to be about 65 Å in diameter, in contrast to the ~100 Å diameter of the intermediate filaments, we now know that the actin filament is also approximately 100 Å in diameter (1, 2).

Microinjection

Microinjection is the technique of injecting materials directly into the interiors of individual cells. It has many applications, including the introduction of: (i) messenger RNA and proteins into frog **oocytes** and cultured mammalian cells to investigate translation and protein function; (ii) **DNA** into **zygotes** or germ cells to produce **transgenic** organisms; (iii) mouse embryonic stem cells into blastocysts to produce **chimeric** mice (see Transgenic Technology); (iv) dyes or colloids into a cell of an embryo to trace **cell division** and differentiation during development; and (v) **sperm nuclei** into **oocytes** to treat human male infertility. Depending on the application, systems for microinjection vary in their degree of sophistication, but all consist of a microneedle inserted into an instrument holder, a pressure source for expelling the injectate, a microneedle micromanipulator, a microscope, and a microinjection chamber. The system may need to be placed on a vibration dampening support.

1. Microneedles

Microneedles are made from thin-wall borosilicate capillary glass tubing using a micropipette-puller. The dimensions of the pulled tip vary according to the application and preferences of the injector; puller settings are established according to manufacturer's guidelines and, to a significant extent, empirically. Bending of microneedles for accommodating them into microinjection chambers is achieved using the heated filament of a microforge or a small flame. The final tip diameters for injecting solutions into mammalian cells are 0.1 to 0.5 µm, and those for injecting solutions into mammalian zygote pronuclei are 0.5 to 2.0 µm. The approximate tip diameter in the lower range can

be gauged under a high-power objective (1). With this method it is difficult to resolve diameters less than ~0.5m, but if the tip diameter can be resolved it is probably too large for microinjection of mammalian cells (2). If pullers cannot be calibrated to pull medium tip diameters, between 0.5 and 2.0 µm, tips can be chipped by bringing them at right angles against a glass bead fused to the filament of a microforge. Alternatively, they can be beveled with a micropipette-beveler. The smaller the tip diameter, the more readily it will be clogged with particulates arising from either the microneedle or the injectate. Particulates can be removed by washing and siliconizing the unpulled glass capillaries (1, 2) and by centrifuging the injectate at ~15,000 g for 15 min. A fiber or filament within the microneedle allows the tip to be filled from the back with the material to be injected. It is deposited inside the microneedle close to the tip, using a drawn capillary attached by tubing to a mouthpiece. It then flows along the fiber to the tip by capillary action. Alternatively, the injectate can be drawn into the tip from a small drop under the microscope if an oil-filled optical transmission system is used.

The final tip diameter for injecting mouse embryonic stem cells into blastocysts should be ~20 µm. The sharpest tips are produced by breaking the pulled glass at the final diameter with a microforge, beveling the tip, then making a small spike at the tip of the bevel with a microforge (3). For simplicity, however, most injectors produce bevels by resting the pulled glass on a silicon pad and cutting at the desired diameter with a scalpel blade under a stereomicroscope (4). Similar tips may be used for the microinjection of spermatozoa under the zona pellucida or directly into the cytoplasm of mammalian oocytes, although smaller diameters are used (5-7).

2. Pressure Sources

2.1. Compressed Gas

A simple system commonly used for injecting mammalian zygote pronuclei is air-filled and consists of a 50-mL glass syringe connected by tubing to the microneedle holder. Injectate is expelled by pushing the plunger in by hand; and as long as the plunger is not pulled out, there is no risk that medium will be drawn into the microneedle and dilute the injectate. An automated system connected to a cylinder of compressed gas and providing three pressures (injection, back and purge), with a foot-operated switch between injection and back pressure, can be made in a workshop (8) or purchased commercially. Back pressure prevents entry of medium into the microneedle, and purge pressure is useful for clearing cell debris or particulates from the tip. Such a unit is desirable for microinjection of cultured mammalian cells, because the greatest control of flow of injectate can be obtained. Nevertheless, consistency of the volume in successive injections is not guaranteed, since the tip diameter alters with the collection of cell debris.

2.2. Hydraulic

The pressure source usually consists of a micrometer syringe connected by tubing to the microneedle holder. The whole system is filled with either light or heavy paraffin oil (the heavier oil being the most stable), silicon oil of similar viscosity, Fluorinert, or water. Injectate is deposited into microneedles as described above, and the rest of the space in the microneedle is filled with oil or Fluorinert from the back with a 30-gauge steel needle attached to a syringe. Such a system has sufficient control for injecting nuclei of mammalian cultured cells (2, 9), although control of flow is not as great as with the automated three-setting pressure system, and is also used for injecting mouse embryonic stem cells into blastocysts. For injecting solutions into cells, tubing for connecting the micrometer syringe to the microneedle holder is often hard-walled and of small diameter, although similar control of flow can be obtained with semihard wall tubing up to 6 mm in diameter connected to a micrometer syringe with a larger barrel. DNA may also be expelled from the micropipette, without the use of pressure, by iontophoresis (10).

3. Micromanipulators

Fully mechanical or hydraulic–mechanical combination units employ ratio reduction mechanics to reduce the movement generated by the hand. When at rest, these units are subject to gravitational

drift. Electronic units employ motors that drive in steps as small as ~150 nm and therefore have the greatest resolution of movement. Because they are driven indirectly by the hand, however, they do not respond exactly with the time and speed of hand movement. Although all three types of units are suitable for all applications, mechanical and hydraulic–mechanical combination units are most suited for use with mammalian ova, because rapid and sudden movements are often required, and electronic units are most suited for injection of mammalian cultured cells, because precise movement over small distances is important. Micromanipulators that fit onto the microscope stage are not subject to the stage being fixed in the vertical axis, but in this case the whole of the stage must be movable in the horizontal plane.

4. Microscope

Inverted microscopes are usually employed for the injection of mammalian zygotes and cultured cells. The large working distance between the condenser lens and the stage accommodates a large range of designs of microinjection chambers and microneedles. Cultured cells can be injected conveniently with the microneedle entering an open dish at a steep angle from above. Upright microscopes with long working distance objectives and a stage fixed in the vertical axis are more limited for chamber design, but they can be used more conveniently for injecting nuclei of cultured mammalian cells under high-power oil-immersion objectives. Differential interference contrast (DIC) optics provide the best resolution of cellular and nuclear membranes, but are expensive and must be used with glass chambers. Hoffman Modulation Contrast optics create a similar effect to DIC providing a less expensive, but lower-resolution, alternative and can be used with plastic chambers. Phase contrast optics can also be used for injecting nuclei of mammalian ova and cultured cells but do not provide good resolution of membranes. Nevertheless, these optics are preferred by many for injecting embryonic stem cells into blastocysts (see Microscopy).

5. Microinjection Chambers

This design of this component of the microinjection system varies greatly, being subject to personal preference. A versatile chamber is one in which the medium containing the target cells is sandwiched between a slide and a coverslip and is surrounded by oil (9). This chamber accepts microneedles from the side, and, if raised a few millimeters on the stage, no bending of microneedles for entry into the medium is required. Optical performance is optimal at all points, because the droplet of medium is flat on the upper and lower surfaces. Also, the medium is extremely stable with respect to movement of the microneedle. Apart from being useful for the manipulation of mammalian ova, this chamber can be used for the injection of cultured mammalian cells attached to the coverslip under high power oil immersion optics (2, 9). Other chambers used for the manipulation of mammalian ova include the hanging drop chamber (11) and the simple depression slide chamber (12).

6. Vibration Dampening

The microneedle must be stable when viewed under the microscope, because vibration will increase the frequency of membrane lysis. If vibration occurs, microinjection systems can be placed onto heavy wood or marble tables or onto metal plates resting on top of rubber, inflated innertubes, or squash balls. Although these supports give some dampening, they do not completely eliminate vibration. Commercially available devices, such as gas cushion tables, usually do eliminate vibration and are a fraction of the cost of the microinjection system as a whole.

7. Microinjection in Nonmammalian Organisms

For organisms commonly used in research, methods of microinjection have been described for the frog (13-15), nematode worm (16), **Drosophila** (17), and zebrafish (18) and are essentially the same as described above.

Micronucleus, Macronucleus

Ciliated protozoa (eg, *Paramecium* and *Tetrahymena*) contain a small micronucleus and a larger macronucleus. The micronucleus, although quiescent in **RNA** production, is the repository for the intact genome, which is usually **diploid** in ciliates. Conversely, the macronucleus is transcriptionally active, but it contains a much larger amount of DNA, all of which exists as small fragments of about

2000 base pairs (bp) that are repeated hundreds to thousands of times. All of the genes necessary for survival of the ciliate are present in and expressed from these small macronuclear DNA fragments.

The life cycle of *Tetrahymena* describes the biogenesis and fate of micro- and macronuclei. Upon conjugation between two *Tetrahymena* cells, the micronucleus in each cell undergoes **meiosis** to form four haploid micronuclei. Three of the haploid micronuclei degenerate, and the remaining one undergoes a single round of **mitosis**. The old macronucleus is still present at this point. The mating cells exchange a single micronucleus (pronucleus) through the cytoplasmic bridge connecting the two cells. The haploid micronucleus that enters the other cell fuses with the haploid micronucleus that remained behind there (fertilization), thus reestablishing the diploid state. After fusion, the diploid micronucleus of the zygote undergoes two rounds of mitosis, leading to four diploid micronuclei in each cell (which have now separated and are called exconjugates). Two of these diploid micronuclei become the precursors of new macronuclei, while the old macronucleus from the previous generation breaks down. One of the other two micronuclei degenerates, leaving only one of the original four. At this point in the life cycle, each exconjugate cell contains two macronuclei and the one remaining micronucleus. Then both exconjugate cells divide. In the process, the micronucleus undergoes mitosis, but the two macronuclei do not. The end result is that each cell contains one macronucleus and one micronucleus.

The conversion of a micronucleus into a macronucleus requires **chromosomal** breakage, followed by genomic DNA deletion and rearrangement (1). In *Tetrahymena*, chromosomal breakage is mediated by a specific 15-bp *cis*-acting element known as a chromosomal breakage sequence (Cbs). The element is found in multiple copies but only within the micronuclear genome. The Cbs elements are necessary and sufficient for breakage, and they are lost from the micronuclear genomic DNA upon cleavage. *Trans*-acting Cbs-recognition factors work in conjunction with **nucleases** to cut the DNA and then with telomerase to stabilize the ends. Next deletion of DNA (up to 15% in Tetrahymena) occurs in segments ranging from several hundred to >13kbp. The segments to be eliminated are AT-rich and are flanked on their ends by short direct repeats that do not play a role in the excisional mechanism. Instead, flanking A_5G_5 sequences within the retained DNA (~45bp from the actual boundaries) direct where the cuts are made. Sequence elements internal to the eliminated DNA are also necessary to promote the deletion process. At least one *trans*-acting protein, Pdd1p, recognizes these internal sequences (2). Coyne *et al.* (1) present a model in which *trans*-acting factors bind the flanking A_5G_5 sequences and then interact with Pdd1p to mediate excision.

Differences between the levels of transcription in macronuclei and micronuclei suggest differences in chromatin composition, particularly with regard to histone H_1. Similar to histone H_1 proteins from other **eukaryotes**, that in *Tetrahymena* macronuclei associates with the linker DNA between **nucleosomes**, is soluble in 5% perchloric acid, and dissociates from chromatin at salt concentrations lower than the other histone proteins (3). It is unusual, however, in that it lacks the central **hydrophobic** globular domain characteristic of other H_1 histones. The micronucleus, on the other hand, has no such H_1 protein discernible. Instead, the micronucleus contains proteins designated a, b, and g that interact with the linker DNA, but display tryptic **peptide maps** that differ from those of the macronuclear H_1 species (4). Macronuclear-specific histone variants have been identified, further exemplifying fundamental biochemical differences between micro- and macronuclei, both of which exist within the same cell.

Microsatellite DNA

Microsatellites and **minisatellites** have become valuable tools in genetic mapping, forensic identity testing, and population studies as a result of their abundance, relatively uniform distribution, and high degree of **polymorphism**.

The human genome contains approximately 50,000 copies of an interspersed dinucleotide repeat with the sequence $(T–G)_n$, where *n* is between 10 and 60. Such repeats have been found in many regions that have been fully sequenced. As with minisatellite DNA regions with longer repeat elements, they often display extensive length polymorphisms (1). Other microsatellite polymorphic sequences, such as $(C–A)_n$. and $(G–T)_n$, have been found in humans (2).

1. Use of Microsatellites for Genome Sequencing

Microsatellites are present in the genomes of all eukaryotes. They have been analyzed for size variation by the polymerase chain reaction (**PCR**) and gel electrophoresis in humans and in mice, among others. If they are sequenced and taken as the substrate for the polymerase chain reaction (see below), they become highly informative locus-specific markers. By analogy with the **sequence-tagged sites** (STS), which serve for the standardization of physical genetic maps, they are termed *sequence-tagged microsatellite sites* (STMS). Genetic maps based on STMS share the advantage with STS-based maps that mapping vocabularies are standardized to the DNA sequence base and that access to any particular locus does not require shipping or storing cloned probes (3).

Microsatellites are sequences consisting of a repeated very simple motif. The most widespread in the human genome is $(C–A)_n$, where *n* varies from 5 to about 50. They are interesting because they are very polymorphic. If such a sequence exists in a certain site of the genome, it is likely to be $(CA)_{17}$ in one given individual, $(CA)_{18}$ or $(CA)_{15}$ in another one, and so on. These sequences are very widespread in the human genome because, on average, there is one every 10 kb. Therefore, they constitute perfect landmarks for a detailed genetic map. However, the polymorphisms cannot be detected by a simple Southern blot, as can restriction fragment length polymorphism (**RFLP**). First, it is necessary to find a microsatellite in the region where a marker is desired, for example, by screening **cosmids** containing this region with a $(CA)_{10}$ probe (because of the average spacing of microsatellites, one is practically certain to detect some). After identifying the fragment containing the microsatellite, it must be sequenced to define the unique DNA flanking sequences. From this information, primers must be synthesized by PCR to target the required region of the genome specifically. Analysis of the DNA from a series of individuals requires amplifying each DNA by PCR and analyzing the amplification product by electrophoresis on a highly resolving polyacrylamide gel, because one must be able to distinguish length variations of two nucleotides in a fragment of 100 to 200 nucleotides. Although more complicated than classic Southern blotting, this

method can be partially automated and is worthwhile because of the power of the method. The markers are almost always informative. Since 1992, linkage maps based on microsatellite markers are regularly put at the disposal of the scientific community (4-6). The most recent human genetic map is based on 5264 short tandem(A-C/T-G)$_n$ repeat polymorphisms, spans a genetic distance of 3,699 centiMorgan (cM), and comprises 2335 positions. The majority of the position can be ordered with a probability of at least 1000:1 against alternative orders. The average interval size is 1.6 cM; 59% of the map is covered by intervals of 2 cM at most, and only 1% remains in intervals above 10 cM (5).

A search of the DNA sequence databases revealed that the location of dinucleotide microsatellites is often conserved among mammalian species, enabling the prediction of the presence of microsatellites by comparative genetic data. In closely related species, this conservation was adequate to allow PCR primers designed for use in one species to be used to analyze microsatellite length polymorphism in the other. The ability to use heterologous PCR primers, coupled with comparative map information, facilitates the use of DNA microsatellites in gene mapping studies in closely related species, such as cattle and sheep, rat, and mouse, or primates (7).

The same type of length variation is found in nuclear genomes and also in the chloroplast genomes of many plants (8).

2. Possible Origin of the Microsatellites

A number of microsatellite repeats have been found associated with the **Alu** type of repeated interspersed DNA elements. The association of an Alu sequence with a microsatellite repeat could result from the integration of an Alu element within a preexisting microsatellite repeat, or Alu elements could have a direct role in the origin of microsatellite repeats. A microsatellite repeat could result from errors introduced during **reverse transcription** of the primary **transcript** derived from an Alu “master gene” or from the accumulation of random mutations in the middleA- rich regions and oligo(dA)-rich tails of Alu elements after insertion and subsequent expansion and contraction of these sequences. These hypotheses have been tested by direct evolutionary comparison of the sequences of some recent Alu elements, found only in humans and absent from nonhuman primates, and older elements present at orthologous positions in a number of nonhuman primates. That the Alu elements were a source for the genesis of primate microsatellite repeats is suggested by the origin of the “young” Alu insertions, the absence of sequences that resemble microsatellite repeats at orthologous loci in chimpanzees, and the gradual expansion of microsatellite repeats in some old Alu repeats at orthologous positions within the genomes of a number of nonhuman primates (9).

Microscopy

The applications of microscopy to molecular biology are rapidly expanding as new microscopes and techniques are developed. Historically, the field of microscopy has been divided into two major realms—light microscopy and electron microscopy. However, with the advent of new microscopies, such as atomic force, scanning tunneling, X-ray, NMR, and acoustic microscopies (1), the need for a new classification is evident, perhaps along the lines of the structural features observable with each kind of microscope. The first question to ask is, "How does one choose the type of microscopy to use for a particular specimen?" To answer this question, one must first know the approximate size of the specimen and the level of structural detail desired. Key aspects of important subfields of microscopy of interest to molecular biologists are treated here along with applications which illustrate the power of each technique.

1. Light Microscopy

1.1. Transmission Light Microscopy

It is important to realize that *bright field (Kohler) microscopy* (as is true for all microscopies) allows for the observation of a magnified image of the specimen and not the specimen itself (2). The imaging process is achieved through the interference of light waves issuing ultimately from the back of the objective lens of the light microscope. Kohler illumination is produced by first positioning a lens in front of the light source so that its image is *not* in the specimen plane. A second (condenser) lens places an image of the surface of the first lens onto the specimen with as short a focal length as possible to obtain as wide a cone of light as possible to illuminate the specimen. The purpose of this illumination is first, to achieve an evenly lit field of view against which the specimen detail can be recognized and second, to attain the maximum resolution of fine detail by having a wide cone of radiation. Specimen visualization with this kind of microscopy relies on stains or contrast in the specimen itself. Fluorescent dyes offer more sensitive visualization than simple absorption contrast.

If the specimen has insufficient contrast for bright field microscopy, then *phase contrast microscopy* may be tried. Examples are unstained specimens which can be described as phase objects because they do not significantly reduce the transmitted intensity, yet differ in refractive index from the background. Hence elements in the transmitted beam can be separated according to differences in the optical path traversed (a product of the distance traveled and the index of refraction). Interference between the reunited elements will then produce detectable differences in intensity in the image. Phase contrast microscopy has remarkable sensitivity, capable of distinguishing differences in optical pathlength of 7/360 of a wavelength (2). However, it has a disadvantage in that the image of each feature is surrounded by a halo of bright light. This halo degrades the resolution of small objects. Phase contrast can be useful for weakly stained specimens, but is not suitable for heavily stained or thick specimens, since the interference from multiple diffractions is uninterpretable.

Nomarski or differential interference contrast (*DIC*) *microscopy* is superb for looking at living cells because it is noninvasive and high contrast is produced along the edges of biological structures (3). This type of microscopy detects abrupt changes of refractive index occurring over a small distance. Thus, for example, mitochondria, nuclear membranes, and lipid droplets are clearly visualized. The images produced with a Nomarski microscope appear three-dimensional because one side of the specimen appears lighter than the other side; this 3-D effect is actually an artifact of the polarized light used. Another useful property of Nomarski imaging is that thin optical sections can be obtained, and, unlike phase contrast imaging, thick specimens can be optically sectioned. Real-time optical sectioning allows for the observation of organelle movement. Nomarski microscopy was used to investigate spiral chloroplast movement in a filamentous alga (4).

Microtubule-Associated Proteins (MAPs)

A large number of structurally diverse microtubule-associated proteins (MAPs) are bound to the surface of microtubules in cells. It is widely accepted that many of these MAPs play critical roles in the regulation of microtubule polymerization and dynamics, in the organization of microtubule arrays, and in the functional interactions of microtubules with other cellular components. MAPs from different species, as well as from different cells and tissues of the same species, differ widely in their molecular properties and functions (1).

The best-studied MAPs to date are several neural MAPs whose functions appear to involve stimulation of microtubule polymerization during formation of neuronal cell processes and stabilization of microtubule dynamics in mature axons and dendrites. One such group of MAPs, called tau proteins, is a family of closely related 55- to 62-kDa phosphoprotein isoforms found predominantly in axons that arise by alternative splicing of the messenger RNA of a single tau gene. Tau may be involved in the etiology of Alzheimer's disease; a hyperphosphorylated form of tau is the major protein component of the paired helical filament lesions found in brains of patients with this disease (2, 3). A second well-studied MAP is MAP2, a 200-kDa protein that exists in two similar isoforms which, like the tau isoforms, also arise by alternate exon splicing of a single MAP2 gene. MAP2 is expressed in neurons and associates with microtubules in dendrites and cell bodies, but not in axons. Both tau and MAP2 contain remarkably similar microtubule-binding domains in their *C*-terminal segments and very different arm-like projection domains in their *N*-terminal segments. The different projection domains of MAP2 and tau presumably reflect the different functions of tau and MAP2 in axons and dendrites. MAP2 and tau are multiply **phosphorylated** on serine and threonine residues in their microtubule-binding domains by a number of **Ser/Thr protein kinases** *in vitro*, including MAP kinase, **cyclic AMP**-dependent protein kinase, and calcium-**calmodulin** -dependent protein kinase, and phosphorylation strongly influences the ability of these two MAPs to bind to microtubules and to modulate their polymerization *in vitro*. A great many other MAPs exist in different cell types and tissues, such as MAP 4, a fairly well-characterized high-molecular weight MAP prominent in mammalian cells (4). Most MAPs, however, remain to be characterized.

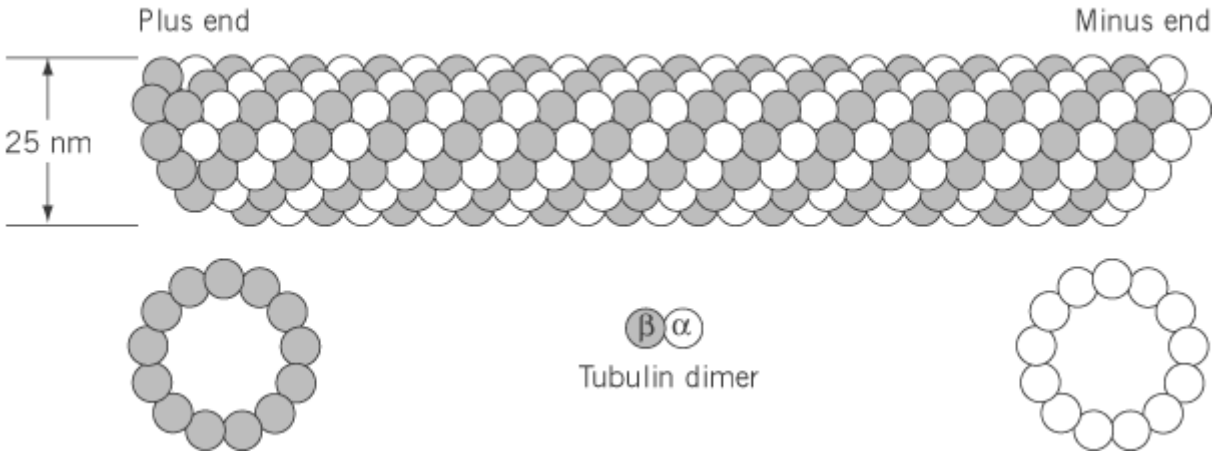
Microtubules

Microtubules are tube-shaped protein polymers, approximately 25 nm in diameter, that can vary from a few to many micrometers in length (Fig. 1). They are present in virtually all eukaryotic cells but are not found in prokaryotic cells. Microtubules are a major component of the cell's cytoskeleton and, along with actin filaments and intermediate filaments, play critical roles in the determination of cell shape, in the organization of the cell's cytoplasm, and in many forms of cellular motility (1). For example, microtubules are prominent in the nervous system, where they are critical for the development, structural organization, stability, and functions of the axonal and dendritic processes of neurons. They are also critical for mitosis, the process during the cell cycle in which the previously duplicated DNA in the form of highly condensed chromosomes is distributed equally with exquisite accuracy to the daughter cells at the time of cell division. The basic building block unit of the microtubule is tubulin, a 100-kDa, ~0.4 – nm × 0.5 – nm × 0.8 – nm dimer composed of two 50-kDa subunits known as a-tubulin and b-tubulin. A large number of additional cellular molecules, called microtubule-associated proteins (MAPs), bind to the surface of the microtubule and determine and control its many functions. Microtubules accomplish their multiple tasks in diverse kinds of cells by a combination of their polymerization dynamics, their interactions with specific MAPs, and their interactions with motor molecules, which transport cargo along the surface of the microtubule. The functions, cellular organizations, and biochemical and molecular properties that determine the ability of microtubules to carry out their many functions are summarized here.

Figure 1. Structure of a typical microtubule. The b-tubulin subunits are darkly shaded and the a-tubulin subunits are lightly shaded. The b-tubulin subunits are exposed at the plus ends (17).



1. Microtubule Structures, Microtubule Organizing Centers, and the Stability and Organization of Microtubule Arrays

Microtubule polymers are composed of ab-tubulin heterodimers arranged in a uniformly repeated head-to-tail fashion, with the long axis of the heterodimer oriented parallel to the long axis of the microtubule (Fig. 1). Thus, all of the b-tubulin subunits face one end of the microtubule, and the a-subunits face the opposite end. The ends are designated either plus or minus, based upon their different dynamic and structural properties. Current evidence suggests that the b-subunits are exposed at the plus ends while the a-subunits are exposed at the minus ends. Each linear array of

tubulin heterodimers is called a *protofilament*, and in cells most microtubules consist of 13 protofilaments arranged into a tube structure. However, many examples exist in which microtubules have a different number of protofilaments (from 11 to as many as 15).

Microtubules in cells are usually organized by an organelle called the *microtubule organizing center* (MTOC) or *centrosome* (2). The minus ends are tethered at the MTOC and the plus ends are away from it, often in a radial distribution. In cultured animal cells, for example, most microtubules are arranged radially in the cell, all or most emanating from the centrosome, which consists of a pair of *centrioles* surrounded by a matrix of poorly understood composition and organization. One of the known proteins of the MTOC is a form of tubulin called g-tubulin, which does not form microtubules itself and does not become incorporated into microtubules, but does appear to function in the nucleation of microtubule formation. Not all microtubules in different types of cells and arrays are anchored to centrosomes, and the origins of such noncentrosomal microtubules are not yet known. Interestingly, the MTOCs in cells from higher plants do not contain centrioles, but they still function as microtubule organizing centers.

Single microtubules abound in a great many cellular microtubule arrays, but many specialized microtubule arrays also exist in which microtubules are fused along their lengths into doublet or triplet microtubule structures (3). Doublet microtubules consist of 10 or 11 protofilaments of a second microtubule fused to an entire 13-protofilament first microtubule, and triplet microtubules have an additional 10 or 11 protofilaments of a third microtubule fused to the second microtubule. Doublet microtubules occur in the long shafts of motile cell appendages called *cilia* and **flagella**. Triplet microtubules occur in the basal body structures that in most animal cells are situated at the base of cilia and flagella and in centrioles, which are situated at the center of animal cell centrosomes.

One of the hallmarks of cytoplasmic microtubules is their rapid dynamics. Microtubules are assembled and disassembled from a large pool of cytoplasmic tubulin subunits, and because of their rapid dynamics, many cytoplasmic microtubules are very labile. There is a continuous exchange of tubulin subunits between the soluble tubulin pool and the microtubules. Half-times for turnover of tubulin in cytoplasmic microtubules can be remarkably short, no more than 15 to 30 s, as for example with microtubules in the mitotic spindles of cultured animal cells (4). Such microtubules polymerize and depolymerize rapidly in response to the cell's needs. Another hallmark of dynamic cytoplasmic microtubules is their sensitivity to cold temperatures; cooling cells to 0°C induces rapid disassembly of labile microtubules. However, many microtubules present in the cell's cytoplasm are relatively stable. For example, microtubules in axons of neurons serve as passive tracks for the transport of cell constituents between the nerve cell body and the nerve ending. Such axonal microtubules, stabilized by specific neuronal MAPs, exchange their tubulin with tubulin in the cytoplasmic pool very slowly. Some microtubules, such as the doublet and triplet microtubules of cilia, flagella, centrioles, and basal bodies, are so stable that, once formed, they do not detectably exchange their tubulin with tubulin in the cytoplasmic pool. It is clear, then, that cells are capable of modifying the stability of their microtubules to accomplish specific functions. Such control of stability appears to be mediated primarily by MAPs that bind to the microtubule surfaces and ends.

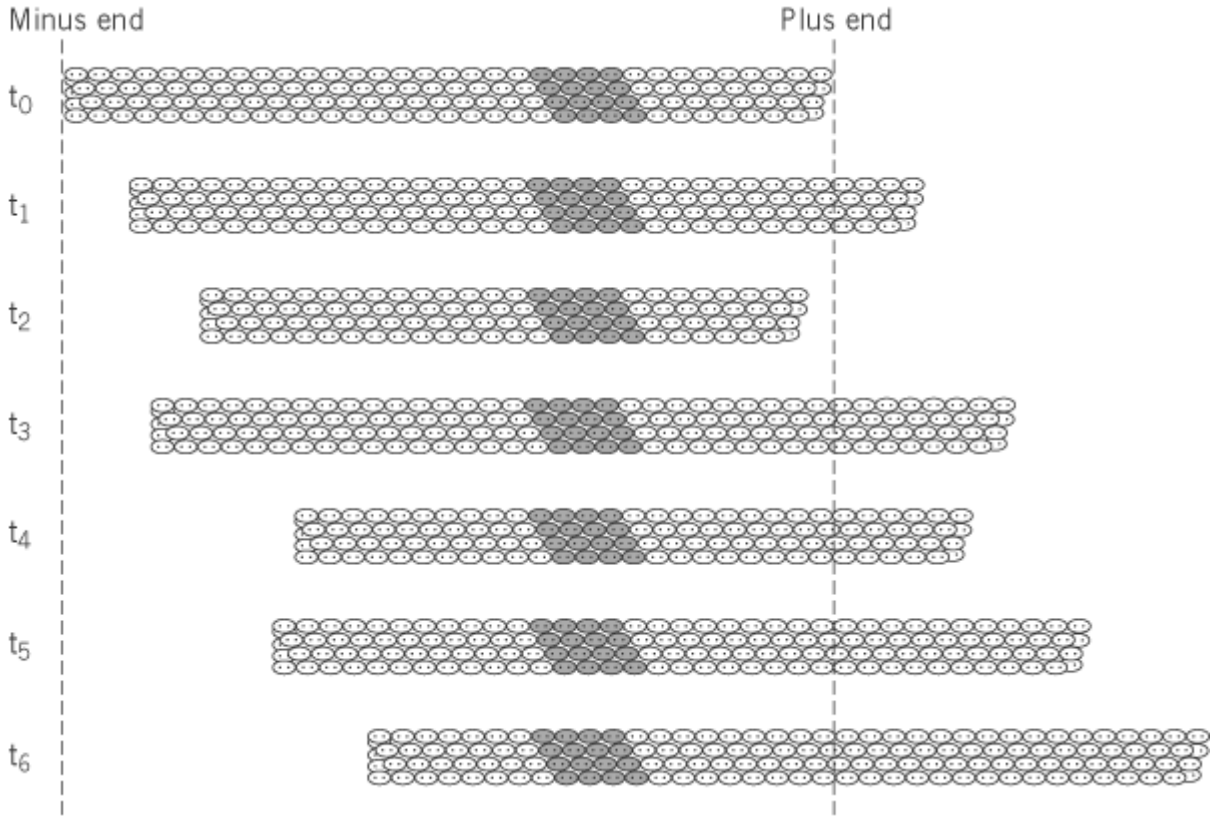
Another important characteristic of microtubules is their ability to form large organized microtubule arrays. Such arrays are especially common in protists, where bundles or sheets of parallel-aligned microtubules, held together by various MAPs, function in the creation of extremely long asymmetric cell structures, such as the dynamic microtubule array in the 400-mm-long axopods in the unicellular organism *Echinosphaerium*, or the axostyle, a remarkable motile ribbon of cross-bridged microtubules that serves as a motility organelle in the flagellate *Saccinobaculus* (5).

2. Microtubule Polymerization and Dynamics

Microtubule polymerization occurs by a nucleation-elongation mechanism, in which the formation of a short microtubule “nucleus” is followed by growth of the microtubule at both its ends by the

reversible noncovalent addition of tubulin subunits. It is well established that microtubules are not simple equilibrium polymers. Soluble tubulin binds GTP reversibly at a site on the b-subunit, and the GTP becomes hydrolyzed to GDP and P_i as, or shortly after, the tubulin polymerizes onto a growing microtubule end (6, 7). The irreversible hydrolysis of GTP during tubulin addition creates polymers with unique dynamics. One such behavior is called *treadmilling* (8-10), which is the net addition of tubulin at one microtubule end and net loss of tubulin at the opposite end. A second behavior is called *dynamic instability*, which is characterized by phase transitions, or switching, between phases of relatively slow growing and rapid shortening at the ends of individual microtubules (10, 11). Both kinds of dynamics appear to be highly important in specifying microtubule function in cells. Originally, dynamic instability and treadmilling were thought to be incompatible behaviors, but it is now known that at or near steady state *in vitro* and in cells, both behaviors coexist in microtubule populations. While individual microtubules may continually change length, net tubulin addition occurs at the plus end and loss at the minus within an individual microtubule, and in a balanced fashion within a microtubule population as a whole (Fig. 2).

Figure 2. Simultaneous treadmilling and dynamic instability of microtubules at polymer-mass steady state. Shown are consecutive "snapshots" of a microtubule exhibiting growth and shortening at its plus and minus ends, with net growth at the plus ends and net shortening at the minus ends. Individual microtubules can change length, as shown here, but net growth occurs at the plus end and net shortening at the minus end. The shaded subunits represent a marked segment. T_0 = zero time; *t*1, *t*2, and *t*3, ¼ are arbitrary equal increments of time.



The mechanism responsible for the nonequilibrium dynamics of microtubules involves the gain and loss of a stabilizing "cap" at the microtubule ends, which involves in some way the irreversible hydrolysis of GTP. While the size, chemical composition, and mechanism responsible for the stochastic gain and loss of the stabilizing cap at microtubule ends are poorly understood, evidence with brain microtubules indicates that the cap may be very small, consisting of only a single layer of GTP- or GDP-P_i-liganded tubulin situated at the extreme microtubule ends (see Refs. 6 and 7).

Dynamic instability is believed to be due to a stochastic loss and regain of the stabilizing cap, with growth occurring when the cap is present, and rapid shortening when the cap is lost. Treadmilling is believed to be due to the overall differences in the critical subunit concentrations at the opposite ends of the microtubule.

3. Mechanistic Basis of Microtubule-Mediated Cell Function

Microtubules serve two primary functions in eukaryotic cells. They function in the development and maintenance of cell shape, particularly in the creation of asymmetric cell shape, and they are used for many forms of cellular movement. Microtubule function at a mechanistic level is probably best understood in the beating of **cilia and flagella**. The microtubules of cilia and flagella are extremely stable, and their movement is not complicated by dynamics. In contrast to our understanding of microtubule-mediated movement in cilia and flagella, it has been difficult to unravel the mechanistic basis of motility mediated by labile cytoplasmic microtubules. In contrast to the stable microtubules of cilia and flagella, most microtubules in the cell cytoplasm are dynamic and it is clear that the dynamics of such microtubules, not just their presence as passive supports for motors, are integrally linked to their functions. Intriguing recent evidence indicates that microtubule motors and polymerization dynamics may work together to effect certain microtubule-dependent movements such as the complex and highly varied movements of the chromosomes during the processes of mitosis and meiosis (eg, see Ref. 12).

It is well established that the dynamic instability behavior of microtubules plays an important role in many microtubule-dependent processes in cells including the attachment of mitotic spindle microtubules to the chromosomes and determination of cell polarity. In addition to dynamic instability behavior, rapid treadmilling of microtubules occurs in interphase microtubule arrays (9), and rapid flux dynamics consistent with treadmilling occurs during metaphase and anaphase of mitosis (eg, see Ref. 13). During metaphase of mitosis, for example, tubulin addition occurs at the microtubule plus ends, attached at the kinetochores of the chromosomes, and balanced tubulin loss occurs at the minus ends, which are tethered at the centrosomes, while the microtubule lengths remain approximately constant. The points of microtubule attachment in the spindle are therefore not static. Instead, these regions must be mechanical protein machines capable of transiently attaching and detaching from the microtubules as the microtubules grow or shorten. The function of treadmilling in cells is not yet known. Treadmilling may be involved with maintaining tension in spindles or with translocation of molecules (signals?) from kinetochores to centrosomes. How microtubule dynamics and the dynamics-dependent functions are determined and controlled in cells at a mechanistic level, and how the dynamics and motors might work together to mediate movement, are poorly understood and are the focus of intense current research.

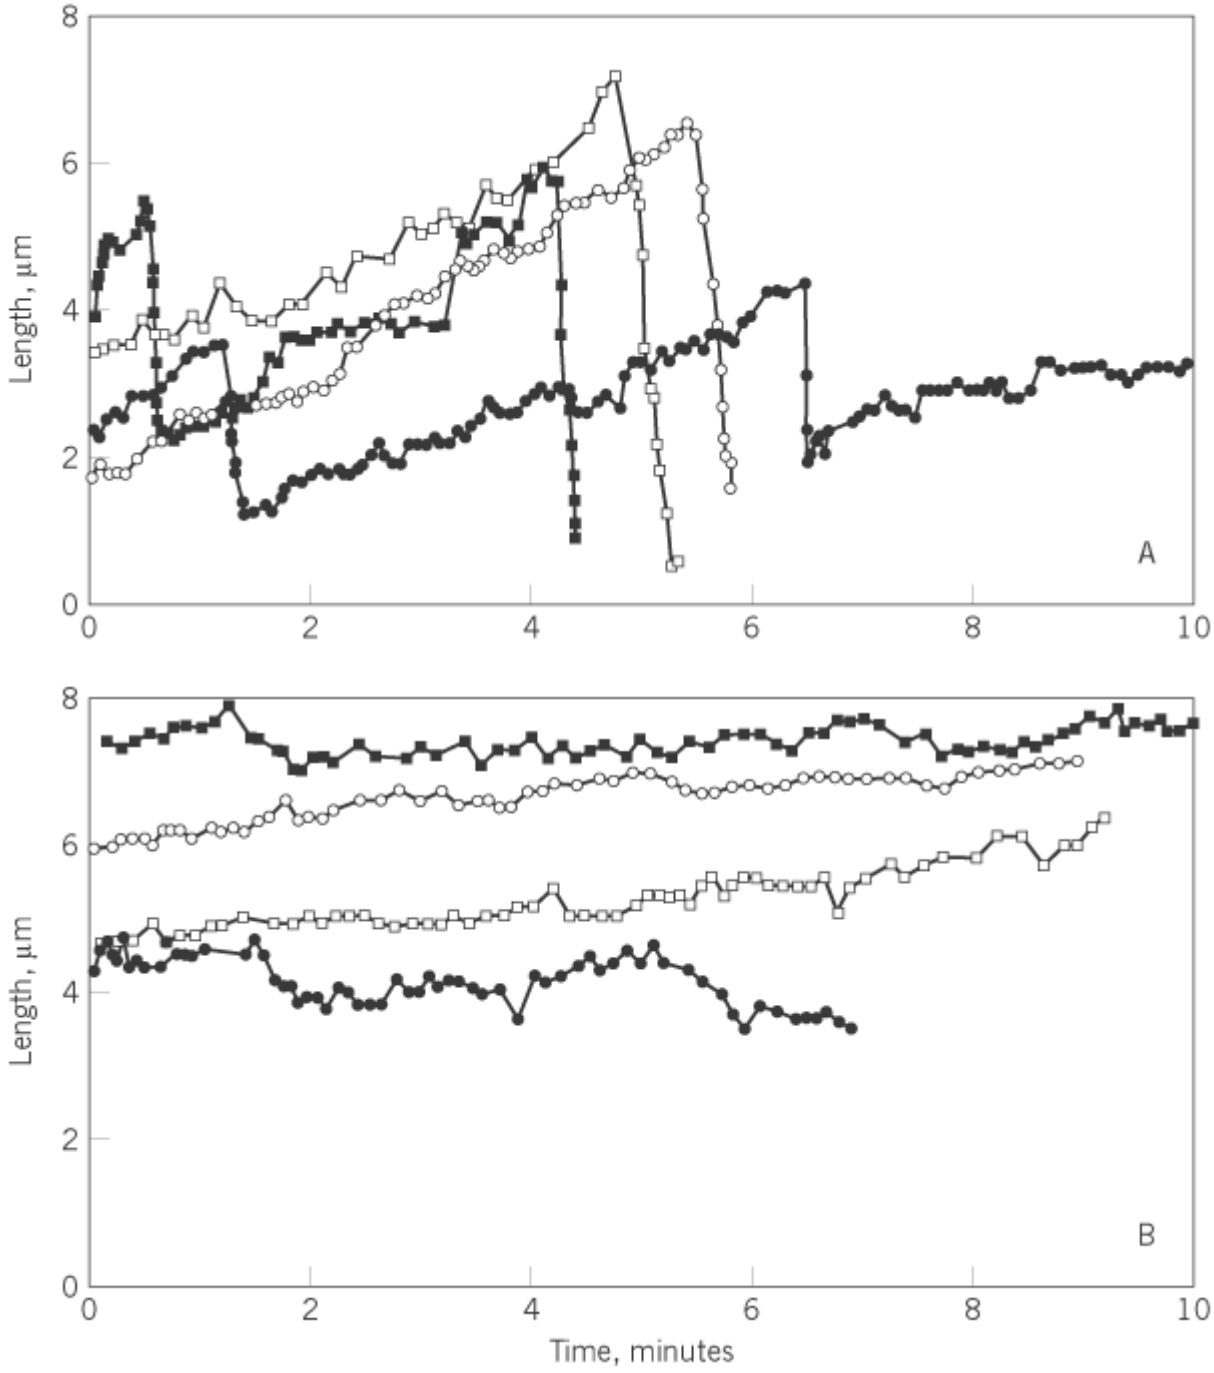
4. Microtubule-Targeted Drugs: The Use of Drugs for Analyzing Microtubule Function and for the Treatment of Cancer

Antimitotic drugs have become important tools in cell biology for the study of microtubule function. For example, colchicine, vinblastine, nocodazole, and taxol have been used extensively by investigators to determine whether specific cell processes involved the participation of microtubules. At relatively high concentrations, most of these drugs inhibit microtubule polymerization, while taxol strongly promotes microtubule polymerization. Thus, inducing microtubule depolymerization or excessive polymerization in cells has revealed whether cell processes are dependent upon microtubules.

Low concentrations of these drugs have a subtle action; they interact with microtubule ends and surfaces and powerfully suppress treadmilling and dynamic instability (eg, see Refs. 14 and 15). Suppression of microtubule dynamics occurs at drug concentrations well below those required to depolymerize or excessively polymerize microtubules. For example, low concentrations of vinblastine, when added to bovine brain microtubules *in vitro*, powerfully suppress the rate and extent of growing and shortening at microtubule plus ends, plus the frequencies at which the ends

switch between the growing and shortening state, without appreciably affecting the polymer mass (Fig. 3). Thus, these drugs have become valuable tools for analyzing the roles of dynamics in cellular microtubule functions, such as in the complex movements of chromosomes during mitosis.

Figure 3. Life history plots of individual MAP-depleted bovine brain microtubules at their plus ends at steady-state *in vitro*. The traces shown are typical examples of the changes in length of the individual microtubules with time. (**a**) Control microtubules and (**b**) microtubules in the presence of 0.4 μM vinblastine. (See Ref. 18.)



Many antimitotic drugs that act on microtubules, including vinblastine, vincristine, vinorelbine, taxol, taxotere, and estramustine, are used in humans for the treatment of various forms of cancer. It appears that the mechanism responsible for the ability of antimitotic compounds to inhibit cell proliferation and kill tumor cells is the kinetic stabilization of spindle microtubule dynamics. HeLa

cells, for example, are blocked at the metaphase–anaphase transition of mitosis at very low concentrations of taxol (16) or vinblastine. While such blocked cells have normal or nearly normal mitotic spindles and chromosome distributions, they cannot progress into anaphase. The powerful antiproliferative and antitumor effects of drugs that act by suppressing spindle microtubule dynamics may involve the metaphase–anaphase cell-cycle checkpoint, which prevents cells from progressing into anaphase until the spindle is fully assembled and the chromosomes are properly poised for separation. It seems that a prolonged block at the metaphase–anaphase transition in sensitive tumor cells, due to suppressed spindle microtubule dynamics, triggers apoptosis, thus killing the cells.

Minicells

Minicells are small spherical cells that are formed in certain mutants of rod-shaped **bacteria**. In these mutant strains, the **cell division** septum is aberrantly placed adjacent to the cell pole instead of at its normal midcell site. The polar septation events give rise to spherical cells (minicells) that lack the bacterial chromosome but otherwise appear normal. The minicells are capable of **protein synthesis** and normal metabolic functions but are incapable of undergoing further rounds of cell division. The first description of a mutation that led to the minicell **phenotype** in *Escherichia coli* was made by Adler et al. (1). Minicell formation has since been described in a number of other **Gram-positive** and **Gram-negative** species (2-5).

The formation of polar septa, and the concomitant production of minicells, results from the use of potential division sites that are located at the cell poles. The polar division sites are probably derived from division sites that had been located at midcell during a preceding division event. In this view, components that had been located at the midcell division site are retained at the new poles of the daughter cells after septation is completed, and these sites are still capable of supporting additional septation events (6). It has also been suggested that the polar sites are induced by changes in the organization or intracellular localization of the bacterial chromosomes, rather than being residues of previous division events (7, 8).

The potential division sites at the cell poles are not used to support septum formation because they are suppressed by the gene products of the *min* genetic locus, as shown by studies of *E. coli* and *Bacillus subtilis*. The minicell **phenotype** occurs when the suppression of polar division events is lost as a result of mutations or experimental manipulations that interfere with function or expression of the *min* genes (9). The minicell phenotype can also be induced by procedures that increase the expression of the cell division gene *ftsZ*, thereby increasing the frequency of septum formation at all sites, both the aberrant sites at the poles and the normal division site at midcell (10). The minicell phenotype is also associated with certain mutations or physiological manipulations that perturb DNA structure or replication pattern (8, 11, 12).

Minicelling populations include two types of cell, spherical minicells and rod-shaped cells that are longer than the cells of wild type populations. The lengths of the rod-shaped cells range approximately from one to six times normal cell length. It has been suggested that this occurs because in each division cycle the cell has only enough "division potential" to support a single septation event (one "quantum" of division potential) (6). In this view, if the polar sites are available because of a *min* mutation, septation can occur either at a polar site or at the normal midcell site; septation at a polar site leads to one minicell and one cell that is almost two cell lengths long. Because a similarly random choice between polar and central division occurs in each generation, a portion of the cells end up being several cell lengths long before a central division occurs. The "division potential" that is postulated in this quantal model of cell division could correspond to the cellular content of FtsZ, because FtsZ appears to be the rate-limiting protein in the division process (see **Cell division**). The quantal hypothesis has recently been questioned on the basis of examination of the division pedigrees of individual cells (8) but still remains an attractive explanation of the known facts.

Minicell mutants have been used primarily for two purposes: (*1*) to better understand the mechanism of cell division, with emphasis on the mechanism used by the cell to identify the correct location for the division site; and (*2*) as factories for the synthesis and characterization of proteins.

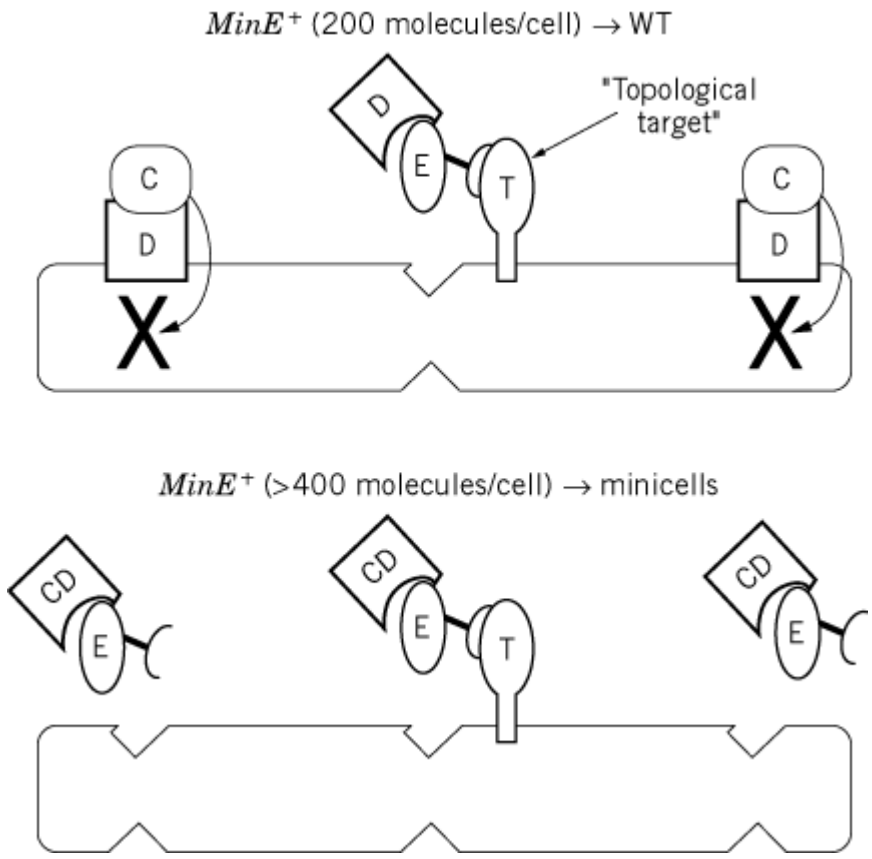
1. *E. coli min* Genes

Most of what is known about the normal regulation of polar division sites has come from studies of *min* mutants of *E. coli* (13). The *min* genetic locus defines an **operon** that includes three genes, *minC*, *minD*, and *minE* (9). This gene cluster is sometimes called the *minB* locus. The term *minB* is a historical anachronism, resulting from the original misconception that mutations in two genetic loci,

called *minA* and *minB*, were required to produce the minicell phenotype. It was later discovered that the original identification of *minA* was an error and that the minicell phenotype resulted from a single mutation in *minB* (ie, in the *minCDE* gene cluster) (14, 15). This mutation later was shown to reside in *minD* (16).

The *minCDE* gene products act in concert to prevent septation at the cell poles. This is accomplished by the coordinated action of a nonspecific division inhibitor, whose activity requires the expression of *minC* and *minD*, and a topological specificity factor (MinE) that restricts the action of the division inhibitor to the polar division sites (Fig. 1). As a result, minicell formation is prevented, whereas septation at the midcell site occurs normally. Consistent with this model, loss of either MinC or MinD leads to septation at the polar sites, with production of the minicell phenotype.

Figure 1. Current model for function of *min* gene products. (Adapted from Ref. 13.)



MinC and MinD act in concert to produce a nonspecific inhibitor of septation, as shown by the observation that expression of *minC* and *minD* in the absence of *minE* leads to the formation of long nonseptate filaments. In the MinCD filaments, septation is prevented at the cell poles, as well as at the normal midcell site. Although at normal levels of expression MinC and MinD are both required for the division block, MinC is believed to be the actual division inhibitor protein. This conclusion is based on the observation that high levels of expression of MinC lead to the formation of nonseptate filaments even in the absence of MinD (17). MinD is believed to function as an activator of the latent or low-level division inhibition activity of MinC. Studies using the yeast two-hybrid system have indicated that MinC and MinD can interact (18).

The MinCD division inhibitor blocks septation by interfering with the earliest detectable step in cell division, the formation of the cytokinetic FtsZ ring that appears at the division site prior to septal

ingrowth (19) (see **Cell division**). Consistent with the idea that FtsZ is the MinCD target, the ability of MinCD to block division is suppressed by the overexpression of FtsZ (20, 21).

MinC also plays an essential role in a second division inhibition system, the *minC-dicB* system. In this system, DicB plays the role that MinD plays in the *minC–minD* system. The *dicB* gene is believed to be part of a cryptic **prophage** in the *E. coli* chromosome (22). Its expression is normally tightly repressed, and there are no known physiological mechanisms to relieve this repression. However, when *dicB* is induced by placing it under control of a regulatable promoter, such as P_{lac} (see Lac Operon), division is blocked completely, leading to formation of long nonseptate filaments (22). The DicB-mediated division block requires the presence of MinC but is independent of MinD (20). Taken together with the observation that high concentrations of MinC can block division in the absence of MinD or DicB (17), this has led to the conclusion that DicB and MinD can act as independent cofactors or activators of the MinC-mediated division inhibition reaction. It is not known how DicB or MinD function to activate the division inhibition systems.

DicB and MinD have no apparent sequence similarity, and it is likely that the two proteins use different mechanisms to activate the division inhibition reaction. The MinD protein has ATPase activity, consistent with the presence of a predicted nucleotide-binding motif in the protein sequence (23). Mutational inactivation of this site results in loss of the ability of MinD to activate the MinC-mediated division inhibition reaction. This suggests that nucleotide binding and/or hydrolysis play a role in MinD function. In contrast, the *dicB* sequence shows no similar nucleotide-binding site. A number of *minC* mutations have been identified that inactivate the division inhibition activity of the MinCD or MinC–DicB systems. Some of the mutants showed some degree of preferential resistance to either DicB or MinD (24), suggesting that the two proteins may act on different regions of MinC or on different aspects of the division inhibition system. The *minC–minD* and the *minC–dicB* division inhibition reactions also can be distinguished by differences in their response to the MinE protein (discussed below).

When *minE* is expressed coordinately with *minCD*, the MinCD-induced filamentation is prevented and the wild type division pattern is restored. Thus, MinE prevents the MinCD division inhibitor from working at midcell, without interfering with its ability to prevent minicell formation by blocking septation at the cell poles. This implies that MinE, either directly or indirectly, can distinguish between the new potential division site at midcell and the potential division sites at the cell poles.

The ability of MinE to suppress the activity of the MinC-mediated division inhibition reaction depends on the presence of MinD. Thus, although MinE can prevent MinCD-mediated filamentation, it has no effect on the division block that results from the coexpression of MinC and DicB, nor on the division block that results from high-level expression of MinC alone. Therefore, it is thought that MinD performs two roles. First, it activates the MinC division inhibitor. Second, it mediates the interaction between MinE and the division inhibition system.

To explain the site-specificity of MinE action, a model has been proposed in which MinE has a high affinity for a topological target protein that acts as a MinE docking protein or receptor (Fig. 1) (25). The target protein is presumed to be located at midcell, where it sequesters MinE. As a result, MinE only counteracts the MinCD division inhibitor at the midcell site. This model is consistent with the low abundance of MinE (approximately 200 monomers per cell) and with the observation that a twofold or greater increase in the cellular concentration of MinE leads to minicell formation. According to this model, the increased level of MinE saturates the topological target, leaving the excess MinE free to counteract the MinCD division inhibitor at the polar sites, leading to the observed minicell phenotype. As predicted from this model, the effect of the excess MinE can be counteracted by increasing the level of MinCD, which restores the wild-type division pattern, presumably due to titration of the excess MinE. Thus it is the relative concentrations of MinC, MinD, and MinE that are important, rather than the absolute concentration of the individual

components.

In a variation of this model, the topological target is located at the cell poles instead of midcell (26). This would lead to the sequestration of MinE at the polar sites, where it would play a positive role, activating the division inhibitor at the cell poles. The evidence available at this time favors the first model in which the MinE target is at midcell; but until the locations of the proteins are directly determined, both models are tenable.

Two functions are defined for MinE. First, it is an antagonist of the MinCD division inhibitor, as shown by its ability to prevent the formation of nonseptate MinCD filaments. Second, it is a topological specificity factor, limiting the action of the division inhibitor to the potential division sites at the cell poles. Genetic deletion analysis has shown that the anti-MinCD function resides entirely within the 22-residue *N*-terminal domain of MinE, $MinE^{1–22}$. Thus, expression of $MinE^{1–22}$ prevents MinCD-induced filamentation (25). However, the $MinE^{1–22}$ domain lacks the topological specificity function of MinE, because expression of $MinE^{1–22}$ in the presence of MinCD leads to a minicell phenotype instead of a wild-type division pattern. In contrast, deletion analysis has shown that the topological specificity function of MinE, as defined by its ability to prevent minicelling, requires a domain that extends close to the carboxy-terminus of the protein (25, 26).

MinE is probably an oligomeric protein, as shown by gel filtration studies using MalE-MinE chimeric proteins. These studies, and studies using the yeast two-hybrid system, have indicated that the domain required for oligomerization lies within the carboxy-terminal half of the protein (26).

2. *min* Genes in *B. subtilis*

Mutations in two *B. subtilis* genetic loci, *divIVA* and *divIVB*, have been shown to lead to minicell phenotypes (2). The *divIVB* locus includes homologues of the *E. coli minC* and *minD* genes (27-29). The homology of the predicted amino acid sequences is strong for MinD (43.7% identity and 83.3% similarity between the *E. coli* and *B. subtilis* proteins) and less so for MinC (17.7% identity and 26.1% similarity). Similar to the results in the *E. coli* system, insertional disruption of the *B. subtilis minD* or *minC* gene leads to a strong minicell phenotype. However, in contrast to *E. coli*, where *minE* is located immediately downstream of *minD*, a *minE* homologue has not been identified in *B. subtilis*.

It is not known whether the *B. subtilis* MinC and MinD proteins function like their *E. coli* homologues. Similarity in function is suggested by the observation that minicelling results from mutation of *minC* or *minD* in both species, and that expression of the *B. subtilis* proteins in wild-type *E. coli* leads to minicelling (27). This suggests that *B. subtilis* MinC and/or MinD can compete with their *E. coli* counterparts and implies some similarity in function. It is possible that the Min proteins function similarly in the two species, but that the topological specificity function that is carried out by MinE in *E. coli* is incorporated into the MinC or MinD protein of *B. subtilis*, thereby eliminating the need for a separate *minE* gene. Alternatively, a *B. subtilis minE* homologue could be located within the adjacent gene cluster that was expressed together with *minC* and *minD* when minicelling was induced in *B. subtilis*, or a *B. subtilis minE* counterpart could be located elsewhere in the chromosome. This would be consistent, for example, with the observation that overexpression in *B. subtilis* of the *B. subtilis minC* and *minD* genes (together with adjacent genes) leads to a minicell phenotype (27). A similar result has been observed in *E. coli* when *minCDE* is overexpressed (30).

Mutations in a second *B. subtilis* locus, *divIVA*, also lead to a minicelling phenotype (2, 31). The *divIVA* gene codes for a 264-residue protein (31). The phenotype resulting from inactivation of *divIVA* differs from that of DivIVB (*minC* or *minD*) minicelling mutants, because the *divIVA* mutants show a lower frequency of minicelling and also show extensive filamentation.

Overexpression of *divIVA* leads to a block in cell division, as shown by the formation of long

nonseptate filaments (31). The DivIVA-induced division block appears to require a functional MinC protein, since filamentation was not observed when *divIVA* was overexpressed in a MinC mutant strain. Further evidence for a functional interaction between DivIVA and MinCD comes from the observation that the phenotype of a *divIVA-minC* double mutant resembles that of a *minC* single mutant rather than that of the *divIVA* mutant alone (31). Taken together with the observation that DivIVA-mediated division inhibition requires MinC function, this implies that MinCD acts downstream of DivIVA and is consistent with the view that the *divIVA* gene product may act by modulating the activity of MinCD. This could occur, for example, if DivIVA acted as an activator of a latent division inhibitor activity of MinC, thereby functionally resembling the *E. coli* MinD and DicB proteins (discussed above).

3. FtsZ and Minicell Formation

Moderate overexpression of the essential cell division protein FtsZ leads to minicell formation (10). However, in contrast to the phenotype associated with mutation of the *min* genes, where the population consists of a mixture of spherical minicells and of rod-shaped cells that are longer than wild-type cell length, overexpression of FtsZ leads to a mixture of spherical minicells and of rod-shaped cells that are shorter than the cell length of wild-type cells. This occurs because the increased concentration of FtsZ leads to an increase in the frequency of septation events, with the extra septations occurring at the normally unused polar sites. As a result, minicell formation leads to the generation of one minicell and one cell that is shorter than normal. Presumably, the excess FtsZ overcomes the normal MinCD-mediated suppression of the potential division sites at the cell poles. This is consistent with the observation that overexpression of *ftsZ* suppresses the filamentation that otherwise occurs when the cellular concentration of MinC and MinD is increased above normal levels.

4. Effect of Minicell Mutations on Chromosomal Organization

Several observations suggest a relationship between minicell formation and chromosome location or the state of chromosomal organization. Åkerlund et al. (8) have shown that minicell formation occurs when aberrant chromosome replication takes place in cells in which *oriC* is nonfunctional and a **plasmid** R1 replication origin is present elsewhere in the chromosome. Minicelling also has been reported to occur when the DNA-binding Fis protein is nonfunctional, and in *gyrA* and *gyrB* mutants (11, 12), although in the *gyr* mutants there is apparently a continuum of cell lengths ranging from "classic" spherical minicells to cells of approximately normal or longer than normal cell lengths. In all of these cases, the **nucleoid**-free regions at the cell poles appear longer than normal. In addition, the nucleoid-free region at the poles has been reported to be longer than normal in *min* mutants (7), and it has been reported that minicell mutants produce a low but significant number of anucleate cells of normal cell length (32). An altered degree of **supercoiling** of some plasmids has also been reported to occur in minicell mutants (7). On the basis of these observations, it has been suggested that the *min* gene products act on chromosome organization or partition, leading in min^- mutants to a nucleoid-free zone at the cell poles. In this view, polar septation occurs as the default mode wherever a sufficiently large nucleoid-free zone exists; and the Min proteins do not act on old division sites at the poles, but directly on the nucleoid or on the chromosome replication or partition system (7, 8).

5. Synthesis of Plasmid-Encoded Proteins in Minicells

Extrachromosomal genetic elements such as plasmids segregate into minicells, although the bacterial chromosome does not. Therefore, when a minicelling mutant strain is **transformed** with a native or recombinant plasmid, the minicells contain plasmid DNA and continue to synthesize plasmid-encoded message after the short-lived chromosomally encoded messenger RNA has decayed. Therefore, when the minicell population is labeled with a radioactive amino acid, essentially all of the labeled proteins that are synthesized are encoded by the plasmid DNA. This has been exploited as a generally applicable method to identify the gene products of desired genes by using plasmids

that include the genes of interest (33).

Minichromosome

A minichromosome represents a **DNA** molecule and associated histones that assemble as chromatin similar to that in the chromosomes of the host cell. Minichromosomes assemble chromatin most efficiently in mammalian cells if they contain **origins of replication** from viral DNA; In **yeast** cells, minichromosomes can be used that contain true chromosomal origins (autonomously replicating sequences, [ARS]). They can also be assembled, although less efficiently, on DNA **microinjected** or **transfected** into cell **nuclei**.

The small size of the SV40 genome (5243 bp long) and the early availability of information concerning its DNA sequence and gene organization made it a convenient model for studying the structure and function of chromatin. Late in infection, the SV40 genome is organized into arrays of **nucleosomes** as a minichromosome that can be isolated from infected cells under appropriate conditions. One region of the minichromosome (ORI) contains several important recognition sites for ***trans*-acting** factors: the origin of replication, the binding sites for the viral regulatory protein (T Antigen), and the **promoters** driving transcription of early and late SV40 messenger RNA. The chromosomal organization of this ORI region was recognized as important for DNA replication and transcription and was shown to differ from the rest of the minichromosome. The first experiments used **nucleases** to digest the minichromosome. In the nuclei of infected cells, the DNA sequence is preferentially cut in the ORI region with **DNase I** (see Hypersensitive Site). This suggested that DNA in the ORI region is more accessible to DNA-binding proteins than in the rest of the minichromosome. Chemical **carcinogens** that interact with the free DNA duplex by intercalation, such as psoralen, bind preferentially to the ORI region in infected cells. Its rapid digestion with a variety of **endonucleases** in isolated minichromosomes is also consistent with preferential accessibility of the ORI region. Finally, electron microscopy reveals that 20 to 25% of the isolated minichromosomes contain a nucleosome-free region (or gap) of approximately 350 bp covering the ORI region. This gap represents the best early documentation of nucleosome positioning on regulatory DNA (1).

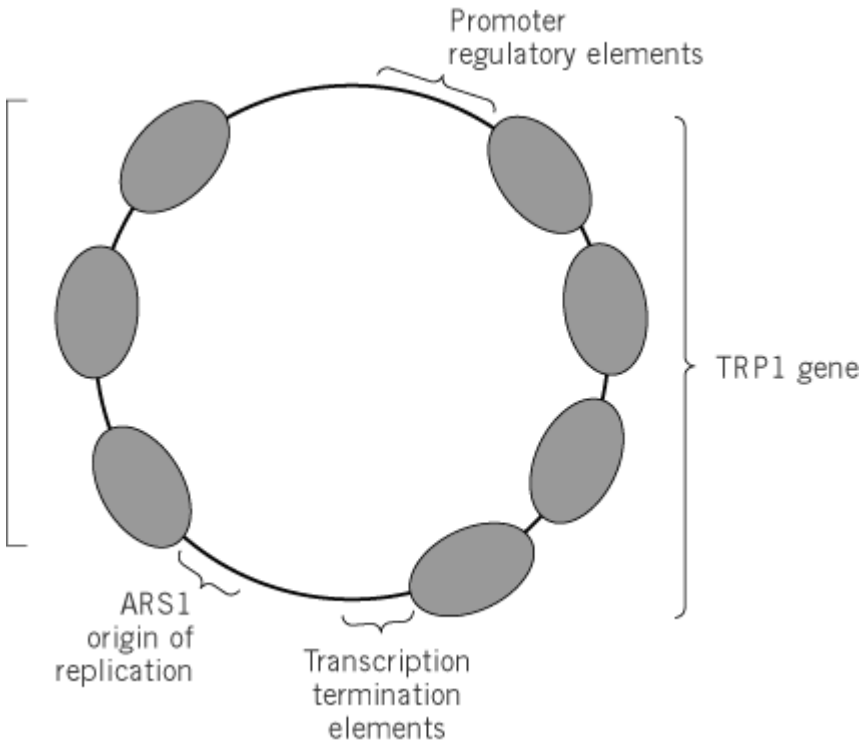
Several genes or **promoter** elements have been introduced into SV40 minichromosomes, and the influence of chromatin structure on **gene expression** was examined. Although generally repressive effects on transcription are observed, the structural basis of this repression has not yet been determined. The advantage of viral genomes for analyzing the interrelationship between chromatin structure and function is that they contain replicative origins. This means that the viral minichromosome can be studied as an **episome**, ie, without being integrated into the cellular chromosomes. Moreover, because chromatin assembly is coupled to DNA replication, the influence and access of *trans*-acting factors on nucleosomal organization are more like that within the true chromosomal context. The only reservation about studies with small viral genomes is that possible regulatory effects dependent on higher order chromatin structure are unlikely to be observed. Again, this is caused by topological constraints in folding small DNA circles in the chromatin fiber. Viral genomes other than SV40 have been very useful for the detailed analysis of chromosomal influences on transcription. These include the bovine papilloma virus (BPV)-based episomes that have been used to investigate the molecular mechanisms by which glucocorticoid receptor activates gene expression. Here, the interplay between specific chromatin structures and transcription factors has been rigorously documented (2).

Viral episomes that are DNA molecules containing a viral origin of replication have been used to establish the organization of *trans* -acting factors and nucleosomes in specific DNA sequences. However, most studies have investigated gene regulation by transiently transfecting **cloned** DNA without a viral origin of replication into eukaryotic cells. Under these conditions, such studies have rarely investigated repressive or stimulatory effects that might be attributed to chromatin. Importantly, the observed regulation due to enhancers, promoters, or other elements often does not

reflect the range of response observed in the natural chromosomal context. Extensive studies by Howard and colleagues demonstrated that the efficiency of chromatin assembly depends on the transfective conditions. The amount of DNA transfected into cells, the method of compacting DNA prior to transfection, and the efficiency with which particular DNA sequences partition to the nucleus greatly affect chromatin assembly. Over 80 to 90% of nuclear plasmid material might not be assembled into chromatin, yet some templates and protocols generate nucleosomal arrays (3). Consequently, it is not surprising that the regulation of transiently transfected DNA does not always completely reflect that found in the natural chromosomal context.

Yeast is a particularly attractive system for examining the influence of chromatin structure on the function of DNA. Experimental work with yeast has many advantages, especially for molecular biologists and geneticists. Among these are the existence of small (1500 bp) extrachromosomal minichromosomes that replicate autonomously. Particular experimental attention has been given to a plasmid present at about 100 copies/cell known as TRP1ARS1. This plasmid is 1453 bp long and consists of (1) one gene coding for N-(5′-phosphoribosyl)-anthranilate isomerase (TRP1), (2) a sequence containing a replicative origin (ARS1), and (3) a segment of unknown function (UNF) but now known to be part of the GAL3 promoter (Fig. 1). Simpson, Thoma, and colleagues have determined the chromatin structure of TRP1ARS1 in some detail (4). Nucleosomal position has been determined by the nuclease accessibility of isolated minichromosomes. Four different regions of chromatin structure have been defined. The UNF region contains three nucleosomes that have very strong DNA sequence-directed positions and are not changed by inserting DNA fragments of various lengths into the plasmid. In contrast, four loosely positioned nucleosomes are found on the TRP1 gene. These nucleosomes can easily rearrange following insertion of additional DNA. Two nucleosome-free regions also present (like the gap in the SV40 minichromosome) are hypersensitive to nuclease digestion. These sequences include the TRP1 promoter and the ARS origin of replication. Although lacking centromeres and **telomeres**, the TRP1ARS1 minichromosome therefore contains many elements associated with normal cellular chromosomes.

Figure 1. The structure of the TRP1 ARS1 minichromosome. Nucleosome (open ellipsoids) and key DNA sequences are shown. The region originally called UNF, for unknown function, is now known to be part of the GAL3 promoter.



Among the DNA sequences inserted into the TRP1ARS1 plasmid was a sea-urchin 5S RNA gene, on which base-pair resolution of the rotational positioning of DNA on the histone core was originally defined. A nucleosome formed including this sequence, with exactly the same position in the yeast minichromosome, as observed in vitro. This important observation shows that yeast histones in vivo recognize the same DNA sequence-directed nucleosome positioning elements as chicken histones in vitro. Similar experiments with yeast genomic sequences inserted into the TRP1ARS1 plasmid consistently reveal that the same nucleosome positioning occurs on the episome as in the chromosome. In certain instances, unstable nucleosomes, like those on the TRP1 gene, may have their positions influenced by the organization of other regions of the episome into chromatin. More recent studies have taken these observations further to dissect the contributions of specific trans-acting factors to nucleosome positioning.

Minigene

A minigene is a shortened version of a cloned **gene** that is produced by recombinant DNA techniques. Most minigenes are made from **eukaryotic** (especially mammalian) genes because of their large size. In most cases, a sequence from the 5′-end of the gene is joined to a sequence near its 3′-end to form the minigene. The smaller size of a minigene facilitates studies of its regulatory sequences (see **Gene regulation**). It is necessary to show that the behavior of the minigene resembles that of the intact gene because internal sequences affect gene regulation (1). In some cases, only a 5′-terminal sequence is used. Such a minigene has been used to obtain high-level expression of proteins in salivary glands (2). A minigene with an intact coding region has been used to introduce mutations at specific sites in the mouse genome (3).

Minisatellite DNA

Minisatellites are dispersed arrays of short, tandem, direct repeats of highly variable DNA sequences found in the **genomes** of most higher **eukaryotes**. They contain core sequences resembling the recombination hotspot **Chi sequence** 5′-GCTGGTGG-3′ of *Escherichia coli*, which is a binding site for proteins involved in genetic recombination. Based on this, a general function of minisatellites may be to provide binding sites for recombination proteins in eukaryotes.

Their name arose for historical reasons. Under certain **density centrifugation** conditions, their density is similar to that of the satellite peak of genomic DNA.

1. Use of Minisatellites for Establishing Physical Genetic Maps

The discovery of minisatellites (1) has resolved the difficulties raised by the relative lack of information provided by *restriction fragment length polymorphisms* (**RFLP**). In the vertebrate genome, the short (10- to 50-bp) tandem, direct, repeat motifs of minisatellites contain variants of a common core sequence. Their lengths are highly variable, which is expressed by their other name, VNTR, for *variable number of tandem repeats* . Interest in them comes from the fact that the number of repeats of a given minisatellite at a certain position in the genome varies from one individual to another. Thus a probe for a particular minisatellite is highly polymorphic and reveals a locus with a great number of alleles that have a high probability of being genetically informative in the great majority of cases. A minisatellite general probe of a tandem repeat of the core sequence can simultaneously detect many variable loci because of their sequence homologies and can provide an individual specific DNA fingerprint of general use in human genome analysis.

But, the real solution has been provided by the discovery of **microsatellites**, named by analogy to the minisatellites.

Mismatch Repair

Mismatches in **DNA** are noncomplementary base pairs in a double helix. There are eight such base pairs and, if the directionality of the duplex is taken into account, the number of mismatches is 12. They are corrected by the phenomenon known as mismatch repair. In addition to simple mismatches, other abnormal DNA structures that do not involve damaged bases are also substrates for mismatch repair. These include the insertion/deletion of single nucleotides, loops consisting of unpaired nucleotides in one strand, and bubbles, which consist of more than one mismatched base in a row.

Mismatches arise from three sources: DNA replication errors, recombination, and base deamination.

1. *Replication errors*. **DNA polymerases** are relatively accurate enzymes that ensure replication fidelity at several stages, including base selection, insertion, and proofreading. Despite all these safeguards, DNA polymerases make replication errors at a frequency of 10^{-3} to 10^{-5}, depending on the polymerase.

2. *Recombination*. Mismatches also arise during recombination between **alleles** of the same gene or between closely related sequences. If these mismatches occur in meiotic chromosomes and remain uncorrected, they can give rise to anomalous segregation of the alleles, or they may lead to **gene conversion** upon correction.

3. *Base deamination*. Cytosines are often methylated at the C5 position, and these 5-methylcytosines deaminate about 10^3-fold faster than does cytosine (1). The extent of methylation varies across species, ranging from a virtually undetectable level in yeast and *Drosophila*, to 1% in *Escherichia coli*. In humans, 20% of cytosines are methylated; consequently, G-T mismatches arising from deamination of cytosine are a common occurrence in humans.

Mismatches are eliminated from DNA by three general mechanisms: general mismatch repair, very short patch mismatch repair, and mismatch repair by base excision. The general mismatch repair system is the most important, and is the system most widely distributed in the biological world. It has been found in all bacteria tested, as well as in model eukaryotic organisms, such as yeast, fruit flies, and humans.

1. General Mismatch Repair Systems

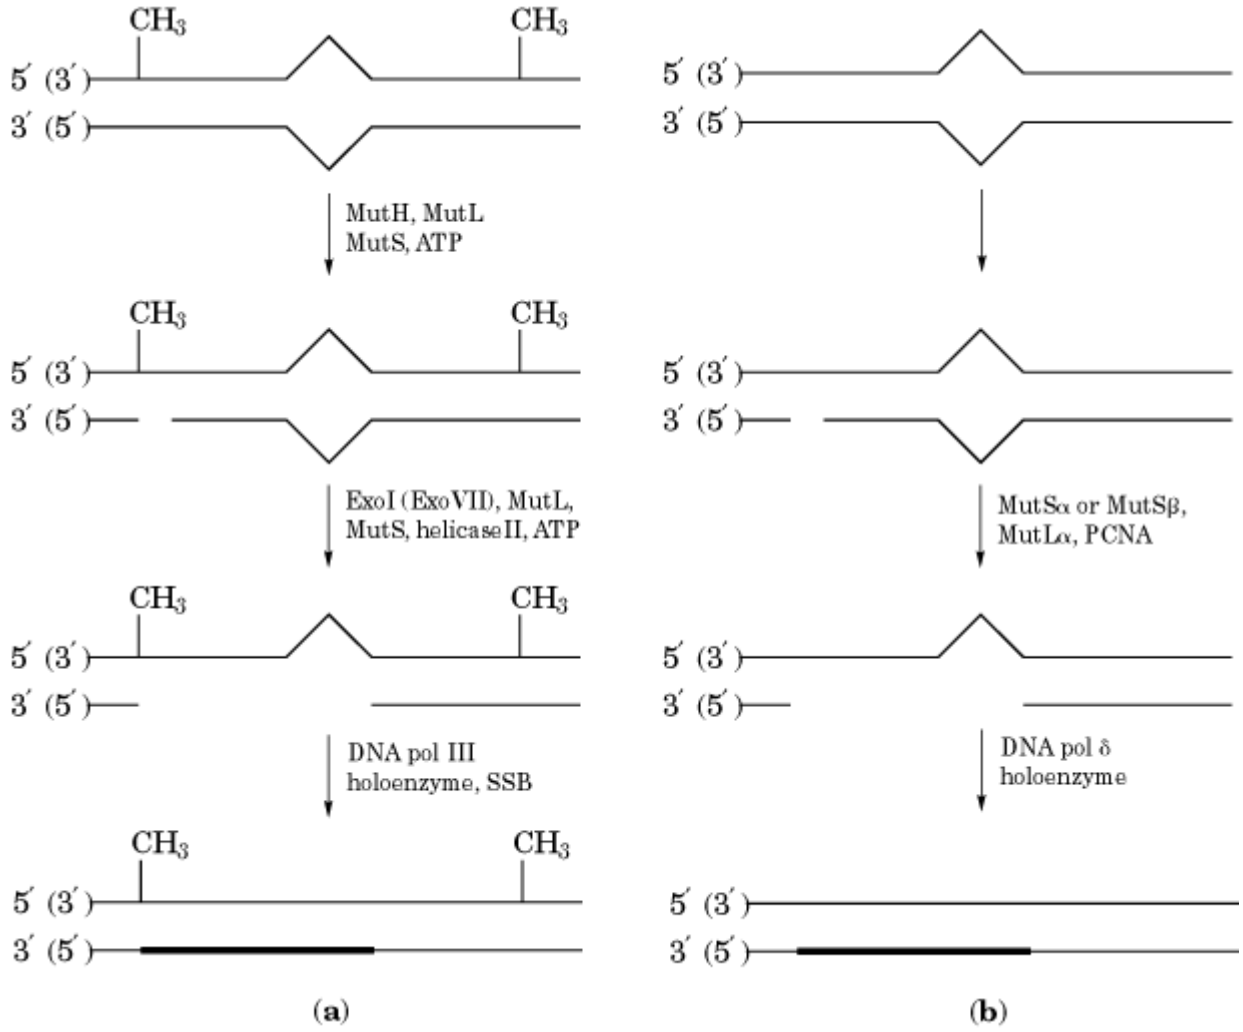
This repair system corrects all mismatches and small insertion/deletion loops in an essentially sequence-independent manner (2). The general reaction scheme is as follows: A nick is made 5′ or 3′ to the mismatch in the newly synthesized strand, which is by definition the "wrong" strand. A 5′ to 3′ or a 3′ to 5′ exonuclease digests the nicked strand, starting at the nick and terminating at some distance past the mismatch. Concomitant with exonucleolytic degradation, repair synthesis takes place, filling the gap generated by the exonuclease with correct nucleotides. Ligation of the repair patch completes the reaction (2). The reaction mechanism of general mismatch repair has been elucidated in considerable detail in *E. coli* and to a lesser extent in humans.

1.1. General Mismatch Repair in *E. coli* (Fig. 1)

In *E. coli* the three key proteins for mismatch repair are known as MutH, MutS, and MutL (2). In addition, the Dam methyltransferase plays a crucial role in strand discrimination. The Dam protein is a sequence-specific adenine DNA methyl transferase; it recognizes unmethylated or hemimethylated GATC sequences and methylates the N6 of adenine (see Methylation, DNA and Methyltransferase, DNA). Under steady-state growth conditions, both strands of the parental DNA are methylated. However, during replication a hemimethylated GATC sequence forms transiently as a result of the incorporation of a canonical (unmodified) adenine at this site by replicase. This hemimethylated GATC serves as a signal for discriminating between the parental (correct) and daughter (potentially incorrect) strands. When the newly synthesized DNA contains a mismatch, the mismatched base pair is recognized by MutS, while the hemi methylated GATC (5′ or 3′ to the mismatch) is recognized by MutH. Then, MutL binds to both the MutS·mismatch and MutH·GATC complexes. This binding activates the ATPase activity of MutS and the endonuclease activity of MutH, which then cleaves the phosphodiester bond 5′ to the G of the GATC sequence in the unmethylated strand. The nick introduced by MutH serves as an entry site for an exonuclease (exonuclease I for 3′ to 5′ and exonuclease VII or RecJ for 5′ to 3′ digestion). One of these exonucleases digests the DNA from the site of the nick, which could be up to 1000 nucleotides away from the mismatch, to a point past the mismatch by 20 to 30 nucleotides. Digestion of DNA between the nick site and the mismatch is concurrent with resynthesis by the DNA replication machinery comprised of **DNA polymerase** III, DNA helicase II, SSB (single-stranded DNA binding protein), and DNA Ligase. A mutation in any of the mismatch repair-specific genes (ie, *mutS, mutH, mutL*) or in the specific methylation gene *dam* increases both the spontaneous and damage-induced mutation frequency by 10^3- to 10^4-fold.

Figure 1. Mechanisms of general mismatch repair in (**a**) *E. coli* and (**b**) humans. A nick 3′ or 5′ to the mismatch in the

newly synthesized strand marks that strand for correction. In *E. coli*, the newly synthesized strand is transiently undermethylated at the Dam site (GATC) and hence is nicked by MutH endonuclease. In humans, the mechanism of preferential nicking of the newly synthesized strand is not known. MutS in *E. coli* and MutSa and b in humans recognize the mismatch, and MutL or MutLa coordinate the nicking and exonucleolytic degradation of the mismatched strand to a point past the mismatch. The resulting gap is filled in by replication polymerases.



1.2. General Mismatch Repair in Humans (Fig. 1)

The basic steps and key enzymes of mismatch repair in humans are similar to those of *E. coli* (3-5). The mismatch is recognized by a MutS homologue, and a MutL homologue coordinates nicking with mismatch recognition. In humans, however, both MutS and MutL are encoded by several related genes (6). There are at least three *mutS* genes and proteins in humans: hMSH2, hMSH3, and hMSH6. The proteins encoded by these genes form heterodimers $(hMSH2)_1(hMSH6)_1$ and $(hMSH2)_1(hMSH3)_1$ which are also referred to as hMutSa and hMutSb and which are the functionally relevant forms. The MutSa is involved in recognition/repair of simple mismatches and small, one- to three-nucleotide insertion/ deletion mismatches. It appears that MutSb is involved in recognition of larger mismatch loops. There are three MutL homologues, hMLH1, hPMS1, and hPMS2, which form heterodimers $(hMLH1)_1(hPMS2)_1$, called hMutLa, and presumably $(MLH1)_1(PMS1)_1$ heterodimer, which may be involved in the repair of larger loops (heterologies). The signaling mechanism that discriminates between the right and wrong strands in humans is not known. In humans, there is no enzymatic activity that methylates adenine. In contrast, up to 20% of cytosine bases are methylated. There is, however, no evidence that cytosine methylation is used as a signal in discriminating between the nascent and parental strands. It is possible that during replication the

natural nicks in the lagging strand and the replication fork, or occasional nicks in the leading strand, provide both the signal for discrimination and the entry point for the mismatch repair exonuclease for mismatch removal. The helicase(s) and exonuclease(s) necessary for carrying out mismatch excision are not known, although DNA polymerases a, d, and e have been implicated in the repair synthesis.

A defect in mismatch repair in humans has two consequences. First, hereditary nonpolyposis colon cancer (HNPCC) is associated with a defect in mismatch repair (6, 7). Apparently, mutations in *MSH2* and *MLH1*, and to a lesser degree in *PMS1* and *PMS2*, that are inherited in heterozygotes are asymptomatic. However, a second mutation in the wild-type allele of an individual (by a somatic mutation) renders the cell mismatch repair defective and leads to development of colorectal cancers. HNPCC family members also develop other cancers at high frequency, including uterine, stomach, ovarian, and squamous cell skin cancers. Cancers that are caused by mismatch-repair defects are characterized by **microsatellite** instability (MIN^+**phenotype**), which includes expansion or contraction of simple repeat sequences, such as $(A)_n$, $(CA)_n$ and $(GGC)_n$ (8). However, not all MIN^+ tumors are defective in mismatch repair. Microsatellite instability in general is a symptom, but not the cause of mutations that eventually convert a normal cell to cancerous phenotype (8). A significant number of these tumors have a mutation, presumably caused by a lack of mismatch correction, in the transforming growth factor (TGF-b) receptor.

The other manifestation of mismatch repair defects is resistance to anticancer drugs that exert their effect by damaging DNA (9-11). DNA damage caused by various anticancer drugs, including cisplatin and adriamycin, causes misincorporation of nucleotides during replication. The resulting lesion in DNA is a mismatch superimposed upon base damage, which is referred to as a "compound lesion." The lesions with or without a mismatch bind to mismatch recognition proteins (12). The binding activates the mismatch repair system, which removes the mismatch. Upon resynthesis, however, the mismatch is regenerated by DNA polymerase at a certain frequency, depending on the lesion. Hence, a futile cycle of excision and resynthesis ensues, which eventually leads to DNA degradation and cell death. If cells are mismatch repair-defective, this suicidal cycle is prevented (10). Although mismatch repair-defective cell lines have been isolated from tumor cell lines exposed to nitrosoguanidine or cisplatin (11, 13, 14), it is unclear at present whether or not secondary mutations in tumors contribute to development of drug resistance in clinical setting. Similarly, it is unknown at present whether or not tumors arising from HNPCC disease are resistant to cisplatin or similar drugs.

2. Very Short Patch (VSP) Repair

This repair system has been defined only in *E. coli* . It is a repair system specific for G-T (or G-U) mismatches. In *E. coli* the sequence CC(A/T)GG is the target for deoxycytidine methylase (Dcm), which methylates the second C in this sequence. Methylated C deaminates at a 1000-fold faster rate than does cytosine. As a consequence, G-T mismatches are produced in the *E. coli* genome at a rate that may be unacceptably high. It appears that the VSP system has evolved to deal with this specific problem. An enzyme encoded by the *vsr* gene specifically nicks 5′ to the T of the mismatch in the context of a Dcm recognition site (15). However, both the Dcm methylase and the Vsr endonuclease also recognize and methylate or cleave at related sequences, albeit at a reduced efficiency. Although the Vsr protein is the only protein absolutely required for this repair pathway system, the VSR pathway is greatly stimulated by the MutL and MutS proteins by an unknown mechanism. In any event, following nicking, excision of mismatch and repair synthesis are carried out by DNA polymerase I, which generates a four- to six-nucleotide-long repair patch.

Although humans do not have a VSR system, they do have a repair system that deals specifically with G-T mismatches. In humans, the cytosines in a CG context in the so-called CpG Islands are heavily methylated and hence are subject to deamination, giving rise to G-T mismatches. In humans, this mismatch is processed by a thymine glycosylase, followed by the other steps common to all

"damaged DNA" excision repair systems. As in the case of VSR, the mammalian system for G-T mismatches also has a sequence context specificity and is more effective on G-T mismatches in CG islands.

3. A-G Mispair Repair System

One of the major lesions produced in DNA by oxidative stress is 8-oxoguanine (8-oxoG). This base preferentially pairs with adenine during replication, giving rise to an 8-oxoG-adenine mispair. A glycosylase encoded by *mutY* in *E. coli* cleaves off the mismatched adenine and the phosphodiester bond 3′ to the resulting apurinic site (16). Then, the abasic sugar is eliminated, and the one- to two-nucleotide gap is filled and ligated. The mutagenic 8-oxoG base is eventually removed from the DNA by 8-oxoG glycosylase (see Base Excision Repair). Although this repair system is most active on the A-8-oxoG mismatch, it also removes the adenine residues from rare A-G mispairs that are generated by replication or recombination.

Missense Mutation

Missense mutations comprise a class of mutations in which one **nucleotide** within the coding segment of a gene is substituted for another, changing a **codon** for one amino acid into a codon for a different amino acid. The effect of a missense mutation depends on the nature of the amino acid change (conservative versus nonconservative; see Conservative Substitutions) and on where it occurs in the **protein** encoded by the gene. Missense mutations in various locations in a protein that give a variety of phenotypes are a powerful aid in analyzing the relationship between protein structure and function. Like nonsense mutations, missense mutations are **suppressed** by mutant transfer RNAs, but these inevitably have deleterious effects because the amino acid sequences of most of the cell's proteins are affected.

Mitochondria

Early **microscopic** descriptions of cells identified the existence in both animal and in plant cells of **organelles** that could be stained with vital dyes such as Janus green. Cytologists in early decades of this century were often struck by the morphological diversity of these structures, and many different names (chondriome, chondriomites) were used, in addition to the now generally used mitochondria, to indicate the same basic structure, which was only clearly identified in the 1950s by electron microscopy. It then became apparent that mitochondria are surrounded by a double membrane. The inner mitochondrial membrane (IM) folds inwards, thereby forming the cristae.

The morphological definition of mitochondria had been preceded, in the 1940s, by the isolation of particulate mitochondrial cell fractions and by the findings that respiratory enzymes were localized in these fractions and that isolated mitochondria could respire and perform oxidative phosphorylation. The three main respiratory electron-transport complexes (NADH dehydrogenase; bc1 complex; cytochrome oxidase) are now known to be localized in the IM, together with ATP synthase, the complex that is responsible for the phosphorylation of ADP coupled to the electron transport. The integrity of the IM is essential for the formation of the proton gradient that drives the phosphorylation (see Proton Motive Force).

New techniques of fluorescence microscopy, based on the targeting to the mitochondria of fluorescent proteins, often coupled with high-speed imaging systems, have recently revealed that mitochondria form in the cytoplasm a largely interconnected tubular network that undergoes continuous rearrangements; electron microscopy shows only sections of this network.

In 1949, Boris Ephrussi (1) in Paris observed that a spontaneous mutation occurred with high frequency (around 10^{-2}) in populations of the yeast *Saccharomyces cerevisiae*, leading to characteristic small colonies. The reduced size of the colony was related to a defect in respiration, which allowed growth only on fermentable substrates such as glucose. These mutants were called

petite (small), to indicate the small size of its colonies, and were later referred to as *rho*$^{-}$ to indicate the absence of respiration. It was soon discovered that the mutation exhibited non-Mendelian inheritance and that it was transmitted to progeny even when fusion of **nuclei** was prevented. This discovery was the origin of yeast mitochondrial genetics, which disclosed several features of the yeast mitochondrial genome [see Mitochondrial DNA (MTDNA)] even before sequencing techniques were available for DNA. Since most of these mutants exhibited defective **absorption spectra** of cytochromes, indicating a defect in mitochondrially localized enzymes (2), it was suggested that the cytoplasmic inheritance might be due to the existence of a genetic determinant localized in mitochondria.

The presence in mitochondria of a mitochondrial DNA was demonstrated in the 1960s, and this was rapidly followed by the discovery of a mitochondrially localized machinery for **protein biosynthesis**. This is used for the *in situ* translation of messenger RNA resulting from transcription of the mitochondrial genes, which mainly code for some of the subunits of the above-mentioned respiratory enzymes. The other subunits of the respiratory enzyme complexes are encoded by the nucleus, synthesized in the cytoplasm, and imported into the mitochondrion, to be assembled with the mitochondrially synthesized subunits.

The mitochondrial protein biosynthesis apparatus has several distinctive features that differentiate it from the cytoplasmic counterpart of the same cell. The most important one is probably the sensitivity of its ribosomes to bacterial-type antibiotics, such as chloramphenicol and **erythromycin**, which are not active on **eukaryotic** ribosomes. This and other similarities with prokaryotic cells have strengthened the hypothesis of an infective origin of mitochondria in eukaryotic cells; a primitive respiring bacterium might have been trapped in a primitive cell and have become a symbiont ensuring the energy supply to the cell, while receiving from the cell metabolites and intermediates for macromolecular syntheses. The majority of its genetic information might then have passed to the nucleus. The opposite theory on the evolutionary origin of mitochondria and **chloroplasts**, called *episomic*, hypothesized a segregation to the organelles of nuclear genetic information, leading to the formation of efficient localized functions such as respiration or photosynthesis. However, the recent finding of a very large protozoan mitochondrial genome (3) strongly supports the hypothesis of the infective origin of this organelle.

In the majority of mitochondrial genomes, mitochondrial ribosomal and transfer RNA are encoded by mtDNA, while other components of the mitochondrial protein biosynthesis apparatus, including enzymes, protein synthesis factors and ribosomal proteins (with few exceptions), as well as factors involved in RNA splicing, DNA transcription, and DNA replication, are coded by nuclear genes. Consequently the question might be posed as to why such a complex apparatus is needed just to ensure the localized synthesis of a few mitochondrially encoded subunits of respiratory enzyme complexes.

Another very relevant aspect of mitochondrial protein biosynthesis lies in its deviations from the universal genetic code. In fact the nonuniversality of the genetic code was first discovered in mitochondria. Actually, the triplet UGA, which has no sense in the universal genetic code (see **Nonsense and unassigned codons**), codes for tryptophan residues in mammalian and fungal genomes. However, deviations from universality are different in various species, or they may not exist, as is the case in the above-mentioned protozoon (*Reclinomonas americana*). This supports the notion that the translation system in the mitochondrial genomes, which code for few proteins, has more relaxed constraints and that this has resulted in the appearance of independent deviations from the universal genetic code and from the general rules that govern protein biosynthesis. Other unusual features have appeared in many mitochondrial protein synthesis apparatus, including the two-letter codon–anticodon recognition, resulting in the diminished number of transfer RNA (tRNA) necessary for protein synthesis (4), and the use of tRNA that have highly modified structures (in mammals) or that are imported from the cytoplasm (in plants and some protozoa). Another quite exceptional feature present in some mitochondria is the phenomenon of editing of RNA (5) consisting in the

addition to RNA of a number of bases not encoded by DNA.

Mitochondrial DNA (MTDNA)

The **genomes** of mitochondria have a wide range of size, structure and informational content, and the recent sequencing of several new genomes has widely contributed to understanding the extent of this diversity (Table 1).

Table 1. Size, Structure, and Informational Content of Some Mitochondrial DNAs[a]

[a] *Key:* 1—the same size and molecular form in all other studied mammals, 2—the size of *S. cerevisiae* in mtDNA is variable mainly because of strain-dependent number of introns, 3—some other yeasts have a linear molecular form, 4—not including ORFs and intronic genes; Hs—*Homo sapiens*, At—*Arabidopsis thaliana*, Sc—*Saccharomyces cerevisiae*, Cr—*Chlamidomonas reinhardtii*, Pf—*Plasmodium falciparum*, Ra—*Reclinomonas americana*.

The mtDNA of **fungi** have sizes ranging between the 18 kbp of *Schizosaccharomyces pombe* and over 100 in some other yeasts. In these genomes, the informational content usually includes three subunits of cytochrome oxidase, two or three subunits of ATP synthase and cytochrome *b*, in addition to the RNAs of ribosomes and transfer RNAs and, in some cases, a ribosomal subunit protein. The wide differences in size are not due to substantial differences in informational content, but to the presence of large intergenic sequences, often AT-rich, and to the presence of **introns** in the genes. An important peculiarity of these introns is the presence of open reading frames (see Gene Structure), sometimes free-standing within the introns (1) or, in some other cases, also utilizing part of the sequences of the gene. These intronic proteins have various functions, including the splicing of the intron itself (2) or its transposition, which is in some cases mediated by a **reverse transcriptase** activity coded by the intron (3). The above-described mtDNA are usually circular (see Circular Chromosome), but linear in some cases. In the latter case, telomere sequences ensure DNA replication of the linear molecules.

By contrast, animal mtDNA are always circular, have a very uniform size of about 16 kbp, and have a standard informational content, which includes the same proteins found in fungal genomes, plus seven subunits of the NADH dehydrogenase complex. The genes are tightly packed, and no intergenic regions are present outside the region involved in DNA replication (4).

In plants, the size and complexity of mtDNA exhibit important variation even in closely related species. The number of mitochondrial genes is greater than in animal or fungal genomes and includes genes coding for several ribosomal proteins. The DNA organization is not clear; both linear and circular molecules have been found, bearing repeated sequences that might originate multiple recombination events.

Perhaps the most interesting developments concerning the functions of mtDNA come from the two extremes of informational content found thus far. The mtDNA of the protozoon *Reclinomonas americana*, although having a size of 69 kbp, smaller than many plant and fungal genomes, contains 92 genes. These include the genes for 27 ribosomal proteins and, interestingly, for the elongation factor tufA and for four subunits of an **RNA polymerase** of bacterial type. Moreover, the genes for factors involved in cytochrome ***c*** biogenesis, in cytochrome oxidase assembly, and even the secY protein import gene, are encoded by mtDNA. At the other extreme, the mtDNA from the parasite *Plasmodium falciparum* has a genome size of 6 kbp and possesses only five genes, which code for cytochrome *b*, two subunits of cytochrome oxidase, and the two ribosomal RNA.

In conclusion, only four genes, namely, those coding for subunit I of cytochrome oxidase, for cytochrome *b* and for the two ribosomal RNA, are present in all mtDNA studied thus far and therefore might be considered to be essential for the conservation of the mitochondrial genome. It may be pertinent that subunit I of cytochrome oxidase and cytochrome *b* are both the heme-carrying subunits of the corresponding respiratory complexes. The small size of mammalian mtDNA results in relatively simple restriction maps. Therefore, comparisons can be used to detect subtle differences among the mtDNA. Moreover, the mutation rate of mammalian mtDNA is much higher than that of the corresponding nuclear DNA (the opposite situation has been observed for fungal and plant genomes). Consequently a large number of mutations accumulate in mammalian populations, and mtDNA comparisons have been used to evaluate **phylogenetic** differences among different species

or taxa, and to study the origins and the migrations of different human or mammalian populations.

Mitomycin C

1. Introduction to the Anticancer Drug Mitomycin C and its Analogs

The mitomycins are a group of natural product antibiotics that were discovered in Japan in the 1950s in the fermentation cultures of *Streptomyces caespitosus* (1). Mitomycin C (MMC), mitomycin A, and porfiromycin represent three well-studied members of this family (Fig. 1). Shortly after the isolation of the mitomycins, their significant antitumor properties were discovered. MMC began use in clinical cancer chemotherapy in the 1960s and subsequently demonstrated a broad spectrum of antitumor activity against a variety of solid tumors (2). MMC continues to be an important component of combination chemotherapy for a variety of cancers, including carcinoma of the anal canal, non–smallcell lung cancer, esophageal and bladder cancer, and others (reviewed in (3). Bone marrow suppression is the principal dose-limiting toxicity that has limited the success of MMC as a single agent. Other members of the mitomycin family, the natural product analogs, FR66979 and FR900482, were discovered in the fermentation products of *Streptomyces sandaensis no. 6897*, and the semisynthetic mitomycin derivatives, E09, KW-2149, and BMS-181174 (previously designated as BMY25067) (reviewed in (4), have also been developed (Fig 1).

Figure 1. Structures of mitomycin antibotics and common analogs. Mitomycin C, mitomycin A, and porfiromycin represent three well-studied members of the mitomycin family. More recently, two other members of the mitomycin family, the natural product analogs, FR66979 and FR900482, were discovered, and the semisynthetic mitomycin derivatives, E09, KW-2149, and BMS-181174 (previously designated as BMY25067), have also been developed.

MMC has served as a model for investigating the family of mitomycins, and the vast majority of knowledge about this group of agents is derived principally from extensive laboratory and clinical studies of MMC over the past 25 years. Like most genotoxic agents, MMC binds to DNA, RNA, and other macromolecules, and MMC–DNA adducts are believed to be principally responsible for the majority of its observed biological effects. Also like many genotoxic agents, MMC requires metabolism from the parent form to a reactive intermediate to bind to macromolecules and exert its biological effects. However, unlike most other organic genotoxins, MMC requires chemical or biochemical reduction rather than oxidaton. Although the chemistry of this reduction has been well characterized *in vitro*, the specific biochemical pathways by which this occurs inside the cell remain controversial. MMC has been shown to induce many of the common biological hallmarks of other genotoxic cancer chemotherapy agents and genotoxic mutagens and carcinogens. MMC has been reported to inhibit DNA replication and RNA synthesis, induce mutations and the SOS response in bacteria, and induce mutations and sister chromatid exchanges in mammalian cells (reviewed in (5)).

Reduced MMC covalently binds preferentially to the N^2 position of guanine in the minor groove of duplex DNA, forming monoadducts, intrastrand crosslinks at adjacent guanines, and interstrand crosslinks at opposite guanines of adjacent basepairs, specifically in the sequence orientation of CpG, but not GpC (see Fig. 2). It is currently presumed that the CpG MMC interstrand crosslink is principally responsible for the cytotoxic and antitumor properties of MMC; however, formal evidence for this is still lacking.

Figure 2. Mitomycin C-DNA adducts. After reductive activation, mitomycin C (MMC) can form two monoadducts, i.e., a monofunctional monoadduct (**1a**) and a bifunctional monoadduct (**1b**), and also two types of cross-links, ie., an interstrand cross-link (**2**) at CpG sites, and an intrastrand cross-link (**3**) at GpG sites.

2. MMC Structure and DNA Adduct Formation

The structures of the mitomycins are unique, containing three different functional groups thought to be important for their properties and present separately in several other known carcinogens. These

reactive groups, the aziridine (three membered ring attached to C^1 and C^2), carbamate ($–OCONH_2$), and quinone (five-membered ring containing ketones at C^5 and C^8), are arranged about a pyrrolo [1,2-*a*]indole nucleus (see 1). In this arrangement, these functional groups are relatively inactive; however, upon chemical or biochemical reduction of the quinone by either a one- or two-electron process, a semiquinone or hydroquinone is formed, respectively, leading to the unveiling of two electrophilic sites (C^1 and C^{10}) for alkylation. According to the proposed mechanism of alkylation (reviewed in (4)), there are two pathways the MMC and follow: the "monofunctional" alkylation pathway, which results in a "monofunctional monoadduct," (**1a**) and the "bifunctional" alkylation pathway, which results either in a "bifunctional monoadduct" (**1b**) or a cross linked adduct (**2** or (**3**). The sequence of events leading to the activation of the C^1 and C^{10} positions of MMC involves the reduction of the quinone ring, the spontaneous elimation of methanol (driving force: formation of the pyrrole), and the opening of the aziridine ring. Once the electrophilic C^1 and C^{10} sites are "unmasked," the next step is the highly specific nucleophilic attack by the N^2 exocyclic amino group of guanine on the C^1 position of MMC. If reoxidation of the quinone ring, by either O_2 (poor redox conditions) or by the presence of excess MMC, occurs at this stage, the compound is no longer activated and is referred to as a "monofunctional monoadduct" (**1a**), where monoadduct refers to one addition product with DNA, and monofunctional refers to a reaction at only one functional group on the MMC ring system. This reoxidation, which is autocatalytic, occurs when the initial reduction of MMC is very slow, ie, when it can be inactivated faster than it is formed.

In the "bifunctional" pathway, after the first alkylation of DNA, the C^{10} position of MMC undergoes decarbamoylation that results in the activation of this position for further nucleophilic attack. If there is a second guanine present adjacent to or on the opposing strand of DNA (ie, at GpG or CpG sequences, respectively), then the N^2 position of this guanine can serve as the incoming nucleophile on the C^{10} position of MMC, forming an N^2-G-MMC-N^2G intrastrand or interstrand crosslink (**2** or **3**), respectively). If there is not a second guanine in either of these two sites, H_2O can serve as the incoming nucleophile and attack the C^{10} position, forming a "bifunctional monoadduct" (**1b**). The term "bifunctional monoadduct" refers to the fact that only one addition product with DNA has formed although the mitomycin complex has undergone nucleophilic reactions at two functional groups. Other less abudant MMC–DNA adducts have also been observed and their biological activity has been investigated *in vitro* (6).

3. Bioreduction

Due to its requirement for reduction prior to alkylating DNA, MMC is referred to as a bioreductive alkylating agent (reviewed in (7)). The bioactivation of MMC can be mimicked *in vitro* by chemical reducing agents such as by H_2 and PtO_2, which favor the formation of a monofunctional adduct with DNA; by sodium dithionite, which favors the formation of a bifunctional adduct; or by various nicotinamide adenine dinucleotide (NAD(P)H)-dependent flavoreductases. The relative proportion of adducts *vitro* or *in vivo* depends on the sequence of the DNA and on the metabolic and redox status of the cells.

Because bioreduction is key to the cytotoxic actions of MMC, a number of laboratories have dedicated a large effort to identifying specific biochemical pathways involved in the activation of MMC. A variety of bioreductive enzymes have been implicated in the reduction of MMC, such as NAD(P)H cytochrome *c* reductase, NAD(P)H quinone oxidoreductase (DT-diaphorase), xanthine oxidase, xanthine dehydrogenase, and NADH cytochrome b_5 reductase (reviewed in (8)). Despite this effort, much controversy still exists regarding the specific roles of each of these pathways in intact cells. The large number of divergent and sometimes contradictory *in vitro* and cell culture studies suggest that no single enzyme is uniquely responsible for MMC activation (reviewed in (7)). These studies also suggest that a number of variables can influence the activation of MMC, at least

in vitro and in cell culture, including the cell type and cell culture growth conditions, pH, and degree of hypoxia (7, 8). For example, *in vitro* chemical reduction studies indicate that the pH can influence both the site of the lesions on guanine (N^7 vs N^{27} alkylation), as well as influence the predominating bioreduction pathway (4). However, whether such parameters also influence MMC metabolism and MMC-induced biological effects *in vivo* is not clear, because pH, oxygen concentration, and other parameters are tightly regulated over a much narrower range under physiological conditions in the intact animal. Such studies demonstrate the limitations of *in vitro* and cell culture systems in modeling the complexities of a whole organism or the microenvironment of a tumor *in vivo*.

Several studies have suggested that DT-diaphorase and cytochrome P450 reductase are often highly overexpressed in cancer cells (7, 9). The terminology "enzyme-directed drug development" - coined with mitomycin as the paradigm - refers to an approach that seeks to identify enzymes that are overexpressed in tumors when compared with normal tissues and that can be used to preferentially target drug effects to these tumor cells (reviewed in (10)). For example, the sensitivity of bladder cancer patients to MMC has been shown to be correlated with the expression of DT-diaphorase and cytochrome P450 reductase in their bladder tumors, suggesting that the lower efficacy of intravesical MMC in these patients may be due, at least in part, to their lower expression of these enzymes (9). An important area of future study will be to determine the precise biochemical pathways by which MMC is bioreduced in tumor and normal cells, and to determine the role of each pathways in the biological effects of MMC in these target and nontarget tissues. This is critical for understanding, and hopefully being able to modulate, the efficacy of MMC and its analogs as antitumor agents against various human cancers.

4. Characterization and Measurement of MMC–DNA Adducts

The structures of the various MMC–DNA adducts have been extensively characterized by a variety of biophysical techniques—including high-performance liquid chromatography, ultraviolet absorbance, thermal melting curves, gel electrophoresis, circular dichroism, chemical footprinting, Fourier transform infrared spectroscopy, fast atom bombardment mass spectroscopy, and a variety of one and two-dimensional nuclear magnetic resonance techniques (4, 11-13)). There is general agreement from these studies that the predominant MMC–guanine monoadducts and the CpG MMC–DNA interstrand cross-link cause little or no perturbation of the DNA double helix, with the attached mitosene ring lying snugly within the minor groove of the DNA. In contrast, the GpG MMC–DNA intrastrand cross-link has recently been shown to bend the DNA helical axis by 14.6° (reviewed in (4)).

Covalent MMC–DNA adducts have been detected and isolated following *in vitro* reactions involving mono- or di-nucleotides, oligonucleotides, and purified DNA (eg, calf thymus DNA, *Micrococcus luteus* DNA, salmon sperm DNA, and poly(dG-dC)·poly(dG-dC) (11, 13)). MMC–DNA adducts have also been detected in various cell culture models, in intact animals, and in human cancer chemotherapy patients (14, 15). Due to the lack of readily available radiolabeled MMC, some studies have substituted the commercially available radiolabeled *N*-methyl analog of MMC, porfiromycin. Porfiromycin has been shown to have similar reactivity and biological properties as MMC, and the corresponding porfiromycin *N*-methyl analogs of the monofunctional monoadduct, bifunctional monoadduct, and cross-links of MMC have been observed (reviewed in (13)).

5. Modulation of Binding Activity at Methylated CpG Sites

Sequence context plays an important role in the types and quantity of MMC adducts formed. MMC–DNA monoadducts and interstrand cross-links have been observed to show a strong preference for the $^{5'}$CpG$^{3'}$ but not the 5′GpC$^{3'}$ dinucleotide sequence (reviewed in (4)). There also appears to be an enhancement of MMC cross-linking at those sequences that have a purine 5′ to the CpG site and a pyrimidine (particularly thymine) 3′ to the guanine (ie, $^{5'}$PuCGPyr$^{3'}$) (4). The CpG dinucleotide sequence has some unique features that are of interest with regard to its specificity for MMC cross-

linking. The CpG dinucleotide sequence is underrepresented in eukaryotic genomes compared to other G-containing dinucleotide sequences, occurring at about one fifth its expected statistical frequency (reviewed in (16)). However, clusters of CpG containing regions, referred to as "CpG islands," are often found at much higher than predicted frequencies within many gene promoters, and 60 to 90% of these sequences are methylated at the 5′ position of cytosine *in vivo*. Cytosine methylation is thought to be one mechanism for transcriptional regulation of genetic material. For example, the degree of cytosine methylation is often but not always inversely correlated with transcriptional activity. Cytosine methylation also alters the local structure of duplex DNA. Thus, an enhancement in MMC cross-linking at methylated CpG sites (reviewed in (4)) may be biologically significant because it has been proposed that DNA-damaging agents may heritably alter DNA methylation patterns. This would provide an epigenetic mechanism for heritable alterations in expressions of genes involved in carcinogenesis, and might also be one way in which MMC exerts its biological effects.

6. MMC–DNA Adduct Recognition and Repair

Little is known about the recognition and repair of MMC–DNA adducts *in vivo*. It is generally assumed that MMC–DNA adducts are repaired by nucleotide excision repair (NER), which is an important cellular mechanism that removes radiation-induced and chemically induced damage for DNA. Repair of the interstrand cross-link in particular is believed to pose a unique and difficult topological challenge to the repair machinery. However, the rapid kinetics of MMC cross-link removal from DNA in cell culture and *in vivo* argues for effective recognition and repair of this lesion, despite this topological problem and the relatively non distorting nature of this lesion. Several specific protein complexes from human and rodent cell nuclear extracts were found to preferentially recognize and bind to the MMC interstrand cross-link with high affinity (17). Several of these complexes appear to contain ERCC-1 (excision repair cross complementation group 1) and/or XPA (xeroderma pigmentosum complementation group A), which have both been shown to be involved in mammalian NER and to be implicated in cross-link repair (18). *In vitro* experiments have demonstrated that both purified XPA and the minimal DNA binding domain of XPA (XPA-MF122) were able to bind MMC–cross-linked DNA with a much greater specificity and higher affinity than to undamaged DNA (19). This occurred in the absence of other proteins from the NER complex (19). Such preferential binding may lead to enhanced recruitment of the NER machinery to the adduct site for subsequent efficient repair. Further studies of this type will be required to fully elucidate the biochemical mechanisms by which DNA interstrand cross-links formed by MMC are recognized and repaired in mammalian cells.

7. Effects of MMC on Gene Expression

In addition to its overt effects as a cytotoxic and antitumor agent, recent studies have demonstrated that lower, noncytotoxic doses of MMC can selectively modulate expression of certain target genes at doses that do not induce apoptotic or stress response, and that have no effect on expression of most other genes. For example, selective suppression of several genes associated with multidrug resistance in cancer cells was observed in several human and rodent cancer cell lines in culture (20), in a mouse tumor model *in vivo* (21), and in the tumors of human cancer patients *in vivo* (22) after a single low-dose MMC treatment. In the cell culture and rodent studies, pretreatment with MMC significantly increased the subsequent antitumor activity of a second agent such as doxorubicin or taxol (20, 21). Extensive dose–response, time course, and mechanistic studies indicated that this was principally a result of the suppression of these drug-resistance proteins by the MMC pretreatment rather than combined toxicity *per se* (20-22). Similar results were seen after pretreatment with other DNA cross-linking agents of divergent chemical structure, including cisplatin and carboplatin, suggesting that these effects were a result of formation of DNA cross-link adducts. These results suggest the basis for development of novel combination chemotherapy approaches, where an agent such as MMC is used as a modulator of the cancer cell phenotype in combination with other cytotoxic agents, rather than, or in addition to, its use as a cytotoxic agent (22).

In addition to cancer applications, MMC has been shown to selectively alter expression of other genes that may also be of benefit in noncancer clinical diseases. For example, MMC has been a useful model compound for examining effects of pharmacological agents on the gene regulation and protein biogenesis of cystic fibrosis transmembrane conductance regulator (CFTR), mutations of which are entirely responsible for the diseases, cystic fibrosis. At low doses, MMC induced a significant increase in both CFTR mRNA and protein expression. Because the problem in cystic fibrosis is essentially a lack of adequate CFTR functional expression, such a drug-induced increase in CFTR expression could potentially be of clinical benefit in treatment of cystic fibrosis patients (23). Identification of less toxic analogs of MMC that also upregulate CFTR expression is therefore of potential interest in this setting.

Low doses of MMC have also been shown to selectively modulate the expression of the xenobiotic- and drug-inducible genes, 5-aminolevulinate synthase (24, 25) and cytochrome P450 *CYP2H1* (24, 25). and the glucocorticoid hormone-inducible phosphoenolpyruvate carboxykinase gene (24, 26)). The mechanistic basis for these selective effects on gene expression is not known. Correlative evidence indicates that these effects are primarily a result of formation of MMC-DNA adducts within or near the promoter regions of these genes. However, whether this is a result of preferential adduction of these regions by MMC (ie, higher levels of adducts at these sites), or a higher sensitivity of these particular genes to nearby MMC–DNA adducts remains to be determined.

8. Mitosene Analogs

Preclinical and clinical trials, as well as basic mechanistic studies, with the mitomycin derivatives KW-2149, BMS-181174, EO9, FR66979, and FR900482 (Fig. 1) have suggested interesting activity profiles. Due to differences in structure, these derivatives can differ from MMC in their mechanism of bioreductive activation, cross-linking efficiency, dose-limiting toxicity, antitumor activity, and/or activity against resistant cell lines (4, 27-30). The aim of such studies with MMC analogs is to develop more effective therapies, in particular treatment regimens that are active in drug-resistant cancers, that do not induce drug resistance after prolonged treatment, and that reduce nontarget tissue toxicities. However, the clinical usefulness of these newer analogs remains to be determined. For example, BMS-181174 initially showed good promise as an antitumor agent in preclinical trials, but subsequent human phase I clinical trials revealed substantial dose-limiting toxicities that precluded its continued clinical use (28). Several other MMC analogs are currently being evaluated in preclinical and early clinical trials.

9. Summary

In summary, MMC and its analog represent a unique group of compounds with respect to both their interesting chemistry and biology, and their usefulness as cancer chemotherapy agents. Although much has been learned about this class of chemicals over the past 25 years, based principally on studies of MMC, there is still much to learn about these agents, including the biochemical pathways responsible for their activation and detoxification, the specific DNA lesions induced *in vivo*, their repair, and their individual roles in the biological effects observed, and the further development of these agents as gene modulators and clinical cancer chemotherapy agents.

Mitotic Recombination

Genetic recombination usually occurs in meiosis, but it can also occur in **diploid** cells that reproduce asexually by mitosis. Mitotic recombination breaks the general rule that genotypes are maintained during asexual reproduction.

Consider a clone of heterozygous cells, genotype *Aa*, that carry the **alleles** *A* and *a* of a certain gene. The clone can be a colony of an unicellular organism or a tissue of a multicellular organism. A recombination event between the gene and the centromere of its chromosome may give rise to two homozygous cells, *AA* and *aa* (Fig. 1). Further mitotic growth will produce two new cell clones, genetically distinct from the original cell. In the absence of cell migration, the new clones form twin

spots in the colony or the tissue. In the case of complete dominance of a cellular genetic marker (eg, the cell color produced by the *yellow* allele of *Drosophila*), only the spot with the recessive marker will be recognized easily. The twin spots will be seen if the phenotype of the heterozygote differs from that of both homozygotes or, with complete dominance, in diploids *Ab*/*aB* when both genes are present on the same chromosome arm and recombination occurs between the centromere and the closest gene (Fig. 2). The concept of mitotic recombination was derived from the observation of twin spots in *Drosophila* (1).

Figure 1. Mitotic recombination between a heterozygous locus and the centromere (C) of its chromosome. Recombination occurs when each chromosome has two chromatids. Depending on the movements of the centromeres in the next anaphase, the recombination event leads to homozygosity of the alleles (above) or to an exchange between the homologous chromosomes (below).

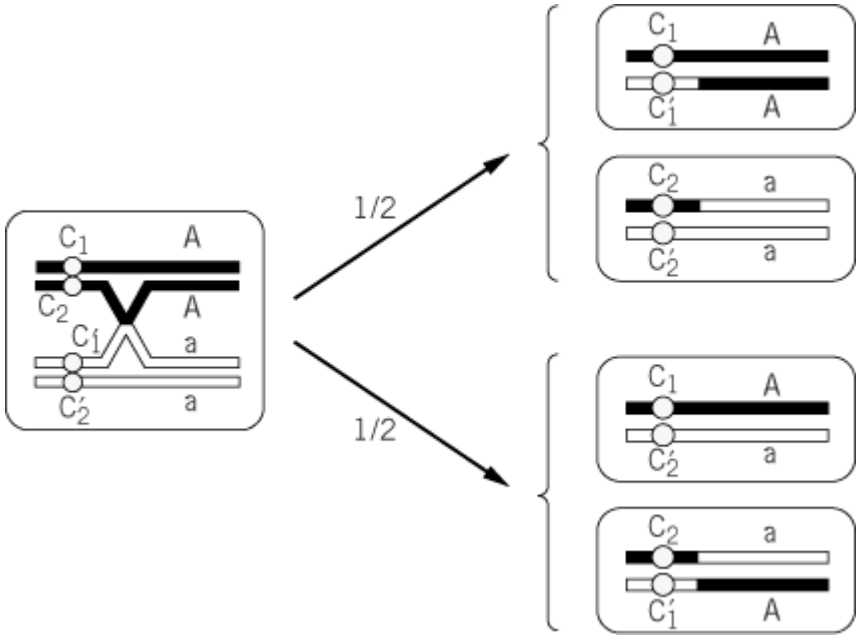

Figure 2. Twin spots in the surface of a *Drosophila melanogaster* adult fly heterozygous for the markers *mwh* (multiple wing hairs) and *f* (forked). Mitotic recombination in the left arm of the the third chromosome led to the formation of a spot with multiple processes per cell and another with bent cell processes, surrounded by cells of wild-type phenotype.

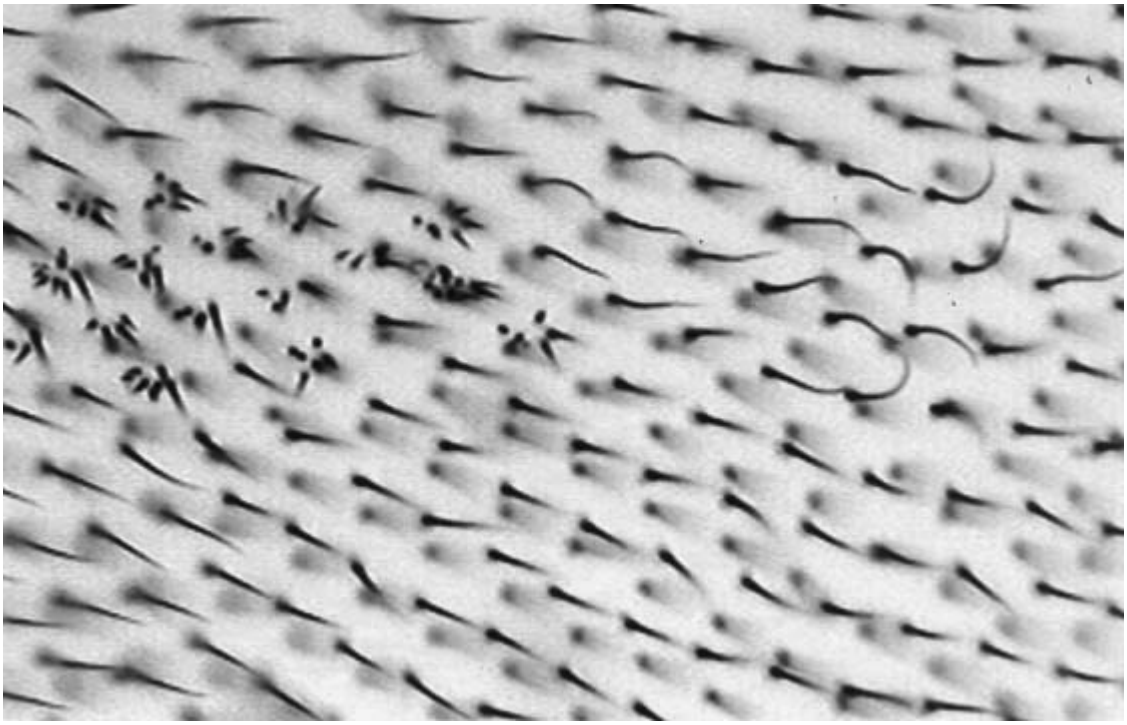
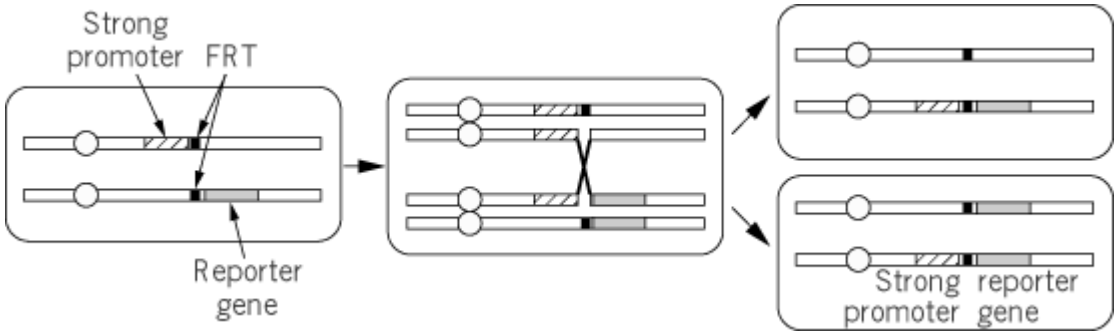


Mitotic recombination is rare; the frequency of alleles that become homozygous lies usually in the order of 10^{-4} to 10^{-5} per nuclear division, and it has been estimated that in *Aspergillus nidulans* the frequency over the whole genome is about 2% per nuclear division. The incidence can be increased by exposure to recombinogenic agents, such as X-rays, other ionizing radiations, ultraviolet radiation, and certain chemicals, including many alkylating agents. With appropriate treatments, the frequency of mitotic recombination reaches the order of magnitude of meiotic recombination.

Mitotic recombination provides a powerful tool to mark all the descendants of a single cell during development of multicellular organisms. A recombinogenic treatment of an appropriate heterozygote at a certain stage of development will produce genetically marked cell clones that can be easily recognized in later stages of development. Mitotic recombination can be made time-controlled and site-specific, as indicated in Figure 3. (see top of next page)

Figure 3. Time-controlled and site-directed mitotic recombination. FRT, a short DNA sequence from the 2-mm plasmid of *Saccharomyces cerevisiae* that is the target for the action of a specific recombinase, is inserted at the site where mitotic recombination should occur. The gene for the recombinase is inserted, under an inducible promoter, elsewhere in the genome. Induction of this promoter will trigger mitotic recombination at the FRT site. Cells derived from this event may be marked by a strong promoter and a reporter gene that are brought together by recombination (see Ref. 2). See previous page.



Mitotic recombination between two genes of the same chromosome may produce new combinations of the respective alleles. The frequency of recombinants correlates with the physical distance between the genes and may be used for the construction of genetic maps. In some fungi, like *Aspergillus niger*, this is the only way to construct genetic maps by recombination. Mitotic and meiotic recombination maps conserve the order of genes, although the respective recombination frequencies are not proportional.

The parasexual cycle, which includes fusion of haploid nuclei, mitotic recombination, and random chromosome loss, allows natural strains to form new combinations of genetic characters independently of the existence of a sexual cycle and meiosis.

Mobile Element

Genomes are surprisingly plastic, containing a variety of different kinds of DNA that can move from place to place. These mobile elements generally move by site-specific recombination—that is, by the action of a specialized recombinase, usually encoded by the mobile element, on special DNA sites at the ends of the element where recombination occurs; these recombination reactions can occur by a variety of mechanisms. One type of mobile DNA present in virtually all organisms examined are transposable elements. A major pathway for transposition is a DNA-based mechanism in which the transposon is excised from flanking donor site DNA by a double-strand break; alternatively, a DNA copy of the element is made by **reverse transcription** of an RNA transcribed from a chromosomal copy of the element. Both these processes result in the production of exposed 3′OHs at the ends of the mobile DNA segment. These exposed 3′OH ends are then joined to the target DNA, covalently linking the mobile element to its new site of insertion. Transposition is used by viruses to join the element to the genome of a newly infected cell. Other transposable elements move within a cell and often encode determinants, such as **antibiotic-resistance** genes that affect the cell. Nonviral transposable elements can also be dispersed between cells by translocating onto plasmids or viruses that move from cell to cell.

Mobile elements include, but are not limited to, transposable elements—that is, those elements that

move between nonhomologous sites via the recombination reaction called transposition, and transposable elements may be called *mobile elements*. There are a number of mobile DNA segments that are not transposable elements and that translocate by mechanisms other than transposition.

Another reaction in which DNA segments can rearrange to make new genes occurs by a pathway distinct from transposition, but involves a recombinase that can carry out transposition-type reactions (1, 2). VDJ recombination is an ordered set of deletion reactions that assembles immunoglobulin genes from multiple gene segments, providing incredible diversity in the immune system (3) (see Gene Rearrangement). As in transposition, the breakage and joining steps also involve DNA breakage reactions to expose 3′OH ends, followed by the joining of these 3′OH ends to intramolecular targets.

Another distinct kind of element translocation that occurs between nonhomologous sites is the movement of **polyA**$^+$ elements such as the LINES and SINES of mammalian genomes that lack all inverted terminal repeats (4). Translocation involves an element-generated nick in the target DNA that serves as a primer for the *in situ* reverse transcription of an element RNA, resulting in a new DNA copy of the element at a new chromosomal location.

Another nontransposable element mobile DNA is exemplified by the lambda phage that integrates into the bacterial chromosome to become part of the chromosome during lysogeny and then excises from the chromosome to enter the lytic phase. These recombination reactions occur at specialized sites on both the viral and chromosomal genomes; these sites are related to each other by protein binding sites and a short region of homology. Recombination occurs by simple breakage and joining reactions at each site (5, 6), in a reaction called *conservative site-specific recombination* (CSSR). This is a very distinct reaction from transposition, where the two transposon ends interact with a nonhomologous target site. Other CSSR-mediated reactions include the inversion of bacterial chromosomal segments to alternate between two configurations for differential gene expression and the monomerization of various dimeric DNA molecules, from plasmids to chromosomes. Yet another kind of reaction that can move different DNA sequences from place to place involves the introduction of gap at a particular site by a double-strand break that undergoes exonucleolytic trimming, followed by the filling of this gap via pairing and DNA replication, with information from a related site containing similar but distinct sequences (7).

Molecular Averaging

Molecular averaging is an important technique in X-ray crystallography for refining the structure generated (see also **R factor**). The structure determined by crystallography is the asymmetric unit of

the unit cell of the crystal lattice. If the asymmetric unit contains more than one molecule of the same kind, these molecules have the same structure, apart from small deviations at their surface due to molecular contacts. This structural similarity is extra information and imposes constraints on the phase angles of the X-ray reflections (see Phase Problem).

Bricogne proposed a very convenient method to employ this information for improving the electron density map of a protein (1). After a first electron density map has been calculated, for instance, based on the measured amplitudes of the reflections and phase angles estimated from isomorphous replacement or molecular replacement, the phase angles can be improved by averaging. In this procedure, the positions of the protein molecules in the asymmetric unit are located in the electron density map as regions of relatively high density. An envelope is constructed around each of them. The region outside the envelopes is occupied by solvent.

For an ideal structure, the electron density within all envelopes should be exactly the same, and outside them it should be flat. In practice this is not true. Therefore, the electron density in the solvent region is flattened in the next step (see Solvent Flattening), and the density of the protein molecules is averaged. This new map of electron density is closer to the correct map than the first map, and structure factors are calculated from it. The phase angles of these new, calculated structure factors are combined with their measured amplitudes, and an improved map is calculated. The procedure is repeated until convergence is reached.

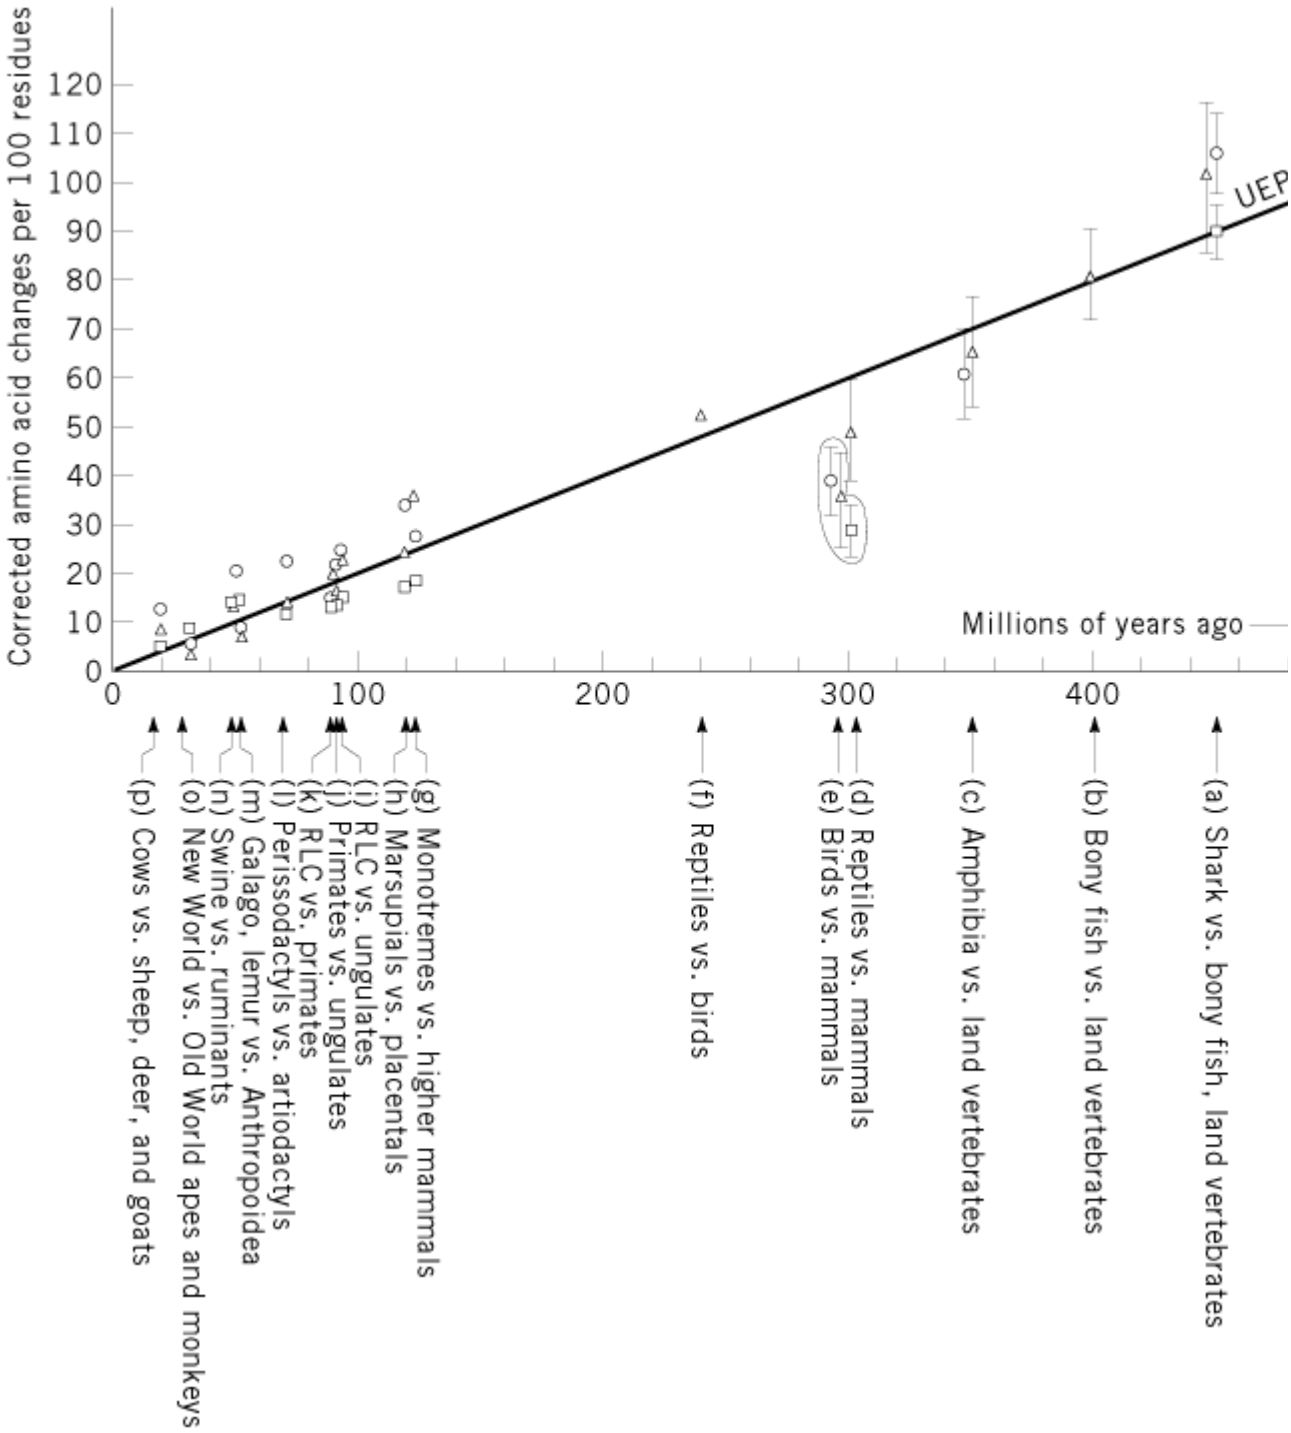
Molecular Clock

The molecular clock is an evolutionary property of **genes** in which the number of nucleotide or amino acid substitutions between a pair of species is approximately proportional to the time since those species diverged (Fig. 1), (1) which is usually given by the fossil record. Nucleotide and amino acid substitutions take place with a certain degree of regularity along evolutionary time, as if one substitution makes the needle of the evolutionary clock move ahead by a given time interval (2). Thus, this property is called “molecular clock” or “molecular evolutionary clock.”

Figure 1. The constant rate of divergence of the amino acid sequences of the hemoglobin and myoglobin polypeptide ch number of amino acid substitutions that occurred between two species is plotted against the time of divergence of the spe deduced from the paleontological record. The vertical error bars for the older divergence times extend over ±2 standard deviations, indicating the 95% confidence level. Triangles represent hemoglobin a chains, circles hemoglobin b, and squ myoglobin (1).



The molecular clock made a tremendous impact on the study of molecular evolution. In particular, the molecular clock guaranteed, to some extent, that the divergence time can be estimated only by sequence comparisons. This estimation can be made even between two species for which their morphological characters are totally different and no fossil records exist. Indeed, immediately after the discovery of the molecular clock, amino acid sequencing was used extensively for the study of long-term evolution of organisms.

The speed of the molecular clock depends on the gene of interest. For example, the rate of amino acid substitutions for histone genes is more than 1000 times slower than that for fibrinopeptides (see Fibrinogen). In principle, the stronger the functional constraints, the slower the rate of amino acid substitution. Moreover, it has become recently known that the speed of molecular clock sometimes

depends on lineages (3). Thus, a molecular clock should be used with caution, particularly when estimating the divergence time.

Molecular Dynamics

Molecular dynamics (MD) simulations evaluate the motion of the atoms in a given system and provide the position or *trajectory* of these atoms as a function of time. The trajectories are calculated by solving the classical equation of motion for the molecule under consideration. This is not unlike the well-known approach by which one evaluates the speed and position of a projectile, starting from the initial velocity, the mass, and the forces by using Newton's equation of motion. However, in the case of molecules, one obtains the relevant forces on each atom from the first derivatives of the given potential functions. The actual evaluation of classical trajectories is done numerically, expressing the changes in coordinates and velocities at a time increment, D*t*, by:

$$\begin{aligned} r_i(t+\Delta t) &= r_i(t) + \dot{r}_i \Delta t \\ \dot{r}_i(t+\Delta t) &= \dot{r}_i(t) + \ddot{r}_i \Delta t = \dot{r}_i(t) - [(\partial U/\partial r_i) m_i^{-1}]dt \end{aligned} \qquad (1)$$

where the dot designates a time derivative and we use Newton's law:

$$m_i \ddot{r}_i = F_i = -\partial U \,/\, \partial r_i \qquad (2)$$

starting with a given set of initial conditions [eg, with the values of r_i ($t = 0$) and $\dot{r}_i(t=0)$], we can evaluate **r**(t) either by numerically integrating eq. (1) or by using the somewhat more complicated but far better approximation (1).

$$\begin{aligned} r_i(t+\Delta t) &= r_i(t) + \dot{r}_i \Delta t + [4\ddot{r}(t) - \ddot{r}(t-\Delta t)]\Delta t^2/6 \\ \dot{r}_i(t+\Delta t) &= \dot{r}_i + [2\ddot{r}(t+\Delta t) + 5\ddot{r}(t) - \ddot{r}_i[t-\Delta t]]\Delta t/6 \end{aligned} \qquad (3)$$

This equation allows one to obtain much more accurate results than those of eq. (1) using the same D*t*s.

The propagation of classical trajectories of the atoms of a given system corresponds to a fixed total energy (determined by the specified initial conditions). However, the evaluation of statistical mechanical averages implies that the system included in the simulation is a part of a much larger system (ensemble) whose atoms are not considered in an explicit way. Thus, in order to simulate a given macroscopic property at a specified temperature we must introduce some type of “thermostat”

in the system that will keep it at the given temperature. This can be easily accomplished by assuming equal partition of kinetic energy among all degrees of freedom. Since each atom has three degrees of freedom with kinetic energy of $\frac{1}{2}m\dot{r}^2 = \frac{3}{2}k_BT$ (where *kB* is the Boltzmann constant) we obtain:

$$\mathrm{T} = \sum_{\mathrm{i}} \mathrm{m_i}\dot{\mathrm{r}}_{\mathrm{i}}^2/(3\mathrm{nk_B}) \qquad (4)$$

where *n* is the number of atoms in our system. In general, we can adjust the temperature during the simulation by scaling the velocities. That is, when *T* is smaller than the target temperature we can scale $\dot{r}$ uniformly by $1+\epsilon$ until the target temperature is obtained. If *T* is higher than the target temperature, then a scaling of $1-\epsilon$ is used. More sophisticated considerations for constant temperature simulations are described elsewhere (1).

MD simulations provide a powerful tool for studies of time-dependent dynamical properties and for evaluation of average properties (see below). The strength of such approaches is associated with the fact that they have the ability to simulate, at least in principle, the true microscopic behaviors of macromolecules. The weakness is associated with the fact that some properties reflect extremely long time processes that cannot be simulated by any current computer.

Early MD simulations of a condensed phase system were performed by Alder and Wainwright (2). This approach was later extended to studies of the properties of liquid water (3). The emergence of MD simulations in studies of biological systems can be traced to a simulation of the dynamics of the primary event in the visual process (4) that correctly predicted a photoisomerization process of around 100 femptoseconds. A subsequent study (5) attempted to examine the **heat capacity** of BPTI by a very short simulation of this protein in vacuum. Unfortunately, at the early stages of the development of this field, it was not possible to obtain meaningful results for average properties of macromolecules due to the need for much stronger computers to reach a reasonable convergence (the heat capacity is drastically underestimated [6], reflecting artificial diffusive motions). Nevertheless, ultrafast reactions, such as those that control the photobiological process could be simulated even at this early stage (4). Eventually, with the increase of computer power, it has become feasible to reach simulation times of nanoseconds and to start to obtain meaningful average properties of macromolecules.

It should be mentioned, however, that it is frequently possible to evaluate properties that occur in a very long time using rather short simulation times (eg, 100 ps). Examples are rate constants that can be evaluated by calculating *activation-free energies*.

The time needed to reach accurate results for average properties depends on the model used and number of local minima. For example, models that trim the protein to a sphere with the proper spherical boundary conditions (7) converge much faster than models that involve periodic boundary conditions (8) because the latter involves more molecules and more minima. As much as accuracy is concerned, the proper treatment of long-range effects is crucial, and improved convergence is usually associated with more proper treatment of long-range forces (7, 9).

MD simulation methods provide a powerful way of evaluating average properties such as **free energies,** but it must be emphasized that such properties have little to do with dynamics per se and can be evaluated by other averaging approaches such as Monte Carlo calculations. Similarly, the most important factors that determine the rate constants of most biological processes do not reflect dynamical properties but rather the probability of reaching the transition state configuration (10). Nevertheless, in cases of light induced ultra-fast photobiological processes, there are probably important effects that can be considered as dynamical properties, and MD simulations provide a direct way of modeling such effects.

Despite ever-increasing computational power, which has pushed the upper limit of simulation time scales to several hundred nanoseconds for condensed-phase systems, there are many interesting

processes that are too slow to be meaningfully simulated by MD approaches. However, some of these slow processes can be handled by **Brownian Dynamics** (**BD**) simulations, which represent the motion of the particles as a stochastic (random) process governed by a modified Langevin equation:

$$m_i\ddot{\mathbf{r}}_i = -\gamma m_i\dot{\mathbf{r}}_i + \mathbf{f}_i(t) + \mathbf{R}_i(t) \tag{5}$$

where $R_i(t)$ is the random force on i^{th} particle, g is the friction coefficient representing the dissipation of the random forces, and $f_i(t)$ is the part of the inter-particle forces exerted on particle i that are not represented by the random-force and friction terms. The average magnitude of the random forces and the corresponding friction acting on them are connected through the fluctuation-dissipation theorem, with the relationship:

$$\langle \mathbf{R}^2 \rangle = n2mkT\gamma \tag{6}$$

where *n* is the dimensionality of the system. The very long time behavior of the Langevin equation reduces to Einstein's diffusion law. The resulting equation of motion

$$\mathbf{r}_i(t+\delta t) = \mathbf{r}_i(t) + \frac{\mathbf{f}_i(t)}{m_i\gamma}\delta t + \boldsymbol{\rho}_i(\delta t) \tag{7}$$

no longer involves velocities and represents a coarse-grained view of the time evolution of the system. $\mathbf{r}_i$ represents the random displacement during a time step of duration dt, and is related to the friction coefficient by:

$$< \rho^2 >= \frac{n2kT}{m\gamma}\delta t \tag{8}$$

In addition to simulating slow processes (11), BD simulation strategies can also be used for simplifying the dynamics in a system in order to study general aspects of dynamics (12) or testing theories that often contain assumptions similar to those used in obtaining the Brownian equations of motion (12).

Molecular Mechanics

Examination of the properties of molecules by **computer simulation** using the corresponding potential functions is called molecular mechanics (MM). This name reflects the fact that a molecular force field considers a molecule as a collection of balls connected by springs and that examination of the mechanical properties of such a system is similar to the study of the properties of the corresponding molecule.

The term *molecular mechanics* usually includes several techniques that are aimed at determining different molecular properties. In particular, with a given set of analytical potential functions, one can evaluate the molecular equilibrium geometries and the vibrations around these configurations. This task can be accomplished in the simplest way using the Cartesian representation, with coordinates (x, y, z). That is, the potential surface for a molecule with n atoms can be expanded formally around the equilibrium configuration $\mathbf{r}_0$ and give

$$U(\mathbf{r}_0 + \delta\mathbf{r}) = U(\mathbf{r}_0) + \sum_{i\alpha}(\partial U/\partial r_{i\alpha})\delta r_{i\alpha} + \sum_{i\alpha,j\beta}(\partial^2 U/\partial r_{i\alpha}\partial r_{i\beta})\delta r_{i\alpha}\delta r_{j\beta} + \cdots \quad (1)$$

where the indices i and j designate atoms while a and b run over the x, y, and z coordinates of each atom. The first term is just the energy of the molecule at the equilibrium geometry. The second and third terms can be used (see below) to evaluate the equilibrium geometry and the vibrational frequencies.

1. Energy Minimization

The first term in equation (1) is just the energy of the system at equilibrium. The second term represents the deviation from equilibrium and the set of $3n$ equations (for i = 1,2,¼, n and a = x,y,z)

$$\partial U/\partial r_{i\alpha} = 0 \quad (2)$$

represents the condition that $\mathbf{r}_0$ is an equilibrium configuration. This set of equations can be solved approximately by the steepest-descent method (1), where the minimum is being searched by simply going in the opposite direction to the first derivative vector. That is, this method obtains the nth step toward the minimum by

$$r_{i\alpha}^{n} = r_{i\alpha}^{n-1} - g(\partial U/\partial r_{i\alpha}) \quad (3)$$

where g is a scaling factor that is changed in an iterative way to prevent **r** from overshooting the minimum.

The steepest-descent method converges very slowly and is not so effective in searching for minima. A much more reliable and efficient approach is the modified Newton–Raphson method (1), (2). This method is based on expanding the gradient as a Taylor series around the given **r** and finding the d**r** that leads to $\mathbf{r}_0$ where the gradient is zero (ie, $\mathbf{r}_0$ = **r** + d**r**). This gives

$$\partial U(r_0)/\partial r_{i\alpha} = \partial U(r_0 + \delta r)/\partial r_{i\alpha} + \sum_{j\beta} F_{i\alpha,j\beta}\delta r_{j\beta} = 0 \quad (4)$$

where **F** is the matrix of second derivatives, that is, $F_{ia,jb} = \partial^2 U/\partial r_{ia}\partial r_{ib}$. Then, by solving equation (4) one obtains

$$\mathbf{r}_0 = \mathbf{r} + \delta\mathbf{r} = \mathbf{r} - \mathbf{F}^{+}\nabla U(r) \tag{5}$$

where $\tilde{\partial}U$ is the gradient vector [with $(\tilde{\partial}U)_{ia} = \partial U/\partial r_{ia}$] and $\mathbf{F}^{+}$ is the generalized inverse of **F**, which is constructed by "filtering" the zero eigenvalues of **F** before inverting this matrix.

It is instructive to note that both the steepest-descent and the Newton–Raphson methods lead in the direction of $-\tilde{\partial}U$; however, the steepest-descent method is unable to tell us how far to go in each step, and therefore we must search for the minimum in a very ineffective way. Equation (5) requires the evaluation of the second-derivative matrix **F**, which is quite involved. Alternatively, one can use the conjugated gradient methods, where an approximation of bFb^{+} is being built while searching the minimum using only the first derivatives vector DU (for a description of these powerful methods and related approaches see Ref. 1).

Energy-minimization methods that exploit information about the second derivative of the potential are quite effective in the structural refinement of proteins. That is, in the process of determination of a structure by X-ray crystallography, one sometimes obtains bad steric interactions that can easily be relaxed by a small number of energy minimization cycles. In fact, one can combine the potential $U(\mathbf{r})$ with the function that is usually optimized in X-ray structure determination and minimize the sum of these functions (3) by a conjugated gradient method, thereby satisfying both the X-ray electron density constraints and steric constraints dictated by the molecular potential surface.

Although the conjugated gradient and related methods are very effective in finding local energy minima, they do not overcome the problems associated with the enormous dimensionality of macromolecules. That is, in systems with many degrees of freedom, we expect to find a very large number of local minima; and it is not clear, for example, how to find the lowest minimum in an efficient way. For this purpose, one must use much more computer time and different types of search procedures (**Monte Carlo** or molecular dynamics), generating different configurations at different regions of conformation space and locating the minimum energy structure of each region. Such methods were, however, useless until the emergence of supercomputers in the early 1980s, and even at the present time they do not allow for a complete search of a protein's conformational space.

2. Normal Mode Analysis of Large Molecules

Finding a local energy minimum by a convergent minimization method allows one to exploit the third term in equation (1) for evaluation of the molecular vibrations around that minimum. Although early works used internal coordinates in studies of molecular vibrations (4), it was realized that much more effectiveness is offered by using the Cartesian coordinates of the given molecule (2). All that is needed in this case is the second-derivative matrix and the atomic masses. That is, the potential for infinitesimal vibrations around the local minimum $\mathbf{r}_0$ can be written as

$$\delta U(\mathbf{r}_0) = \frac{1}{2}\delta\mathbf{r}'\mathbf{F}(\mathbf{r}_0)\delta\mathbf{r} \tag{6}$$

where **F** is the second-derivative matrix of equation (1). The kinetic energy for the system can be written as

$$\delta T = \frac{1}{2}\delta\dot{\mathbf{r}}'\mathbf{M}\delta\dot{\mathbf{r}} = \frac{1}{2}\sum_{i,\alpha} m_i \delta\dot{r}_{i,\alpha}^2 \tag{7}$$

where d**r** is the vector of the atomic velocities, **M** is the diagonal matrix of the atomic masses ($M_{ia,jb} = M_i d_{ij} d_{ab}$) and **r** = dr/dt (t is the time). The expression for the potential energy can be greatly simplified if we transform the Cartesian coordinates to a new set of coordinates called **normal coordinates**, $\mathbf{Q}_i$, using

$$\delta\mathbf{r} = \mathbf{M}^{-1/2}\mathbf{L}\mathbf{Q} \tag{8}$$

where the matrix **L** is constructed from the column vectors $\mathbf{L}^S$ that are obtained by diagonalizing the mass-weighted **F** matrix

$$(\mathbf{M}^{-1/2}\mathbf{F}\mathbf{M}^{-1/2})\mathbf{L}^s = (2\pi\nu_s)^2\mathbf{L}^s \tag{9}$$

Here v_s is the vibrational frequency of the sth molecular mode and $\mathbf{L}^s$ is the normal mode that describes the motion of the atoms in this particular mode.

Normal mode analysis based on analytical potential functions has been found to be quite effective in studies of spectroscopic properties of various organic molecules and of molecules of biological interest (eg, Refs. 5-7), as well as in refinements of force fields (eg, Ref. 2). The harmonic normal mode description was also found to be quite useful for approximate evaluation of various molecular properties. For example, one can use this description in a convenient way to evaluate the average thermal atomic motions. Normal mode analysis of protein motion is also quite useful (8, 9).

Molecular Replacement

If the structure of a macromolecule has been determined by X-ray crystallography, it can be used to elucidate a homologous structure without the need to determine the phases of the X-ray reflections directly by methods, such as isomorphous replacement (see Phase Problem). Proteins that are homologous in their amino acid sequence have essentially the same tertiary structures. Therefore, the known structure can be employed as a first model for the unknown structure.

The problem is where to put this model in the unit cell of the unknown structure. This problem is solved in two steps:

1. The orientation of the model is found by applying a rotation function.
2. It is moved translationally to the correct position using a translation function.

The method was pioneered by Rossmann and Blow (1) based on principles given by Hoppe (2). The rotational and translational processes can most easily be understood by regarding the Patterson function (see Patterson Map). With this function a vector map is calculated. Vectors between atoms in the real structure show up as vectors from the origin to maxima in the Patterson map. Most of the intramolecular vectors are short, and their end points are found in a region around the origin of the Patterson map. If intermolecular vectors were completely absent, this inner region in the Patterson map would be the same for the same protein in different crystal structures and very similar for homologous structures, apart from a rotational difference. Although the intermolecular vectors disturb the situation somewhat, in many cases the required rotation can easily be obtained by finding the maximum overlap of the observed Patterson map for the unknown structure and that calculated for the known model.

With the translation function, the positions of the model molecules in the unit cell with respect to symmetry axes are determined. The principle here is also that the calculated and observed Patterson functions should overlap to a maximum extent. An excellent computer program for molecular replacement, AMoRe, has been written by Navaza (3).

After successful application of the rotation and translation function, the preliminary structure obtained is the starting model for a refinement process.

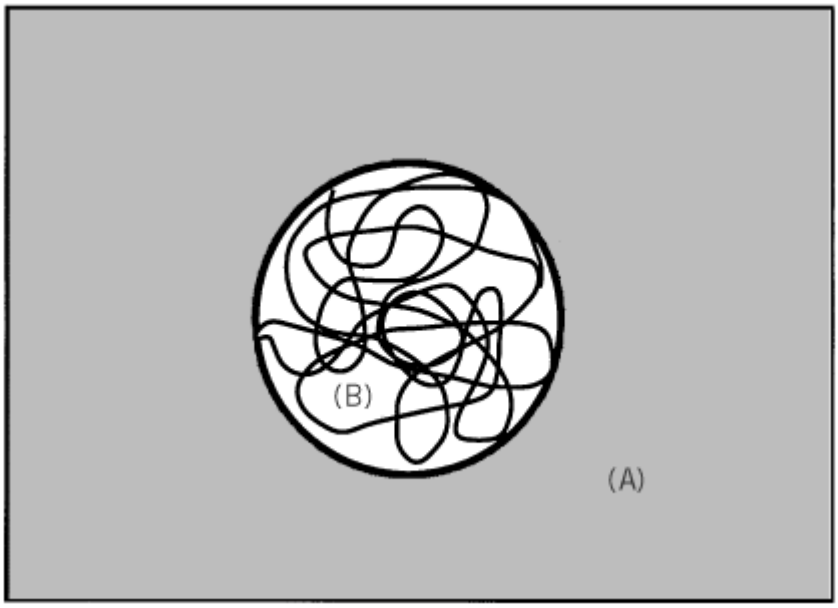
Molecular Sieve Resins

Molecular sieves are the materials used for preparing the stationary phase used in size exclusion chromatography (SEC), or gel filtration, to obtain information about the hydrodynamic volume and Stokes Radius of a macromolecule. Figure 1 illustrates the essential features of molecular sieves (1). These resins are porous beads that are constructed from noninteracting or “inert” polymeric materials. When transported through a mobile phase in a column packed with this resin, a solute potentially has access to all the pores in the resin bead. The sizes of the pores in the beads are, however, not uniform but are best described as a distribution. If very small, a solute may have access to all pore sizes. A very large solute, in contrast, would not be accommodated in the pores at all and would be totally excluded. Solutes of intermediate size would partially partition into the pores of the molecular sieve. The extent of partitioning of the solute into the pores is inversely proportional to its size, with larger solutes partitioning to a lesser extent than smaller solutes. Here the properties of available molecular sieve resins are discussed, as well as phenomenological and mathematical

descriptions of the function of these resins.

Figure 1. Schematic representation of a molecular sieve partitioning system. The dotted area represents the mobile-phase exterior to the resin particle. The porous gel particle enclosed by the circle represents the stationary phase. The gel particle consists of two regions, the internal solvent (**B**) and the polymeric gel matrix or curved lines (**A**). Solute molecules introduced into the system partition between (**A**) and (**B**), with the extent of partitioning into (**B**) depending on the size of the solute.



Molecular sieve resins are prepared from a range of materials. The two major classes of stationary phase materials are derivatized glass or silica and crosslinked gels. The crosslinked gels are further subdivided into natural or synthetic; the former are based on polysaccharides and the latter on polymerized hydrophilic monomers. Advantages of the silica-based packings include their rigidity, uniform pore size, and uniform particle size (2). A summary of the types of available derivatized silica resins is provided in Table 1 of Reference 2. The major disadvantages of the derivatized silica resins are their adsorptive properties and tendency to degrade with use. The first problem results from incomplete reaction of the SiOH groups, which results in a negatively charged surface with which proteins have been found to interact (2-4). The problem with degradation of the derivatized silica based resins limits the composition of the mobile phase. The common crosslinked polymers include crosslinked dextrans or agarose, the polyacrylamide resins, and composite polyacrylamide/agarose resins (2). Table 2 of Reference 2 contains a summary of the types and properties of a large number of these hydrophilic polymer gels. An inherent assumption of size exclusion chromatography is that the solute that is chromatographed does not interact with the resin. As indicated in the preceding discussion, silica-based resins are the least desirable in this respect. Polymeric resins are, however, by no means inert, and care should be exercised in choosing the composition of the mobile phase used in chromatographic experiments, in order to minimize interaction with the resin (2).

In a molecular sieving process, solute molecules partition between the solvent spaces or the pores in the resin particles (the stationary phase in the chromatographic column) and the solvent space exterior to the resin particles (the mobile phase in the chromatographic experiment). The stationary phase consists of the sieving resin equilibrated with the solvent used for the mobile phase. There are three compartments within the experimental system (1): (1) the volume exterior to the resin particles, or the *void volume*, V_0; (2) the solvent region in the interior of the gel particles, or the *internal*

volume, V_i; and finally (3) the volume occupied by the gel matrix, V_g. The experimental methods for measurement of these volumes are provided in size exclusion chromatography. The total volume of the column is simply the sum of these three volumes:

$$V_t = V_o + V_i + V_g \tag{1}$$

The behavior of a solute, typically a protein, in gel filtration chromatography is expressed in terms of the extent of partitioning of the solute into the pores of the resin, which is measured quantitatively by the partition coefficient, s. It is defined as the amount of solute distributed in the gel per unit internal volume, V_i, and solute concentration in the external space of the column, C. A partition isotherm that relates the weight of solute, Q_i, inside the gel and the solute concentration in the space exterior to the gel, or the void, can be written in terms of s.

$$Q_i = \sigma V_i C \tag{2}$$

The partition coefficient is thus a measure of the degree of partitioning of the solute into the interior space of the gel matrix. At equilibrium, the penetrable volume, V_p, of the gel that is occupied by solute molecules is given by

$$V_p = Q_i / C_p \tag{3}$$

where C_p is the solute concentration in the region of distribution. Combining Equations (2) and (3) leads to

$$\sigma = V_p / V_i \tag{4}$$

which indicates that the partition coefficient is the fraction of the internal volume of the resin that is penetrable by the solute molecule. This relationship works reasonably well at low solute concentrations. At high solute concentrations, however, corrections must be introduced to take into account the effects of nonideality. Values of s range from 0, for very large solutes that are totally excluded from the pores, to 1 for very small solutes that are completely included in the pores.

The partition coefficient can also be related to the total volume of the gel phase $V_t - V_o$. Using this formalism the partition isotherm is expressed as

$$Q_i = K_{av}(V_t - V_o)C \tag{5}$$

Assuming no concentration-dependence of the partition coefficient or nonideality:

$$K_{av} = \frac{V_p}{V_t - V_o} \tag{6}$$

At low solute concentrations, K_{av} is the volume fraction of the stationary phase that is occupied by the solute. This coefficient is frequently used in analysis of SEC data. The coefficient K_{av} is related to s by the following expression:

$$\sigma = K_{av}(1 + \overline{V}_g / S_r)$$

where *ovl*V*ovl*$_g$ is the partial specific volume of the gel matrix and S_r is the solvent regain of the gel material. For a detailed discussion of these two terms, the reader is referred to Reference 1. Note that if the solvent regain and partial specific volumes for two gel materials are known, a measured value for a partition coefficient obtained in one system can be converted to the value in another. Moreover, for any sieving resin, a constant ratio exists between the two partition coefficients, s and K_{av}.

Molecular Surface, Volume

Protein structure can be described with the spatial coordinates of all the constitutive atoms in terms of **alpha-helices**, beta-sheet, turns, irregular regions, etc. But this useful information has not yet led to a complete understanding of protein structure, particularly its dynamic nature. The efficiency of packing of atoms and residues in a protein molecule (the packing density) has important implications for its structure and its thermodynamic, mechanical, and functional properties. Related structural parameters are the surface area and the volume, which make it possible to grasp intuitively the overall structure of a protein. It is difficult, however, to define the complex surface and volume of all its atoms, including all the intramolecular cavities, so there are a number of definitions of surface and volume for protein molecules.

The geometrical surface and volume of the individual atoms of a macromolecule (the van der Waals surface, volume) can be evaluated on the basis of the structure determined by X-ray crystallography . The surface and volume of this collection of atoms can be computed, but many atoms are in the interior and will normally not make contact with a molecule in the solvent. A more relevant surface is that which normally is in contact with the solvent. This is defined by rolling a spherical probe, representing a water molecule, over the van der Waals surface of the macromolecule (see Fig. 1 of Accessible Surface). Those parts of the van der Waals surface in contact with the surface of the solvent molecule are designated the contact surface. When the probe is simultaneously in contact with more than one protein atom, its interior surface defines the reentrant surface. The contact surface and the reentrant surface together make a continuous surface, which is defined as the molecular surface, and it defines a molecular volume. The surface defined by the center of the probe molecule is the accessible surface.

Special thermodynamic volumes, such as the partial specific volume, are introduced for understanding the physicochemical properties of proteins in solution. The pressure and temperature coefficients of the volume (compressibility and expansibility) also give useful information on the atomic packing and flexibility of protein molecule.

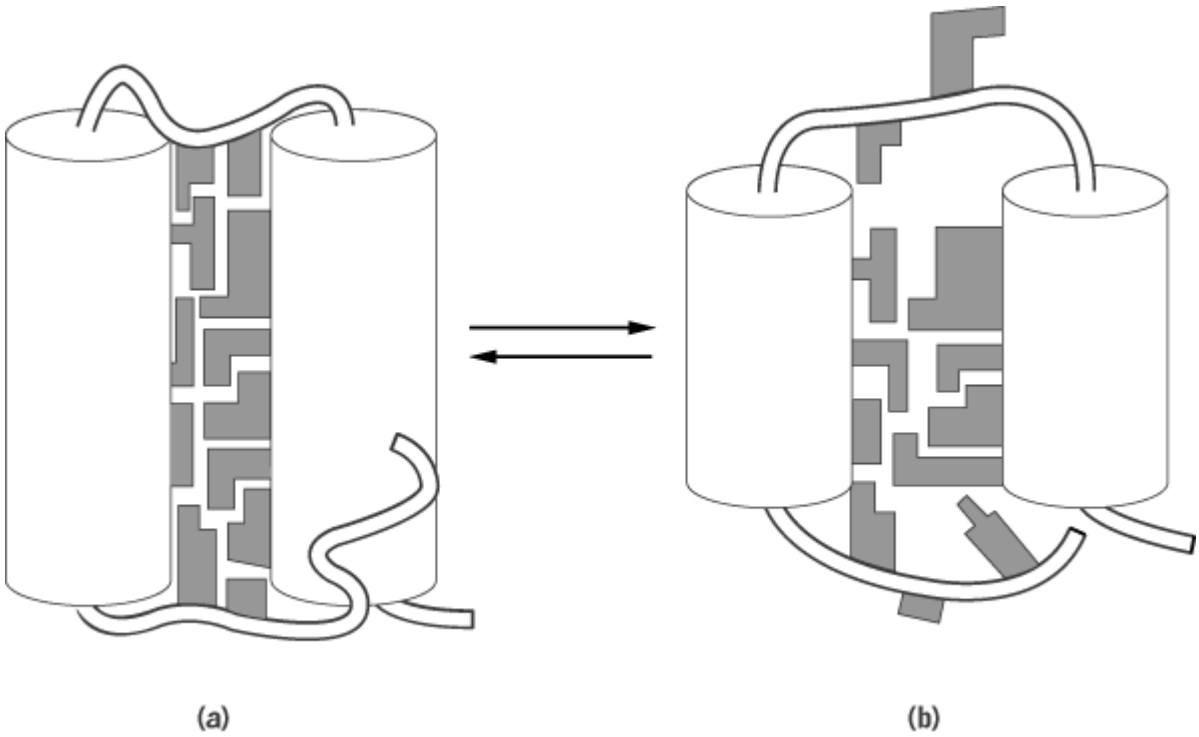
Molten Globule

The molten globule state is an intermediate conformational state between the native and the fully unfolded states of a globular protein (see **Protein folding** and **Protein unfolding**). Many proteins can be observed in this state when partially unfolded at equilibrium, under mild **denaturation** conditions, or as a transient intermediate kinetic species, being formed rapidly from the unfolded state upon transfer to refolding conditions. The characteristics of the molten globule state are:

1. the presence of a native-like content of **secondary structure**;
2. the absence of a specific tertiary structure produced by the tight packing of amino acid side chains;
3. compactness in the overall shape of the protein molecule, with a radius 10 to 30% larger than that of the native state;
4. the presence of a loosely packed **hydrophobic** core that increases the hydrophobic surface area accessible to solvent.

Thus, in short, the molten globule is a compact globule with a “molten” side-chain structure that is primarily stabilized by nonspecific hydrophobic interactions (Fig. 1).

Figure 1. A schematic model of the native (**a**) and the molten globule (**b**) states of a protein molecule. Only two **a-helices** are presented for simplicity. According to this model, the molten globule preserves the mean overall structural features of the native protein but differs from the native state mainly by looser packing and a higher mobility for the loops and ends of the protein molecule. (From Ref. 13, reprinted with permission.)



Experimentally, the molten globule state is characterized by having a native-like circular dichroism (CD) peptide spectrum below 250 nm, which arises from the secondary structure, and by an unfolded-like CD spectrum of the aromatic side chains between 250 and 320 nm, due to the absence of specific side-chain packing interactions (Fig. 2). Hydrogen atoms of the peptide backbone involved in secondary structure of the molten globule state appear to be protected from hydrogen exchange with the solvent protons, but the protection factor for the molten globule (10 to 1000) is much smaller than that for the native state, which is often greater than 10^6. The nuclear magnetic resonance (NMR) spectrum of the molten globule state is closer to that of the unfolded protein, and there is little, if any, chemical shift dispersion in the spectrum, reflecting the absence of a specific tertiary structure (Fig. 2). The individual resonances in the NMR spectrum are, however, broader than those in the unfolded state, reflecting conformational fluctuations in the molten globule state. It is known that the structure of the molten globule state, as determined by hydrogen exchange and NMR spectra, is heterogeneous in proteins, including **a-lactalbumin**, cytochrome ***c***, and apo myoglobin. In these proteins, one portion of the structure is more organized and substantially protected in the molten globule state, with other portions of the structure being less organized. Solution X-ray scattering has been used to characterize the molten globule structure (1). The presence of a clear peak in the Kratky plot and the radius of gyration evaluated from the Guinier plot of the X-ray scattering curve in the molten globule state show that the protein molecule in this state is compact and globular. Limited **proteolysis** by proteolytic enzymes has also been used for probing the partly folded structures of proteins; the key result is that the molten globule can be sufficiently rigid to prevent extensive proteolysis and it appears to maintain significant native-like structure (2). A hydrophobic fluorescent dye, such as 8-anilinonaphthalene-1-sulfonate (**ANS**), which binds to solvent-accessible hydrophobic surfaces of a protein molecule, has also been used for characterizing the molten globule state. The molten globule binds ANS much more strongly than does either the fully folded or fully unfolded form of the protein; the latter can be generated in a concentrated solution of a strong denaturant (6 *M* **guanidinium** chloride or 8 *M* urea).

For some proteins, the molten globule state is an equilibrium intermediate observed at an intermediate concentration of a strong denaturant (eg, 2 *M* guanidinium chloride) as part of a denaturant-induced unfolding transition. On the other hand, many globular proteins show a **cooperative** two-state unfolding transition without the intermediate. Whether or not the molten globule state is observed as a stable intermediate depends upon its stability relative to that of the native and the unfolded states (3). The unfolding intermediates of carbonic anhydrase and of a-lactalbumin are typical examples of a molten globule state that is stably populated at an intermediate concentration of denaturant. For these proteins, the partially unfolded states at acidic or alkaline pH are identical to the unfolding intermediate in the denaturant-induced transition, so the acidic or alkaline transitions also produce the molten globule state. For some other proteins, such as cytochrome *c*, apomyoglobin, and **b-lactamase**, the acidic or alkaline transition is known to produce a more extensively unfolded state; in these cases the addition of salt refolds the protein molecule from the unfolded to the molten globule state. The salt-induced refolding to the molten globule state is caused by counterion binding of the salt to the protein molecule, which eliminates the **electrostatic** repulsion between the charged groups. Other mildly denaturing processes that lead to the molten globule state include denaturation induced by hydrostatic pressure and by alcohols. Removal of the bound metal ion in a metal-ion binding protein sometimes results in a molten globule state, as in the case of apo-a-lactalbumin produced by removal of the bound Ca^{2+}. Covalent modification of a protein can also sometimes result in a molten globule state.

In many globular proteins, the molten globule state is observed at an early stage of the kinetics of refolding from the unfolded state. The early formation of the molten globule might be a way by which these proteins can be folded efficiently without wandering into the huge conformational space available for the proteins. Two experimental techniques, stopped-flow CD (4) and pulsed hydrogen-exchange combined with either two-dimensional NMR or electrospray ionization mass spectrometry, have been used successfully to characterize the transiently formed molten globule-like states during the kinetics of refolding of many globular proteins. The stopped-flow CD studies have shown the rapid formation of the peptide secondary structure occurring within the dead-time of the stopped-flow mixing (~10ms), although how much of the secondary structure is rapidly regained depends on the protein species (3). The pulsed hydrogen-exchange technique, when combined with two-dimensional NMR, can identify the specific location of stabilized secondary structure segments in a transient intermediate of a protein. For apomyoglobin (5) and ribonuclease HI (6), comparison of the kinetic refolding intermediate and the equilibrium molten globule state has shown that the two are identical. Identification of the molten globule intermediate has also been well-established for a-lactalbumin by time-resolved CD and NMR studies (4, 7). Molten globule-like folding intermediates have also been detected and characterized in many other globular proteins. Nevertheless, this does not necessarily mean that the molten globule state must be an obligatory, universal intermediate of protein folding. Because the formation of the molten globule-like folding intermediate is usually too rapid to be coupled kinetically with the subsequent folding reactions, it is very difficult to determine whether or not the molten globule is an obligatory folding intermediate. Furthermore, several small globular proteins with approximately 60 amino acid residues are known to refold very rapidly to the native state within a few milliseconds without accumulation of the molten globule intermediate (8).

When considering the role of the molten globule state in protein folding, it is important to address the question as to whether or not the molten globule is a **thermodynamic** state. Analysis of the cooperativity parameters for denaturant-induced unfolding transitions of some proteins has suggested that the transitions from the molten globule state to the unfolded state and from the native state to the molten globule state are both all-or-none transitions, indicating that the molten globule state is a thermodynamic state. Furthermore, stability studies of mutants of apomyoglobin (9) and cytochrome *c* (10) have concluded that the molten globule states of these proteins show cooperative unfolding and are stabilized by native-like tertiary interactions, in addition to nonspecific hydrophobic

interactions, which is consistent with the proposal that the molten globule state is a distinct thermodynamic state. However, for the best-characterized molten globule of a-lactalbumin, calorimetry, NMR, vibrational **Raman spectroscopy** (11), and other techniques (12) have clearly shown that the unfolding of this molten globule is not a cooperative two-state transition. Such diversity in the unfolding behavior of the molten globule state among different proteins may arise from the diversity of the molten globule structure. Because the native tertiary interactions are at least partially lost in the molten globule state, its structure must be more diverse than the native structure, and how cooperatively the molten globule unfolds may depend on how many residual native tertiary interactions are retained in this state. A good example is the molten globule state of the equine lysozyme, which is a calcium-binding protein and homologous to a-lactalbumin. Although the equine lysozyme molten globule apparently resembles that of a-lactalbumin, a rigorous analysis of its spectroscopic and thermodynamic properties has shown that its structure is significantly more highly organized and that its unfolding is a cooperative first-order transition accompanied by a large change in enthalpy. Because of this diversity in the intermediate conformational states of proteins, it is difficult to provide a clear structural definition of the molten globule state. Consequently, this causes some controversy, with the formation of native-like tertiary fold considered to be a characteristic of the molten globule state in certain cases, while in other cases structures with non-native tertiary folds are also molten globules. Furthermore, more than one intermediate conformational state is often observed between the native and fully unfolded states (10). Nevertheless, the four characteristics itemized at the beginning of this article are those generally accepted as the characteristics of the molten globule state.

It is now well established that not only the native state, but also non-native conformational states, play an important role in a biological cell. The protein states recognized by various **molecular chaperones** are non-native. The non-native conformation is also required for translocation of a protein across a biological membrane (see Protein Secretion). Various genetic diseases can be caused by the misfolding of translated polypeptides, and this misfolding results from an increased propensity of the mutant proteins to form non-native conformations. Because the molten globule state is regarded as a denatured state under physiological conditions, it definitely assumes some role in the above phenomena *in vivo*. It is also true, however, that there is a much greater diversity in the non-native conformations of proteins than in just the conformations characterized as the molten globule state.

Monocentric Chromosome

Chromosomes with a single centromere are monocentric. The majority of metazoan animals and **plants** have monocentric chromosomes. Monocentric chromosomes are also called **acrocentric** if the centromere is visible at the end of the chromosome, **metacentric** if it is toward the middle, and **telocentric** if it is at the chromosome's end.

Monoclonal Antibody

1. Monoclonal Antibodies

Monoclonal antibodies are of special significance in immunology because of their direct correlation with fundamental immunological principles at the cellular, genetic, and protein levels (1). Before the recognition and understanding of monoclonal antibodies, immunologists appreciated the biological benefits to the host of the extensive heterogeneity that characterized the mammalian polyclonal humoral immune response to most antigens. Heterogeneity equated with immunological diversity and represented a crucial component in a competent and protective immune system. Understanding antibody heterogeneity at the molecular level led to the hypothesis that heterogeneous immune

responses were comprised of arrays of antibodies of similar (but not identical) specificity and affinity for a given antigen. It was further surmised that each antibody was the product of a single lymphocyte, a fundamental doctrine in the Clonal Selection theory (2). Clonal selection had many biological implications that led to the following precepts: 1) fully differential lymphocytes would have a finite genetic capacity to synthesize antibody; 2) upon antigen stimulation, responding activated lymphocytes would rapidly proliferate, generating progeny-synthesizing identical antibody molecules; and 3) antibody molecules produced by a single cell and subsequent progeny would be homogeneous in specific interaction with antigen. Thus, the term "monoclonal antibody" embodies basic elements that collectively characterize the immune system. Experimental proof of these basic tenets established the foundation for modern molecular immunology.

Monoclonal antibody is by definition a homogeneous population of immunoglobulin macromolecules produced by a single lymphocytic cell and progeny. Homogeneity of antibody macromolecules can be assessed at various physiochemical levels to verify monoclonality.

First, every molecule in a monoclonal antibody population is of the same heavy (H) and light (L) chain isotype. Isotype is equated with the class of each chain (eg, IgG or IgM as H chain designations and kappa or lambda for L chains) reflecting identical primary structures in the constant domains. Thus, every lymphocyte synthesizing and secreting the Ig protein expresses identical gene products.

Second, when the variable domains associated with the H and L chains combine to form a functional active site of a given specificity in a monoclonal antibody population, all sites are idiotypically identical. Idiotype refers to the shape, conformation, configuration, and dynamics of the antibody-active site constituted by the unique non-covalent association of the two variable domains. Idiotypic relationships are determined by eliciting anti-idiotype antibodies specific for the unliganded active site of the monoclonal antibody. Similarly, when ligand or antigen is bound to the variable domains of a given idiotype, the monoclonal antibodies assume the same unique liganded conformation as evidenced by identical metatypic properties. Epitopes associated with variable domain interactions that constitute idiotype (non-liganded state) or metatype (liganded state) of a monoclonal antibody are non-linear or conformational in nature (3). Both idiotype and metatype represent unique conformational properties of the active site of a monoclonal antibody and differ due to the presence or absence of antigen.

Third, homogeneous or monoclonal antibody populations display identical binding properties for the homologous antigen or ligand. Thus, in terms of affinity, the same binding constant (M^{-1}) describes each active site within the monoclonal population. In contrast, an affinity of a polyclonal antibody population represents an average of the molecules present. In addition, identical specificity and cross-reactivities are exhibited by all molecules. Homogeneity of binding can be quantitatively measured by constructing antigen-antibody binding plots, such as Scatchard and Sips plots. In the Scatchard plot, as the binding sites become saturated, the abscissa intercept of the plot represents the valence (N) of the antibodies comprising the population (eg, N = 2.0 for IgG antibodies). In a monoclonal antibody population, the Scatchard plot will characteristically yield a straight line indicative of homogeneous reactivity with antigen. Importantly, the corresponding Sips plot yields a Sipsian heterogeneity index based on a scale ranging from 0 to 1.0. When the constant or index (slope of the line) is equivalent to 1.0, the antibody population is judged to be monoclonal or homogeneous.

Fourth, monoclonality can be ascertained by determining the amino acid sequence of the H and L chains of the antibody protein population. Since antibodies of differing specificities or affinities vary in their primary structure within the H and L chain variable domains, the ability to determine primary structures verifies population monoclonality. Heterogeneous antibody populations are not amenable to primary structure determinations reflecting significant differences.

Finally, it is instructive to mention a procedure to be used with reservation to ascertain monoclonality because the results are often misleading. In particular, isoelectric focusing yields aberrant results when analyzing monoclonal antibodies. Analyses of a monoclonal antibody population on the basis of isoelectric point determinations are often distorted by microheterogeneity that is attributable to the multiple carbohydrate moieties attached to the antibody molecules. Although the Fc-associated (ie, constant domains of H chains) carbohydrate content is of a relatively small percentage on a weight basis (eg, IgG is 2% to 3% carbohydrate, while IgM is 10% to 12% carbohydrate), the carbohydrate content varies within an antibody population that is homogeneous at the protein level. Microheterogeneity can be explained, in part, due to differential sialic acid content as the terminal sugars constituting the individual carbohydrate moieties. Microheterogeneity results in a spectrum of different isoelectric points, even in a monoclonal antibody population. Enzymatic or chemical removal of charged sialic acid residues converts heterogeneous isoelectric profiles to relatively more homogeneous patterns consistent with the uniform primary structure of the Ig protein.

When an antibody population satisfies the various criteria listed, the protein can be determined as monoclonal and the product of a single cell.

2. Myeloma Proteins

Before the development and universal application of hybridoma methodology to generate monoclonal antibodies of defined specificity, immunologists relied on the existence of homogeneous pathological immunoglobulins called myelomas. Myeloma proteins are produced spontaneously in humans due to transformation of a lymphocyte to the malignant state. Myeloma proteins can also be generated in specific strains of mice through administration of various reagents, such as mineral oil, administered in the peritoneal cavity. Initially, myeloma globulins produced during human and animal disease were considered devoid of functional properties and were classified along with normal immunoglobulins as non-specific and lacking antigen-binding capacity. With the advent of the previously cited Clonal Selection theory (2), homogeneous myeloma proteins become antibodies in search of antigen. Myeloma proteins in humans appear in a frequency that parallels their concentration in serum and, therefore, the respective number of lymphocytes synthesizing that class of antibody. Thus, human IgG myelomas appear most frequently (~90%) followed by IgM (10%), etc. Myelomas in the other classes, such as IgA, IgD, and IgE are quite rare in humans. In contrast, induced myelomas in mice are predominantly IgA followed in incidence by IgG and IgM. A predominance of IgA reflects the administration of mineral oil into the peritoneal cavity, which is rich in IgA-producing lymphocytes.

Myeloma proteins proved homogeneous at the protein level, and, because they were produced in high quantities, they were easily purified to homogeneity. These homogeneous proteins provided the foundation upon which the first primary structures of immunoglobulins were based. L chains of myeloma proteins in human patients exist in excess and are harvested from urine as monomers or stable dimers called Bence-Jones proteins. Since L chains were of lower molecular weight (approximately 22 kd to 23 kd) and lacked carbohydrate moieties, they were used to obtain the first primary structures. Putnan, Titani, and Whitley (4) published the first complete sequence analysis of a Bence-Jones protein called Ag, a sequence that became the standard by which all subsequent L chain primary structure analyses were compared. Roy was the second completed L chain sequence and was significant because it was the comparison of primary structures that yielded critical structure-function information. Comparison of several primary structures of H and L chains normalized for isotype revealed the existence of the variable and constant domains (5). Further comparisons within the variable domains showed that the H chain consisted of four hypervariable regions termed “complementarily determining regions” (CDRs). The L chain variable domains consisted of three CDR segments. This finding, combined with similar results from analyses of hybridoma proteins, led to delineation of the molecular basis of immunological specificity.

3. Hybridomas

Classical seminal studies by Köhler and Milstein in 1975 (6) led to the generation of monoclonal antibodies with defined specificity. Hybridoma methodology was based on fusing murine immune lymphocytes with a malignant mouse myeloma lymphocyte cell line that possessed certain important genetic and biochemical properties. This important methodology was necessitated by the fact that immune antibody-producing B lymphocytes were difficult to maintain as stable cell lines under tissue culture conditions. However, fusion of antibody-producing cells with a malignant myeloma cell line resulted in proliferative cells that can be maintained indefinitely.

Spontaneous fusions between lymphocytes are rare events, so, to generate large numbers of fused cells, the frequency of fusion was increased by using surface-active agents such as inactivated Sendai virus or the chemical polyethylene glycol. Upon mixing immune lymphocytes with myeloma cells and the fusing reagent, a selection system was mandatory to eliminate unfused parental cells and to assay for appropriately fused cells that synthesized antibodies with a desired specificity. The tissue culture selection process was dependent on the procurement of myeloma cell lines that no longer synthesized an immunoglobulin and lacked genes for thymidine kinase (TK) or hypoxanthine-guanine-phosphoribosyl transferase (HGPRT). These enzymes catalyzed important steps in the salvage pathway used in DNA synthesis by dividing cells. Unfused myeloma cells are unable to proliferate in the HAT selection medium (containing hypoxanthine, aminopterin, and thymidine) because aminopterin inhibited the *de novo* DNA biosynthetic pathway forcing the cells to utilize the non-functional salvage pathway. Fused myeloma cells proliferate in HAT medium because the immune lymphocytes (fusion partner) furnish the essential TK and HGPRT enzymes for the salvage pathway. Thus, cells that survived incubation with HAT medium represented a successful immune B cell-myeloma cell fusion usually on a 1:1 cellular basis. The second phase in hybridoma production was the selection of those fused cells that synthesized and secreted antibody of the desired specificity. This was generally achieved by diluting fused cell populations to a single cell and then generating clones by proliferation of the single cell. Extracellular fluid or medium from the single cell and resulting progeny was assayed for the appropriate antigen binding. Methods and technologies used to detect monoclonal antibody activity are usually based upon some variation of the solid-phase immunoassay (eg, ELISA or radioimmunoassay formats).

Hybridoma methodology and consistent generation of relatively large amounts of monoclonal antibodies with defined specificities has proven to be a source of important immunological reagents. First, the provision of adequate quantities of monoclonal antibody has facilitated the routine determination of primary structures of both the H and L chains at the protein level. Second, various monoclonal antibodies can be crystallized on a regular basis providing atomic resolutions of 2 to 3 Å by X-ray crystallographic procedures. In general, Fab fragments (four domain substructures of antibodies including the variable domains of both chains) with bound ligand crystallize most efficiently. Approximately 100 resolved structures of monoclonal antibodies (Fab fragments) have now been reported. Third, this methodology provides large homogeneous hybridoma cell populations from which mRNAs responsible for the synthesis of H and L chains can be obtained. Through development of polynucleotide primers, PCR technology can be used to generate cDNA copies for sequencing at the gene level. Fourth, gene cloning experimentation with antibody genes has been important in successful site-specific mutagenesis studies. Such studies have been critical in deciphering structure-function relationships governing antibody activity. Fifth, hybridoma methodology has led to the development of antibody derivatives such as single-chain or Fv antibodies (7). The latter represent ~25,000d structures containing only the variable domains of the H and L chains of a specific antibody molecule. Variable domains constituting single-chain antibodies are usually covalently attached through the use of flexible polylinkers (10 to 15 amino acids) encoded in the single-chain synthetic gene. Single-chain genes are subsequently incorporated into the appropriate plasmids and expressed in either procaryote or eucaryote cell lines. Sixth, antigen-antibody interactions can now be studied on a homogeneous basis yielding important information regarding the thermodynamics of antigen binding. Finally, provision of monoclonal antibodies by hybridoma technology has led to the development of standard diagnostic procedures as well as therapeutically important immunochemical reagents.

Monoclonal antibodies of defined specificity generated through hybridoma methodology have been used to solve many issues related to structure-function relationships within the antibody molecule. Based on studies with monoclonal antibodies, the property of Fab (active site) segmental flexibility within the IgG class of antibodies was solved. Homogeneous binding at both active sites within a bivalent molecule ruled out allosteric effects within antibody molecules. Thus, binding at one active site does not influence antigen binding at the adjacent site. Conformational changes transmitted throughout the molecule subsequent to binding of antigen were dismissed as an explanation for such important phenomena as complement binding and fixation. In all cases, availability of monoclonal antibodies proved important to definitively examine these significant basic questions.

Although hybridoma technology has been the method of choice to produce monoclonal antibodies of defined specificity, new techniques have now emerged. Similar to the construction of single-chain antibodies, gene segments encoding the H and L chain variable domains are genetically fused to genes encoding a bacteriophage coat protein (8). The engineered bacteriophage infect bacterial hosts, and the resulting phage particles express active antibody products on their surface. The latter can be combined with mutagenesis so that the resulting phage display library expresses many different antigen-binding domains. Phages that specifically bind antigen are selected and used to infect bacteria in a second cycle. Each selected phage produces a monoclonal antigen-reactive particle. Primary structures of the variable domains can be determined, and those genes can be fused to the antibody constant region genes to reconstruct a monoclonal antibody. Such genes transfected into myeloma cell lines are expressed and the antibody products secreted. Phage display methodology has important implications for the future.

Monoclonal antibodies proved to be the "tool of nature," whereby immunologists first learned of the structure-function relationship in antibody molecules. However, these basic relationships extended beyond the antibody molecule when it was determined that other members of the immunoglobulin superfamily of molecules (eg, T-cell receptors, major histocompatibility molecules, T-cell accessory proteins, and adhesion molecules) utilized the same basic motifs and canonical structures first recognized in monoclonal antibodies (9).

Monolayer

A *monolayer* (*mono*molecular *layer*) formed at aqueous interfaces by amphipathic compounds, such as fatty acids and phospholipids, is one of the early structural models for one-half of the bilayer leaflet (1) (see Membranes). Amphipathic molecules are oriented at the interface with the polar moiety embedded in the aqueous phase. Lipid monolayers form physical states and exhibit properties that are analogous to those found for these materials in bulk (2). Thus, "gaseous" and liquid-like monolayers, plus a first-order transition between these states, have been observed (3) with energies of the same magnitude as the comparable systems in bulk. Crystalline monolayers on water have not been observed, although the formation of highly viscous films has been reported.

There are two principal methods of forming monolayers on water, each of which provides a different aspect of the thermodynamic properties of films on water. For materials that are soluble in water, the surface-active solute adsorbs at the interface, and an equilibrium between the surface and the bulk solution is established. This approach provides a method for analyzing the adsorption of amphipathic materials at aqueous interfaces. The **free energy** of adsorption may be obtained from the *Gibbs adsorption isotherm*, which relates the measured surface tension g(mN/m) with the concentration C of the dissolved surface active solute as $dg = -RT\Gamma d \ln C$; Γ represents the concentration of the solute in the surface (moles/cm^2), R is the gas constant, and T is the absolute temperature. The surface tension decreases as solute adsorption increases; the maximum lowering of the surface tension is attained for saturated solutions of the solute.

The second method for forming monolayers is applied to compounds that are poorly soluble in water. The film-forming material is dissolved in a volatile organic solvent, and a dilute solution is deposited in the surface; the solvent evaporates, leaving a monolayer of the material at the interface. The films that form are considered to be insoluble, but in reality some of the material dissolves into a thin (~100 μm) unstirred region just beneath the interface, where it slowly diffuses into the bulk of the aqueous phase. The amount of material that dissolves is governed by the Gibbs adsorption isotherm (see text above). Because the material is poorly soluble in water, the amount of lipid that dissolves is usually insignificant relative to the total amount that is deposited initially, and the film behaves as if it is insoluble (3). The surface concentration of the lipid is generally manipulated by moveable barriers to increase or decrease the area in which the film is confined. The surface tension lowering from the film-free surface tension g_0 is usually represented by $p = g_0 - g$, as the *surface pressure*. The film balance is an instrument that combines a surface tension measuring device with a trough whose surface area, and therefore the area/mole of lipid $A = \Gamma^{-1}$, may be manipulated (4). The p–A relationship obtained with the film balance provides a systematic experimental basis for evaluating thermodynamic properties of films, including the energetics of phase transitions, and of mixture formation with simple lipid components (3). The properties of "insoluble" films are continuous with those obtained from the soluble surface-active compounds, provided that the surface tension lowering for a saturated solution of the material is not exceeded. "Insoluble" lipid monolayers often may be supercompressed to surface pressures that exceed the values for a saturated solution of the lipid. These supercompressed films are metastable and are usually formed from lipids that contain aliphatic saturated hydrocarbon chains of 14 or more carbon atoms.

Monosomy

Monosomy is a special case of aneuploidy in which one chromosome (or part of a chromosome) is represented by one copy instead of two in the normal **diploid** genome.

Partial or total monosomies of all chromosomes in humans have been described. Partial monosomies are due to chromosomal **translocations**. As an example chosen among many, a partial monosomy of chromosome 21 is caused by an unbalanced translocation between the long arms of chromosome 11 and chromosome 21. In this patient, the anomaly had been reported as a full 21 **autosomy** by using cytogenetic banding techniques. The translocation was established by a combination of a high resolution banding technique, chromosome painting, and DNA **polymorphism** analysis (1). In this respect, other descriptions of total monosomies should be reconsidered, because the occurrence of complete autosomal monosomies is now generally considered to incompatible with life. The nonlethal monosomy affecting the X-chromosome (Turner's syndrome) will be considered below.

Studies on the correlations between **karyotypes** and clinical **phenotypes** have led to the following conclusions:

1. Monosomy for an autosomal segment leads to more severe alterations to the phenotype and restricts survival more than trisomy for the same segment. When the clinical pictures of these two aneuploid states are compared, they do not go in opposite directions, as would be expected by the type-contratype approach.
2. For certain types of minor anomalies, the aneuploid segment can be narrowed down to a very short region. These regions are closer to the telomere both in trisomy and in monosomy.

1. Monosomy of the Sex Chromosomes

Turner's syndrome is the phenotype associated with the absence of a second sex chromosome in humans. Only about half of all patients with Turner's syndrome are monosomy 45, X on karyotyping, and there are grounds for supposing that cryptic mosaicism for at least part of the Y-Chromosome may be present in some patients. If so, this would be clinically important because of the risk to patients of gonadal neoplasm and virilization. Although cytogenetic analysis did not detect any Y-chromosomal material, specific nucleotide sequences from the **sex-determination** region of the Y-chromosome (SRY gene) were found by Southern blot analysis of **PCR** material from the patient's DNA (2).

Recent observations support the hypothesis that the Turner's syndrome **phenotype** results from a haploid dosage of genes that are common to the X- and the Y-chromosomes and escape X inactivation. A goal of current studies is identifying these putative "Turner" genes (3). Individuals with Turner's syndrome are short and present a characteristic pterygium colli. Most often, they are sterile because ovarian agenesis. Sometimes, functional ovaries allow pregnancies, but the children are often malformed.

Monte Carlo Calculations

Computer simulation calculations of average macromolecular properties by statistical mechanical approaches require one to evaluate the Boltzmann-weighted average of the given property over the entire conformation space (see equation (1) of Free Energy Calculations). Fortunately, it is possible to estimate such an average without actually sampling the entire enormous conformational space by exploiting the fact that points with high energy do not contribute significantly to the overall average. A powerful and systematic approach of doing so is the so-called Monte Carlo method devised by Metropolis et al. (1) This approach generates random conformations by moving several atoms or torsional angles and uses the corresponding value of the potential surface to accept or reject each new conformation. If the energy of the new conformation (n) is lower than the previous one (n–1), the new conformation is accepted. If the energy of the new conformation is higher than that of the previous one, a random number, R_n, between 0 and 1 is generated and compared to the Boltzmann factor

$$P_n = \exp[-(V_n - V_{n-1})/k_B T] \tag{1}$$

If the random number is larger than P_n, the move is rejected. If R_n is smaller than P_n, the conformation is accepted. The desired average is then simply evaluated by

$$\langle A \rangle = \frac{1}{N} \sum_{i=1}^{N} A(\mathbf{r}^N) \tag{2}$$

This random procedure generates a probability that corresponds to the proper Boltzmann distribution of the entire system if enough points are evaluated. In principle, one needs an enormous number of points, but in practice one can obtain reasonable results with a reasonable amount of computer time (if the property has similar values at different conformations). In fact, Monte Carlo approaches do not involve complete random searches, because they are usually implemented with umbrella sampling or free energy perturbation approaches that bias the search toward important regions in the

conformational space (see Free Energy Calculations).

Average properties that can be evaluated by molecular dynamics (MD) techniques can also be evaluated by Monte Carlo approaches. Thus, the selection of the proper method depends on the problem at hand. The advantage of Monte Carlo approaches is the fact that they do not require the evaluation of the first derivatives of the potential functions, which is a prerequisite for MD approaches. Thus, one can use Monte Carlo approaches to nonphysical moves in studies of folding processes and related problems while using lattice models. On the other hand, MD approaches are much "smarter" in that they use derivatives that allow, in fact, much more systematic local searches. Thus, one can state that MD does a much better job in exploring local problems while Monte Carlo allows more uniform global searches. This is useful, for example, in particle insertion methods (2). Of course, one can combine the benefits of both approaches, using Monte Carlo calculations to generate starting conformations and MD for local exploration. Approaches that exploit this and related ideas have been developed (eg, Refs. 3 and 4). In fact, Brownian dynamics is a form of a smart Monte Carlo approach.

Morphogenesis

Morphogenesis is the creation of pattern and form during development. It occurs through changes in cell number, cell shape, and cell adhesion. The first morphogenetic changes occur after gastrulation has formed the three germ layers. The germ layers undergo morphogenesis to form the organs of the embryo. The ectoderm forms the epidermis and nervous system. The mesoderm forms the muscles, the vascular system, the lining of the body cavity, and the gonads. The endoderm forms the gut and digestive glands.

Morphogens

A morphogen is a chemical which exists in a concentration or activity gradient and to whose different concentrations or activity cells respond in a qualitatively distinct manner.

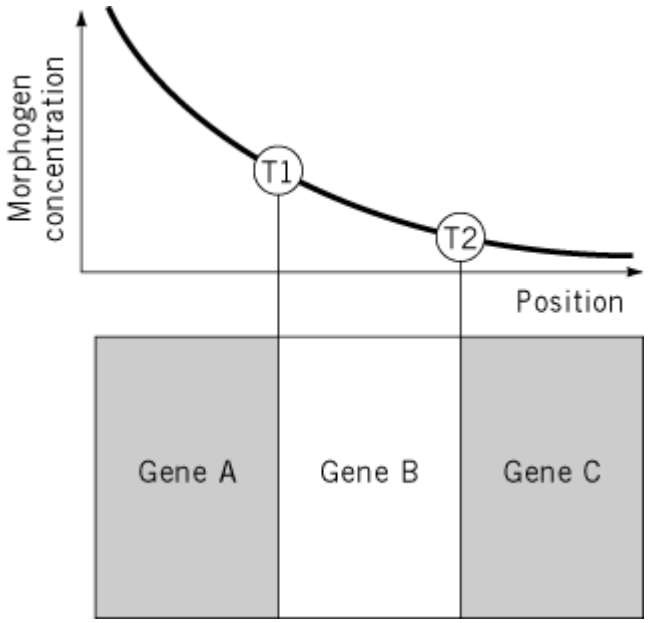
Gradient models have been proposed by developmental biologists to explain certain graded responses and regulative phenomena observed in embryos following experimental manipulations such as tissue transplantations and ablations. In the simplest gradient model, a secreted morphogen diffuses from a local source through a tissue and a concentration gradient is created as a function of the distance from the source by simple dilution. Cells would then respond according to the local morphogen concentration they experience. Gradient models are able to explain many morphogenetic phenomena but convincing molecular evidence for the existence of morphogens has only been documented in a few cases. These examples which are discussed below illustrate a variety of ways by which the concentration gradient of morphogens is created and suggest that the gradients are subject to complex cellular control.

The fundamental question of development is how a fertilized egg progresses from almost homogenous initial conditions to a fully differentiated multicellular organism. It was realized early that many cells appear to "know" their place when subjected to certain experimental conditions, as if under the influence of a morphogenetic field. The concept of a gradient field to explain such phenomena was introduced a century ago by Boveri and prooved useful for many schools of embryologists working on diverse systems, most prominently on sea urchins.

However, the notion of what is in fact graded remained necessarily vague in the premolecular era. The term "morphogen" was introduced 1952 by Turing (1), who described the mathematical formalism according to which spatial concentration patterns can be generated if two chemicals with different diffusion rates react with each other (reaction-diffusion models). He referred to such diffusible chemicals as morphogens but as we know now such pattern-generating chemicals need not necessarily be diffusible and the term is better defined by the more general definition given on top.

The more tangible formalism of "positional information" for the gradient concept was developed by Wolpert (2). He proposed that in a gradient field cells can read their position - or distance - from a boundary. In the simplest case the gradient is generated by diffusion of a localized morphogen from a source at a cellular boundary. At distinct threshold concentrations these cells respond differently and differentiate accordingly. This is illustrated by the French flag model (Fig. 1).

Figure 1. The French flag model. A morphogen gradient (top) provides positional information encoded by the local concentration which can be read by cells. At distinct threshold concentrations (T1, T2) cells respond with differential activity of genes A-C. The tricolore exemplifies the cell fate pattern resulting from the morphogen read-out.



1. Criteria for Morphogens

Many chemicals have been proposed to act as diffusible morphogens mostly based on the observation that they can elicit qualitatively different effects in a dose-dependent manner under experimental conditions (3). However, this criterion is not sufficient evidence for a morphogen. A factor which activates a morphogen would indirectly set in motion the same range of responses via signal relay. Activin for example induces different mesodermal cell fates at distinct threshold concentrations in Xenopus (4) and it is instructive to study its long-range patterning effects (5, 6), but a role as a physiological mesoderm inducer is doubtful. Therefore, to provide sufficient evidence for a morphogen the following criteria should be fulfilled:

1. The chemical should elicit qualitatively different effects in a dose-dependent manner. Experimentally this can be tested by applying increasing doses of the chemical or in case of gene products by overexpression. An important prerequisite is the possibility of a complex read-out of cellular responses, eg, by being able to score multiple cell fates using molecular differentiation markers.

2. Dose-dependent removal of the chemical should yield qualitatively different effects. Technically this is maybe the most difficult to achieve. Application or expression of specific inhibitors in a dose-dependent manner may be used (7). Genetically, a series of hypomorphic mutants for the decapentaplegic morphogen have been used to show a dose-dependent requirement for patterning (8, 9). However, given the redundancy of many morphogenetic processes, removal of the morphogen may be without effect unless back-up systems are also inhibited.

The chemical should naturally be present in a concentration gradient. The bicoid and wingless morphogen gradients can be detected by **antibodies** (10, 11). However, as highlighted by the decapentaplegic and BMP-4 morphogens (see below), what is graded may not be the protein itself but its activity, which may be difficult to detect by antibody.

The chemical should exert its dose-dependent effects directly and not by relay, eg, by inducing a morphogen or a cascade of other pattern-generating factors. For growth factor type morphogens that act by receptor-mediated signal transduction this question translates typically in demonstrating that intracellular activation of the signalling pathway does not lead to dose-dependent effects at long-range. This test fails for cases of nonsecreted morphogens, such as the transcription factor dorsal or

for cases of growth factors which diffuse poorly but whose activity becomes graded by a diffusible antagonist (see below).

Examples of factors in which these criteria for a morphogen have been largely met are discussed below and summarized in Table 1.

Table 1. Identified Morphogens

Morphogen	Protein Class	Process Involved	Mechanism of Gradation	Ref.
Drosophila *bicoid*	transcription factor	a/p blastoderm	diffusion	(10, 27, 12)
Drosophila *hunchback*	transcription factor	a/p blastoderm	translational control, diffusion	(12)
Drosophila *dorsal*	transcription factor	d/v blastoderm	nucleo-cytoplasmic distribution	(13, 28)
Drosophila *decapentaplegic*	growth factor	d/v blastoderm, a/p wing	activity gradation, diffusion	(8, 9, 14, 15)
Drosophila *wingless*	growth factor	Drosophila d/v wing	diffusion	(17, 11)
Xenopus *BMP-4*	growth factor	d/v mesoderm	activity gradation	(7, 22)

2. Bicoid and hunchback

The transcription factors bicoid and hunchback were the first morphogens described. They are involved in anteroposterior patterning of the Drosophila blastoderm, which at the time of action of these two morphogens is a **syncitium**, allowing free diffusion of cytoplasmic components. *Bicoid* mRNA encoding a *homeodomain* protein is localized and translated at the anterior pole from where the protein diffuses through the syncitium towards the posterior pole. This diffusion gradient can be detected by antibody staining. Overexpression of *bicoid* leads to dose-dependent cell fate changes. The **zinc finger** protein hunchback forms a similar anteroposterior gradient, which is created by translational control. Hunchback and bicoid protein are thought to cooperatively pattern the anterior of the embryo (12). Since this patterning process occurs in a syncytium this example may not occur widely in other multicellular organisms.

3. *Dorsal* in Drosophila blastoderm

As predicted and as was experimentally found for the transcription factor *dorsal*, a morphogen must not necessarily be diffusible. The essential feature is that the graded parameter reflects distance from a boundary and cells respond at distinct threshold concentrations. Yet, commonly, a morphogen is referred to as a diffusible molecule. Dorsal acts as a morphogen in dorsoventral patterning of Drosophila blastoderm where it is both necessary and sufficient for dose-dependent patterning (13). Antibody staining revealed a gradient of nuclear localization of dorsal protein along the dorsoventral

axis. Since only nuclear dorsal protein activates transcription this leads to a gradient of effective dorsal protein concentration. The gradient is set up by a cascade of proteases culminating in the local and probably graded activation of the toll receptor which controls the nucleo-cytoplasmic distribution of dorsal. However, it is unclear how the toll receptor signal becomes graded in the first place.

4. *Decapentaplegic* and *wingless* in Drosophila wing development

Decapentaplegic functions in Drosophila anteroposterior wing patterning. Misexpressing decapentaplegic leads to dose-dependent and long-range changes of marker gene expression. The effects are direct, as they are not observed by misexpressing an activated form of the decapentaplegic receptor (14, 15). Partial loss of decapentaplegic signalling leads to changes in marker gene expression which are consistent with a requirement for dose-dependent decapentaplegic signalling (16). A decapentaplegic gradient has not been physically described in the wing but is made plausible by localized decapentaplegic mRNA expression.

Dorsoventral patterning in the wing is regulated by the secreted growth factor wingless. Similar to decapentaplegic, misexpressing wingless leads to dose-dependent and long-range changes of marker gene expression. The effects are direct, as they are not observed by misexpressing intracellular components of the wingless transduction pathway. Hypomorphic mutant alleles of *wingless* lead to changes in marker genes consistent with a requirement for dose-dependent wingless signalling (17, 11). Wingless mRNA expression is localized and a protein gradient has been detected by antibody staining surrounding mRNA expressing cells (11).

5. *Decapentaplegic* in Drosophila blastoderm and *BMP-4* in Xenopus mesoderm

Decapentaplegic is a Drosophila homologue of vertebrate BMP proteins and both are members of the TGF-b superfamily. In the blastoderm, microinjection of decapentaplegic mRNA leads to different cell fates in a dose-dependent manner. Likewise, an allelic series of decapentaplegic mutants with different severity leads to different fate changes. Thus, both gain- and loss-of-function of decapentaplegic lead to dose-dependent effects (8, 9). An evolutionarily conserved patterning process occurs during dorsoventral patterning of Xenopus mesoderm (18). Here, microinjection of BMP-4 mRNA induces different cell fates in a dose-dependent manner and microinjection of a dominant-negative BMP receptor, an inhibitor of BMP signalling, leads to dose-dependent fate changes in the reverse order (7). A concentration gradient has not been detected for either decapentaplegic nor BMP-4. However, decapentaplegic is antagonized by a secreted inhibitor, short gastrulation, whose vertebrate homologue chordin has been shown to antagonize BMP-4 and is expressed in the Spemann organizer. These antagonists bind and inactivate decapentaplegic and BMP-4. Since in Drosophila as well as Xenopus embryos the inhibitors are expressed opposite to decapentaplegic and BMP-4, an activity gradient is most likely created (19, 20-22). Thus, the antagonists create the morphogen gradient of an instructive signaling molecule. The directness of decapentaplegic action has not been tested in this context but Xenopus BMP-4 acts in a direct and long-range fashion (7).

6. Regulating gradient shape

It is evident that morphogen gradient may be of crucial importance for embryonic patterning and thus be expected to be subject to regulatory mechanisms. The BMP-4 signal spreads about 5-10 cell diameters from the expressing cells within the mesoderm (7). However, the diffusion of BMP-4 as well as of other TGF-b homologues may be more limited in other cells (23, 24) and hence more tightly controlled by yet unknown mechanisms. Besides chordin, the BMP-4 antagonist noggin is expressed in the Xenopus organizer which diffuses over more than 20 cell diameters (7, 22). A further complexity is introduced by the existence of tolloid proteases that cleave the chordin/BMP-4 and sog/decapentaplegic protein complexes. Loss of *tolloid* function leads to changes in patterning both in Drosophila blastoderm and Xenopus mesoderm and hence these proteins play an important

role in regulating the shape of the decapentaplegic/BMP-4 activity gradient (25, 26).

7. Read-out of morphogen gradients

Little is known about how the positional information provided by morphogens is translated into distinct cellular responses. The bicoid transcription factor for example binds to and activates its target gene *hunchback* only at a certain threshold concentration. The *hunchback* promoter region contains multiple sites to which bicoid protein binds in a cooperative manner, leading to a sharp threshold concentration at which bicoid can lead to activation of hunchback in an on/off manner (27). Bicoid functions synergistically with *hunchback* to regulate directly further downstream target genes (12). The dorsal protein binds to regulatory sequences in the promoters of its target genes snail, twist and decapentaplegic, leading to activation or repression at distinct threshold concentrations. Thresholds are set by a combination of low and high affinity binding sites for dorsal protein leading to on/off responses (28). Thus, in these cases the target gene promoters serve to convert positional information into distinct cellular responses.

In the case of the diffusible morphogens decapentaplegic/BMP-4 and wingless, signal transduction pathways lead to the activation of downstream target genes encoding transcription factors. Expression of these target genes is typically not graded and occurs in an overlapping fashion indicating that the morphogen signal has been digitized. Different target genes require distinct threshold doses of morphogen signalling (7, 3). It is unclear in these cases which component of the intracellular signal transduction machinery serves to convert positional information into a more digital response.

Morula

The morula is a stage during early embryonic development in embryos with holoblastic cleavage, where there is little yolk and the entire zygote is involved. After fertilization, the cleavage furrows in holoblastic embryos completely separate the cells. After a few divisions, the cell mass forms a small ball that resembles a mulberry (morula is Latin for mulberry). As the cleavage divisions continue, a hollow space called the *blastocoel* forms with a single layer of cells surrounding it. This stage is called the **blastula** stage.

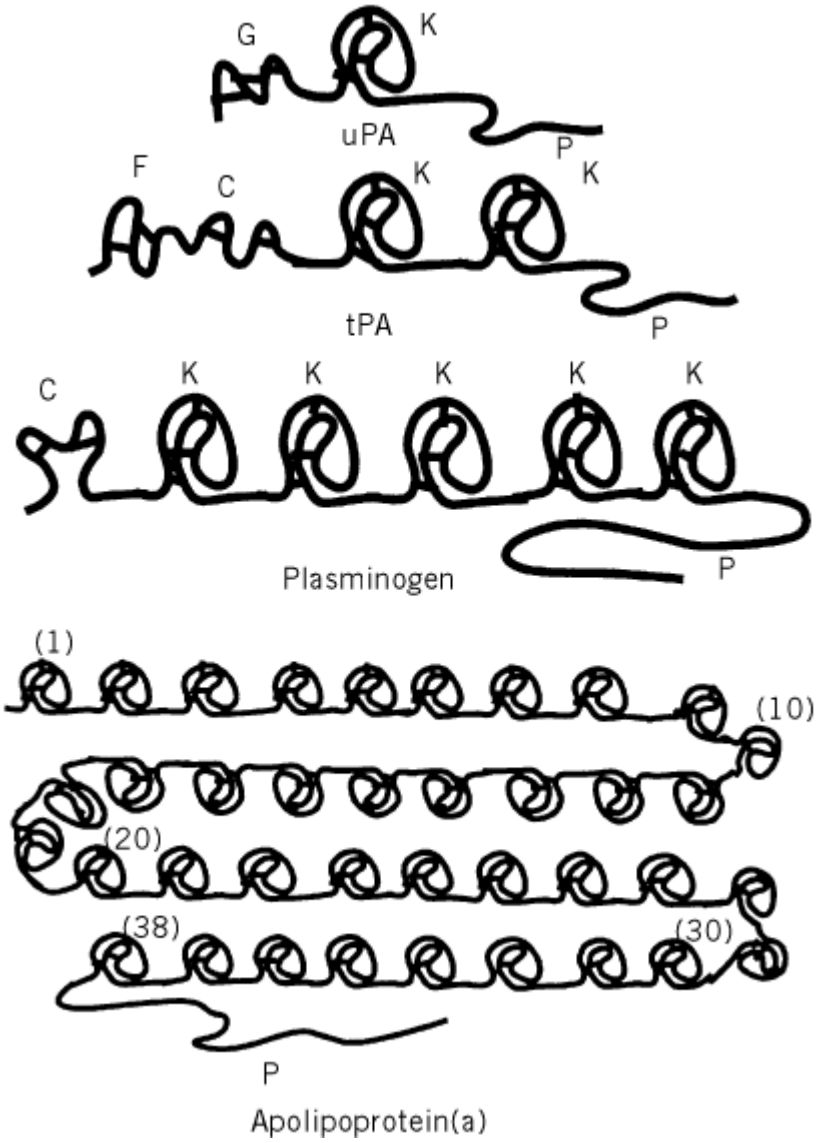
Mosaic Protein

A mosaic protein is one that is composed of more than one functional **domain**. A typical example of a mosaic protein can be seen in tissue plasminogen activator (tPA) (Fig. 1). tPA contains at least four functional domains; an epidermal growth factor–like domain (**EGF motif**), two Kringle domains, and a serine proteinase domain. These DNA segments coding for these domains are believed to have been collected together into a single gene by either domain shuffling or exon shuffling during evolution.

Figure 1. The domain structures of a number of related mosaic proteins. Kringle domains are indicated by "K" and schematically, (F—finger motif; C:—Ca^{++} binding domain; P—serine protease domain; G—EGF motif; uPA—urokinase; tPA—tissue plasminogen activator).



Most proteins possess more than one functional domain and can be considered mosaic proteins (Fig. 1). Each such domain usually carries its own function, so a mosaic protein can be considered to be a

multifunctional protein. Consequently, mosaic proteins are evolutionarily important, because they can create diverse functions of proteins. For more detail, see Exon Shufflingand Domain Shuffling.

Motor Proteins

A motor protein hydrolyzes ATP to generate movement or force along the cytoskeleton in eukaryotes. The actin filaments and **microtubular** components of the cytoskeleton have distinct plus and minus ends, which extend to different regions of the cell. Cells use motor proteins that read the filament polarity to direct specialized cargoes to specific locations. Two motor protein families move along microtubules. The **dyneins** move toward the minus ends of the microtubules, and the **kinesins** move toward the plus ends of microtubules. Flagellar dyneins generate the sliding force between axonemal microtubules that is the motive force for eukaryotic **cilia** and flagella bending. Cytoplasmic dyneins are responsible for moving membrane-bounded organelles and, **kinetochores** and for assembling the spindle. Kinesin family members are also responsible for intracellular transport of membranous organelles moving chromosomes, and assembling the spindle. Myosins, the third motor protein family, interact with actin filaments and move toward the plus end of actin filaments. Myosin family members are responsible for a variety of functions in cells: contraction in muscle, cytokinesis in dividing cells, crawling locomotion, some forms of membrane-bounded organelle transport, and localization of determinants. The three motor proteins are multisubunit complexes that have specific heavy and light chains. All of the members of the three motor protein families are defined by a conserved, force-generating "head" domain that is part of the heavy chain. The heads bind the appropriate cytoskeletal polymer and hydrolyze ATP to move along the polymer. The divergent domains of the heavy chains, the "tails," and the light chains target the motors to various cargoes or locations and in some cases specify oligomerization of the molecules.

Mouse

The mouse is an important tool in studying vertebrate biology, including evolution, genetics, ecology, development, physiology, and pathology. The mouse is increasingly important in molecular biology, and its most relevant properties are described here.

1. Inbred Strains

The house mouse complex consists of four commensal species, *Mus musculus domesticus*, *M. musculus musculus*, *M. musculus castaneus*, and *M. musculus bactrianus*. In addition, three aboriginal species are known, *M. spicilegus*, *M. macedonicus*, and *M. spretus*. The classic laboratory strains carry a single type of mitochondrial DNA [see the section thus titled] and primarily the nuclear genes of *M. musculus domesticus*. However, some of the nuclear genes, including the Y-Chromosome, are derived from other commensal species. Although laboratory inbred strains have been established from diverse wild-caught animals by brother-sister matings and back-crossing of offspring with their parents over numerous generations, most of them are predominantly of *M. musculus domesticus* origin. Approximately 430 different mouse inbred strains are currently known. From most inbred strains, several substrains have been generated that are used for different research purposes. Table 1lists examples of some widely used mouse inbred strains. The characteristics and molecular biology of the inbred strains and their substrains are well known. Most of the inbred strains can be traced back to the beginning of the nineteenth century. Although most differences between substrains and strains are due to mutations or residual heterozygosity, there is also evidence of genetic contamination (1).

Table 1. Examples of Inbred Mouse Strains and Their Use in Medical Research

Strain	Substrain	Features
129	129/Re	High incidence of spontaneous testicular teratomas
	129/RrJ	
	129/Sv-ter/+	
AKR	AKR/J	High incidence of lymphatic leukemia, presenceof the Thy 1a T-cell antigen, expression of the ecotropic retrovirus AKV

	C57BL/10	
	C57BL/10ScSn	
	C57BL/10Cr	
	C57BL/Ola	
	C57BL/Fa	
CBA	CBA/Ca or CBA/H	Low incidence of mammary tumors
	CBA/Br	
	CBA/CaN	
	CBA/J	
	CBA/St	
	CBA/H-T6	
DBA	DBA/LiA	Unfostered substrains have a high incidence ofmammary tumors and carry a tumor virus
	DBA/1	
	DBA/2	

When some laboratory inbred strains, such as C57BL/10, are crossed with some wild mice from *M. musculus* species, the resulting F_1 male hybrids are sterile (hybrid sterility), whereas the females are fertile (2). Other inbred strains, such as C3H/Di, produce fertile progeny when crossed with wild-type *M. musculus*. Hybrid sterility is also observed when crossing *M. musculus domesticus* and *M. spretus*. Both species separated from a common ancestor about 3 million years ago. The male hybrids are completely sterile, whereas the females are fertile. In both cases, hybrid sterility is caused by a specific configuration of several loci on chromosome 17, which have been described as t-complex or t-haplotypes. T-haplotypes are variant forms of the proximal part of mouse chromosome 17 that were introduced from an unknown species to the present-day mice about 100,000 years ago (3). During evolution approximately 2.5 million years ago, the inversion in (17)2 occurred within the ancestral chromosome. Although this inversion rose to high frequencies, it was never fixed in the wild population. Instead, the ancestral chromosome continued to evolve and accumulated three new inversions, in (17)1, in (17)3, and in (17)4. Finally, the ancestral chromosome became extinct, so that at present only the inverted forms are represented in the population. Consequently, the initial inverted chromosome in (17)2 is called the wild-type chromosome, whereas the three other inversion are called the t-haplotypes.

2. Genome

A haploid mouse genome consists of 20 chromosomes, 19 autosomes and either an X or a Y sex chromosome. Normal somatic cells of a mouse contain a **diploid** genome, or 40 chromosomes. As in other mammals, the physical size of a haploid genome is approximately $3\times10^9 bp$. The number of genes within the mouse genome and other mammalian genomes is still a matter of discussion, but most estimates are of the order of 100,000 genes. To assess the number of murine genes, a large expressed sequence tag (EST) project is being carried out under the coordination of the Washington University School of Medicine, St. Louis, Missouri. In the course of this project, approximately

400,000 complementary DNA (cDNA) clones from different murine tissues will be analyzed. From each of these clones, the 3′ end will be sequenced and the sequence put into the dbest section of genbank (site currently unavailable). More than 260,000 mouse ESTs have already been deposited into the nucleotide sequence databases. This means that some sequence information is available on almost all mouse genes although most of the ESTs are not yet linked to complete genes with an assigned function. Simultaneous with the sequencing of all the genes, there are also efforts to monitor the expression of all genes in different tissues and during different stages of development. With detailed data on the spatial and temporal expression patterns of specific genes, for example, transcription factors, it will become feasible to understand the molecular basis for mammalian development. The expression data are collected in the gene expression database (GXD) that is maintained at the Jackson Laboratory, Bar Harbor, Maine (http://www.informatics.jax.org/).

As mice are genetically so well characterized through numerous studies with mouse mutants [see below], they have been chosen as one of the model organisms whose genome is to be completely sequenced within the next few years. As a prerequisite to the sequencing, an almost complete **contig** of **yeast artificial chromosome** (YAC) clones of the mouse genome has been established (http://www-genome.wi.mit.edu/). For many regions, there are also ordered arrays of **cosmids** available, which will probably serve as the actual sequencing startpoints. From these cloning efforts, extremely dense physical maps were generated, in addition to the longer-existing linkage maps of the mouse genome (4, 5). The combined physical and genetic map can be found in the Mouse Genome Database (MGD), which is also maintained at the Jackson Laboratory (http://www.informatics.jax.org) (6). This database features a graphic representation of each chromosome with all the mapped loci, together with information on homologous human sequences. In addition to the genetic and physical position on the chromosome, the database is linked to other databases, so that individual **DNA** or protein sequences can be quickly retrieved. Other links provide information on the **phenotypes** that are associated with mutations of certain genes.

3. Repetitive Sequences in the Mouse Genome

The mouse genome contains several different types of repetitive sequences. Apart from simple-sequence repetitive elements, such as **microsatellites** and **minisatellites**, the most common high-copy sequences in the murine genome belong to the SINE and LINE families of **retroposons**. The most abundant repetitive sequence is the B1 element, it occurs in about 1 million copies per mouse genome (7). This SINE sequence is derived from the 7SL RNA, like the human **Alu** sequence. B1 elements are found in all rodents, and they can be grouped into three to six subfamilies (8). Another member of murine SINEs are the B2 elements, which are present in much lower copy numbers than B1 elements (9). Intracisternal type A particle (IAP) elements, which are present also in other rodents, represent a middle repetitive class of sequences, with high similarities to retroviruses. They contain *gag*, *pol*, and *env* genes, as well as long terminal repeat sequences at the 5′ and 3′ ends (10).

4. Mitochondrial DNA

The genome of murine mitochondria is a double-stranded circular DNA molecule of 16295 bp. Its complete nucleotide sequence has been determined (Genbank Accession: J01420) (11). It encodes the 12 S and 16 S **ribosomal** RNAs, 22 transfer RNAs, and 13 proteins. The genetic code of murine mitochondria is different from that of other mammals in that it uses four initiation codons: AUA, AUC, AUG, and AUU. The codons AGA and AGG are not used. The termination codons are UAA and UAG, but some messenger RNA transcripts end with U or UA, and a complete termination codon is formed on polyadenylation. AUA codes for methionine, and UGA codes for tryptophan in the mouse mitochondria.

Each strand of the mitochondrial genome is **transcribed** from a single major **promoter**, the heavy strand and the light strand promoters (LSP). In mitochondria, DNA replication and transcription are closely related. In mouse mitochondria, all major nascent DNA strands initiate within approximately

200 nucleotides downstream of the light strand promoter. In mice, three species of LSP transcripts were observed, one that extends beyond the replication start sites, one with its 3′-terminus mapping exactly at or close to the start sites of the nascent DNA strands, and one that is covalently attached at the 5′-termini of nascent DNA from the leading-strand origin of replication (O_H) (12). This type of transcript forms a stable RNA-DNA hybrid also known as an R-loop and serves as a mature primer for DNA synthesis after endonucleolytic processing. The stability of the RNA-DNA hybrid is probably due to the formation of intramolecular structures involving G:G base pairs stabilized by Hoogsteen base pairing (G-quartet tetraplex model).

Mitochondria, and hence mitochondrial DNA, have an almost exclusively maternal mode of inheritance (uniparental). Sperm mitochondria and their DNA are eliminated from the **oocyte** cytoplasm in intraspecies crosses at the late **pronucleus** stage (13). However, studies with hybrids between inbred strains (C57BL/6J) and *M. spretus* have shown that heteroplasmy may arise from paternal mitochondrial DNA (14). The persistence of cytoplasmic genomes is observed only in interspecies crosses that rarely occur in nature.

In general, the mutation rate of the mitochondrial DNA is higher than that of the nucleus. Compared with other mammals, however, the mouse mitochondrial DNA again seems to have an even higher rate of mutations (15); the rate per unit time is 40-fold faster in mice than in humans. Postmitotic tissues—for example, the brain, kidney, heart, or skeletal muscle—especially accumulate mutations with age. The etiology of the higher rate of mutations is not yet clear, but mitochondrial DNA is not associated with protective proteins, and it has a less efficient mechanism of DNA repair. In addition, mitochondrial DNA is exposed to reactive oxygen species generated in oxidative phosphorylation at the inner mitochondrial membrane.

5. Imprinting, Gametic

Imprinting is a phenomenon that has been observed in a wide range of phyla from both plant and animal kingdoms. To elucidate the mechanisms underlying imprinting, however, the mouse has been used most extensively. Currently, at least seven terms are used to describe imprinting (*chromosomal*, *parental*, *genomic*, *genetic*, and *gametic imprinting*, as well as simply *imprinting*) (16). Regarding the actual effects and processes associated with imprinting, the term *gametic imprinting* describes the phenomenon best. Gametic imprinting can be grouped into four classes, namely: (*1*) differential phenotypic effects of parental **alleles**, (*2*) monoallelic expression, (*3*) allele-specific **methylation**, and (*4*) monoallelic genome changes (17). In other words, the activity of a specific gene depends on its parental origin. But not only single genes are regulated by gametic imprinting. It has been shown using **parthenogenetic** (gynogenetic, androgenetic) mouse embryos that mammalian development depends on both parental genomes. From these findings, it is conceivable that gametic imprinting may regulate more than a single locus. Thus far, in fact, nine imprinted loci have been identified in the mouse. Six loci—Igf2, SnRPN, SP2, Ins1, Ins2, and Xist—are repressed on the maternal chromosome. Two loci, Igf2r and H19, are repressed on the paternal chromosome, and one locus, Wt1, has a yet uncharacterized monoallelic expression (16). However, the overall number of genes showing parental effects might remain small, taking into account that mice can be disomic for one parental type of six chromosomes without any obvious effect on the phenotype.

DNA methylation plays an integral role in the maintenance, and probably the establishment, of imprinting. With methylation of the cytosine in the CpG-dinucleotide, binding of transcription activators or repressors is modulated. From several analyses, it is clear that *trans*- as well as cis-acting modifiers of imprinting (imprintor loci) exist.

A well-studied imprinted gene is that of the murine insulinlike growth factor type 2 receptor (Igf2r). Igf2r has been mapped to chromosome 17 within a region that was previously shown to be responsible for early embryonal death if two overlapping deletions T^{hp} and t^{Lub2} are inherited from the mother only [see “Inbred Strains” above]. In earlier analysis, the effect of the two loci on the

development of mouse embryo was explained by a theoretical gene called Tme (T-associated maternal effect). The Tme locus is located in the same region as Igf2r on chromosome 17 at 7.35 cM. Embryos that have inherited the Tme deletion from their mother do not express the Igf2r gene and die on day 15 of gestation. Therefore, the Igf2r is a candidate gene for Tme. Later it was shown that the Igf2r gene is gametically imprinted in the oocyte primarily by methylation of a region in intron 2 (region 2), where repressor proteins can normally bind (18). The paternally derived allele of Igf2r is not methylated in this region and, therefore, the repressors can bind. At a later stage of development, the paternal allele becomes methylated at the promoter region, causing inactivation of the gene. This process is also referred to as secondary somatic imprinting. Hence, if the Igf2r gene is inherited from the father and becomes inactivated during development, and the Tme deletion is transmitted by the mother, the lack of Igf2r gene expression causes embryonal death.

6. Mouse Mutants

A vast number of mouse mutants have been described and characterized genetically. Mice are used as models for all types of genetic variations in mammals, as they reproduce fast and can be kept at relatively low cost per animal. Many significant findings about gene function in higher **eukaryotes** have been derived from mouse mutants. The most comprehensive collection of mutant mice is maintained and distributed by the Jackson Laboratory in Bar Harbor, Maine (http://www.jax.org/), which is also the administrator of the major mouse genome databases. Mutations in the mouse genome can arise spontaneously or they can be induced. To induce undirected mutations, chemical mutagens like ethyl-nitrosourea or ionizing radiation can be used. Mutants can also be created by introducing additional genetic information into the mouse genome. The resulting **transgenic** mice [see the following section] can be used to study the effects of the introduced gene construct *in vivo*. Finally, it has become possible to introduce virtually any change into the mouse genome by so-called targeted mutations. Targeted mutations rely on homologous recombination of a DNA construct with its genomic **homologue** in embryonic stem cells. When the desired mutation has been achieved in a stem cell, **chimeric** mice can be produced with these cells. If the engineered stem cells become part of the **germ line**, the chimeric mice will pass the mutation on to their offspring, which are then genetically homogeneous. The availability of murine embryonic stem cells was the reason why mice were for a long period the only mammalian species in which targeted mutations could be introduced. To perform targeted mutations in other mammalian species, it is necessary to have either embryonic stem cells or the ability to **clone** the whole organism from a single differentiated cell. The technology of targeted mutations is used primarily to create **knockout** mice in which a single gene is disrupted and thereby completely inactivated. However, it is also possible with targeted mutations to modify genes in order to achieve a specific change in the amino acid sequence of the corresponding translation product or to change expression patterns by promoter mutations. Commonly used mouse mutants are listed in Table 2.

Table 2. Examples of Widespread Mouse Mutants

Mutant	Affected Gene	Phenotype	Type of Mutation	Reference
Agouti	Agouti (*a*)	Many alleles, for example, *A*⟨*y*⟩, agouti yellow; homozygous lethal; heterozygous	Spontaneous	*a*, *b*

		yellow coat color; obesity; immune defects		
Scid	DNA-activated protein kinase (*Prkdc*)	Severe combined immunodeficiency; homozygotes lack VDJ recombination of immunoglobulins; no functioning B and T cells	Spontaneous	[c]
Obese	Leptin (*Lep*)	Extreme obesity; endocrine defects	Spontaneous	[d], [e]
Nude	HNF-3/forkhead homologue 11 (*Hfh11*)	Homozygotes are hairless because keratinization is defective; skin abnormalities; immune defects; growth, viability, and fertility greatly reduced	Spontaneous	[f]
Myc	*c-Myc*	Early development of lymphomas	Transgenic	[g]
CF	Cystic fibrosis transmembrane conductance regulator (*Cftr*)	Similar to human cystic fibrosis (CF): intestinal obstructions, pancreatic and lung symptoms less severe than in human CF	Targeted mutation (knockout)	[h]
Mdx	Dystrophin (*Dmd*)	Related to human Duchenne muscular dystrophy; mdx mice show muscle weakness but normal life span	Spontaneous	[i]
Utrn/Dmd	Utrophin (*Utrn*) and Dystrophin (*Dmd*)	Very similar to human Duchenne Muscular dystrophy; progressive muscle weakness; mice die of respiratory failure before they reach 20 weeks of age	Targeted mutation (double knockout)	[j]

7. Transgenic Mice

Transgenic mice carry additional genetic information that is not derived from the mouse genome. There are several ways to introduce foreign genetic material into the mouse germ line so that it is faithfully passed to succeeding generations. The most popular way is the microinjection of a DNA construct into a fertilized oocyte (19). Fertilized oocytes are isolated from hormonally superovulated females that have been mated before the procedure. The DNA construct is microinjected with a glass capillary into the male pronucleus of the fertilized oocyte. The microinjected oocyte is then implanted into a hormonally treated recipient mouse. About 50% of the microinjected oocytes will survive the microinjection and implantation process. Of the resulting offspring, up to 50% will have integrated the gene construct into their genome, so that the overall efficiency is between 20% and 25% under optimal conditions. The gene construct is usually integrated in multiple copies (up to approximately 100) in a head-to-tail concatemer arrangement. The integration site is random and, in some cases, rearrangements of the DNA, such as deletions, duplications, or translocations, have been observed in the neighborhood of the integration site. Experimental verification of an integration event is done by **PCR** or **Southern blotting**. Mouse genomic DNA for these experiments is usually extracted from a piece of tail. Whether the additional genetic material is expressed depends not only on the regulatory sequences present on the introduced DNA construct but also on the site of integration. Integration sometimes takes place at transcriptionally silent parts of the chromatin, and even genes under the control of strong viral promoters will not be expressed. Whether a transgenic mouse expresses an introduced DNA construct has therefore to be determined experimentally for each individual transgenic mouse line. The integration efficiencies are higher if the DNA construct has been linearized and if all unnecessary vector sequences have been removed. A big advantage of this method is that the size of the injected DNA construct can be very large. As long as intact DNA molecules can be injected through the glass capillary, they will be integrated, and constructs of more than 100 kbp have been successfully introduced into transgenic mice by this method. For example, it is possible to introduce whole YACs into transgenic mice. This ensures that the original chromosomal structure of the transgene and all *cis*-acting regulatory elements are much better retained than in experiments in which only a cDNA construct or a smaller piece of genomic DNA is injected.

Another method for introducing genetic information into mice is to treat mouse embryos with recombinant retrovirus (20). As retroviruses integrate with high efficiencies into the host genome during their normal life cycle, they can be used as vehicles to introduce foreign DNA into the mouse genome. The constructs used for this purpose contain all necessary viral elements for their integration into the genome but are replication-deficient, so that no active retroviruses are produced within the target cells. Treatment of the mouse embryo with the recombinant retrovirus can be done either *in vitro* prior to implantation into a recipient mother or *in utero* after implantation of the

embryo, although with much lower transfection rates. The integration of retroviral DNA is very efficient, and usually one copy of the retrovirus will integrate at a random site in the genome without major rearrangements of the integration locus. Genetic transfer with retroviruses is usually achieved after the single-cell stage of mouse development, so that the resulting mice will be genetically heterogeneous. Genetically homogeneous transgenic mice can be produced in the F1 generation of these mice. With retroviruses, the size of the introduced DNA construct is limited to approximately 8 kb. Therefore, it is not possible to use this approach for very large genes or for genomic constructs with multiple introns.

The third commonly used method for producing transgenic mice is the introduction of genetic material into embryonic stem cells. With this technique, it is possible to modify specific sites in the genome (21). Additional DNA can introduced, but endogenous DNA can also be deleted by this technique, which is mostly used to produce knockout mice.

8. Mutagenesis Models

Very often, the **mutagenic** potential of a chemical compound is estimated with the Ames test. In this test, a strain of *Salmonella* that has a mutation in a gene of the his operon coding for an enzyme of the histidine biosynthesis pathway is treated with the putative mutagen and plated onto a medium without histidine. On this medium, only bacteria with intact histidine biosynthesis will grow, ie, bacteria that have reverted to the wild type or acquired a compensating mutation for the original defect. The number of colonies in an Ames test is therefore a direct measure of the mutagenic potential of a compound. This test is commonly used because it is very easy and cheap to perform.

However, some chemicals exhibit different mutagenic potential in bacteria and in eukaryotes. Within multicellular eukaryotes, there are also tissue-specific mutation frequencies. Two mouse models have been developed that allow a more accurate analysis of mutagenesis in mammals. The Big Blue mouse is a transgenic mouse that carries a DNA construct derived from lambda phage containing a *lacI* gene (1). The *lacI* gene codes for the lac repressor, which prevents the expression of the lac operon. This DNA construct can be recovered easily from high molecular weight DNA isolated from a Big Blue mouse if lambda packaging extract is added. Because of the phage lambda regulatory sequences on the transgene, the construct will be excised by the packaging extract and packaged into infectious phage particles. These phage are then plated together with a bacterial host onto X-Gal containing medium. If the phage contains an intact lac repressor, the plaques will be clear. If the lacI gene is mutated, however, blue plaques will be generated. It is then also very easy to investigate the exact nucleotide change of the mutation. The region containing the *lacI* gene is amplified by PCR primers, and the PCR product is sequenced and compared to the wild-type sequence.

A similar mutagenesis model is provided by the MutaMouse (2). This is also a transgenic mouse carrying a lambda-derived DNA construct. However, the additional DNA in the MutaMouse contains an intact *lacZ* gene (for b-galactosidase) instead of the *lacI* gene. The experimental procedure is the same as with the Big Blue mouse. The only difference is that mutant phage will produce clear plaques and wild-type phage will produce blue plaques in this assay. This system was further improved by incorporating a positive selection for $lacZ^-$ bacteria. In this system, only mutant phage can form plaques, and very large numbers of phage particles can be analyzed (3).

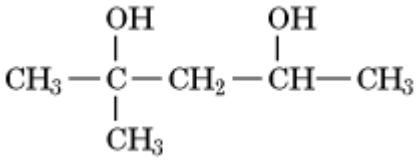
MPD (2-Methyl-2,4-Pentanediol)

MPD is commonly used to crystallize proteins for X-ray crystallography (see Crystallization). It is a relatively nonpolar molecule



although soluble in water. It decreases the solubility of proteins because it is excluded from the solvent region around their surfaces by a strong repulsion between MPD and the electric charges of the ionized groups on the protein surface. The surface of a globular protein is a mosaic of many charges, and the charge density may be very high, even if the net charge on the protein is close to zero. MPD is repulsed by the charges and concentrates in the bulk solvent. The presence of MPD lowers the solubility of the protein. When the solubility limit of the protein is reached, it precipitates or crystallizes.

The exclusion of MPD from the surface of a protein results in preferential hydration of the protein, which would be expected to stabilize the protein folded conformation (see Stabilization And Destabilization By Co-Solvents). However, unfolding reduces the charge density on the protein molecule and, consequently, the repulsion of MPD. Furthermore, MPD interacts favorably with the nonpolar surfaces of proteins that are exposed upon unfolding. Consequently, MPD interacts more favorably with the unfolded state and actually destabilizes folded proteins. So it must be used with caution.

Mu Phage

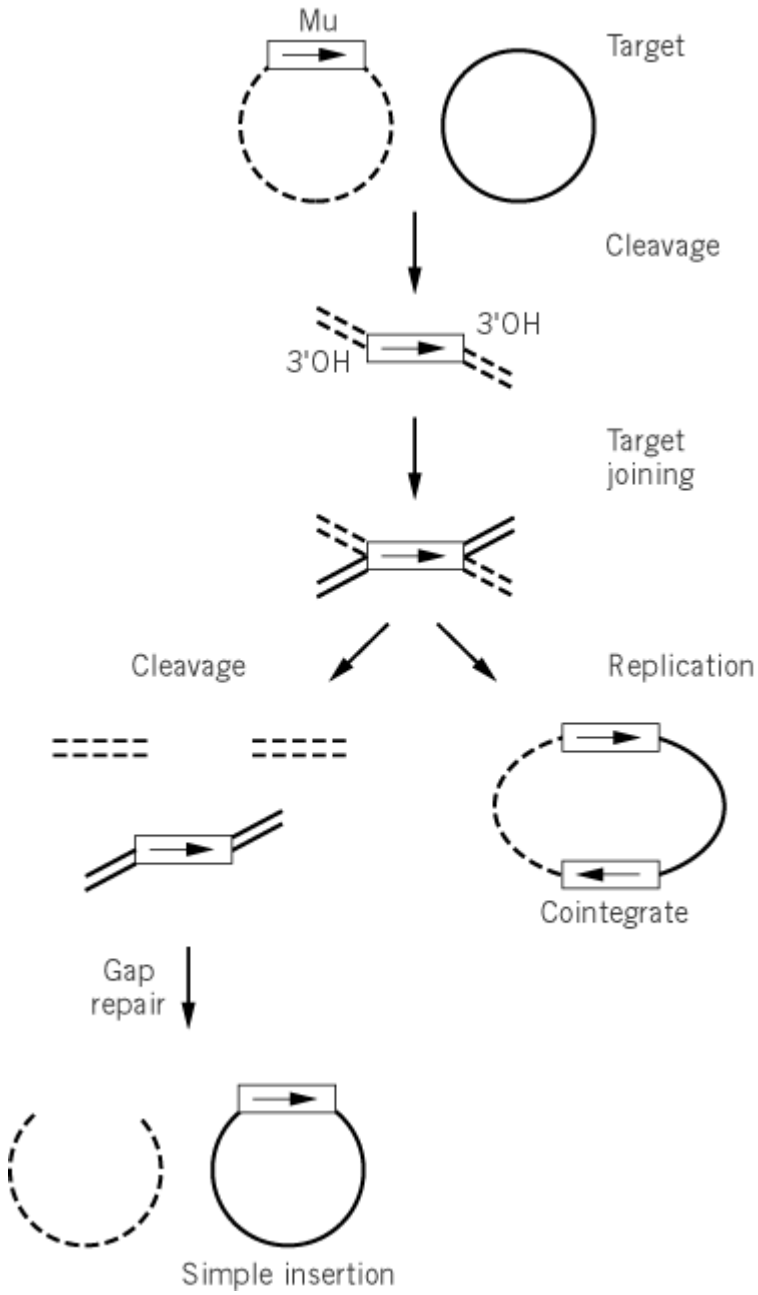
The bacteriophage Mu is a transposable element (1). It uses transposition to insert into the *E. coli* chromosome after infection and form Mu **lysogens**. The low target-site selectivity of insertion results in insertion mutations at many different locations, reflecting the disruption of many different genes, leading to a “mutator” (“Mu”) phenotype. Mu also uses transposition to replicate its DNA during lytic growth; multiple rounds of transposition result in the formation of multiple Mu-specific replication forks, and DNA replication from these forks produces multiple copies of Mu. Understanding Mu has played a key role in the dissection of the control and mechanism of transposition. Mu has also been key in studying the mechanism of transposition, because Mu transposition occurs at a high frequency during lytic growth, rather than the low frequency observed for most other elements. Indeed, the first *in vitro* transposition system was established in 1983 by Mizuuchi using Mu (2).

The DNA of Mu is about 40 kbp in length and, in addition to a number of viral proteins, encodes two transposition proteins: One is MuA, the transposase that binds specifically to the ends of Mu DNA and executes the DNA breakage and joining reactions; the other is MuB, an ATP-binding protein that interacts with the target DNA and also regulates the activity of MuA. There are special transposition sequences at each end of the element, including multiple MuA binding sites near each terminus and, at about 1.2 kbp internal from the end, an enhancer site that can strongly stimulate recombination from different positions in either orientation (see Fig. 1 in Transposable Elements). The enhancer also contains several MuA sites flanking a binding site for a sequence-specific DN-bending protein called *integration host factor*. Another nonspecific DNA-bending protein, called

HU, also participates in recombination. Both of these proteins probably promote a particular architecture of the transposase-end complex. A key early step in recombination is the three-way synapsis of the MuA-bound transposon ends and enhancer. This step is critical in promoting a conformational change in MuA that converts it from a simple DNA-binding protein to an active recombinase that can execute DNA breakage and joining. Although not essential, MuB bound to target DNA can also play a role in regulating end synapsis. Thus, by influencing the assembly of the synaptic structure, MuB, via its interaction with target DNA, can play a key role in controlling transposition.

The first chemical step in Mu transposition is the introduction by transposase of a nick at the 3′ ends of the transposon; no double-strand breaks are made (3) (Fig. 1). These exposed 3′OH transposon ends then attack the target DNA at staggered positions. The product of these reactions contains the transposon covalently linked to the target DNA through its 3′ ends and also linked to the donor DNA by its 5′ ends; it is variably called a *fusion product*, a *strand transfer product*, or a *Shapiro intermediate* [Shapiro first proposed this intermediate in a model for Mu transposition (4)]. This intermediate can undergo either of two alternative processing reactions. In one pathway, an endonuclease activity (possibly provided by the host) clips the 5′ Mu ends, disconnecting the target DNA from the transposon inserted into the target DNA; thus, Mu forms a simple insertion product by a two-step mechanism. In the other processing reaction, replication across both strands of the phage initiates from the two 3′OH target ends that flank the transposon in the fusion product intermediate. Once the replication of both strands is completed, there are now two copies of the transposon linked by the donor DNA and the target DNA, in a structure called a *cointegrate*. Thus, a transposition event can provide two replication forks that mediate Mu replication; that is, two copies of transposon are derived from the transposition product formed by a single Mu substrate DNA. Formation of a cointegrate is an example of replicative transposition.

Figure 1. Mu transposition pathways. Mu transposition initiates with cleavages that expose the 3′OH ends of the element; these exposed ends are then joined to target DNA to make a fusion product that contains the transposon attached to the target DNA via its 3′ ends and still attached to the donor DNA via its 5′ ends. In replicative transposition, replication initiates from 3′OHs in the flanking target DNA at both ends of Mu. This replication results in a cointegrate, a single DNA molecule containing two copies of the transposon, the donor backbone, and the target DNA. In the nonreplicative pathway, another set of cleavages occur that disconnect the 5′ ends of the transposon from the flanking donor DNA. A simple insertion results after host repair of the gaps that flank the newly inserted element (see Fig. 1 in Transposable Elements).



The key chemical steps of Mu transposition are cleavages to expose the 3′ ends of the elements and the joining of the 3′OH transposon ends to the target DNA. This polarity was first described with Mu, and we now know it is true of all other transposition reactions examined that involve processing of a DNA intermediate. The X-ray crystallography structures of the MuA transposase (5) and human immunodeficiency virus (HIV) retroviral integrase (6) demonstrate that the catalytic centers of these transposases are very similar in structure, although there is little amino acid sequence homology between these proteins. A notable feature of these structures is a cluster of acidic amino acids that are not adjacent in the primary sequence. These acidic residues form a binding site for Mg^{2+}, which is an essential cofactor in all known transposition reactions and probably places a key role in the actual execution of the DNA breakage and joining steps. Many other transposable elements in bacteria and eukaryotes execute the same 3′OH steps in transposition, and it is likely that their catalytic regions will be related to the common form found in MuA transposase and HIV integrase (7, 8).

Multifunctional Proteins

Multifunctional proteins combine several autonomous functions on a single polypeptide chain. In this sense autonomy implies that each function is assigned to a different region or **domain** of the polypeptide chain. Multifunctional proteins contrast with multienzyme complexes, in which different polypeptides are noncovalently associated. The definition excludes enzymes that catalyze different reactions using the same active site, such as *asparaginase* functioning as a glutaminase, *phosphoglyceromutase* , which can catalyze three different reactions using the same reaction center, or cystathionine-g-synthase which can catalyze a whole series of analogous reactions because of its relative lack of substrate specificity. **Allosteric** enzymes are not considered multifunctional. Even though they possess binding sites for effector ligands (inhibitors or activators) situated in different regions of the polypeptide chain, they are defined only with respect to the catalytic function.

Multifunctional proteins generally have different catalytic functions residing in separate domains of the same polypeptide chain. A few examples in *Escherichia coli* are **DNA polymerase I**, phosphoribosylanthranilateisomerase-indoleglycerolphosphate synthetase ((1), (2)) (see TRP Operon), the aspartate kinases-homoserine dehydrogenases ((3), (4)), and chorismate mutase-prephenate dehydrogenase ((5),(6)). In *Neurospora crassa*, the two functions of tryptophan synthase (see TRP Operon), namely the cleavage of indoleglycerol phosphate and the combination of indole with serine, reside on the same polypeptide chain, whereas in *E. coli* each is carried by an independent chain, noncovalently linked to the other. In this case, the *E. coli* enzyme is not a multifunctional protein but a multienzyme complex ((7),(8)).

Other examples are the flavocytochrome b_2 of *Saccharomyces cerevisiae* (9), a homotetramer that is both an l-lactate-cytochrome *c*-oxidoreductase (a flavoprotein) and a cytochrome b_2.

1. More than two Catalytic Functions may be Fused on the same Polypeptide Chain

DNA polymerase I from *E. coli* is a monomer endowed with three activities: DNA polymerase, 5′-3′ exonuclease, and 3′-5′ exonuclease (10). Carbamylphosphate synthetase from ascites hepatoma cells is a homotetramer also endowed with aspartate transcarbamoylase activity (in *E. coli*, these activities are carried by independent proteins) ((11),(12)). In *N. crassa* a single polypeptide chain, organized as a homodimer, is responsible for five of the biochemical reactions leading to the biosynthesis of the aromatic ring (13).

There are situations where the two systems coexist. The fatty acid synthetase of *S. cerevisiae* is a multienzyme complex (a_6b_6) composed of two multifunctional proteins. One of the polypeptides carries the malonyl transacetylase, the b-hydroxyacyldehydrase, the enoyl reductase, and the palmityl deacylase activities, whereas the other polypeptide chain carries the b-ketoacylsynthase, the b-ketoacylreductase, and the acylcarrier protein. In combination with acetylCoA carboxylase, the complex catalyzes the condensation of acetyl subunits to the final product, palmitic acid (14). The avian fatty acid synthetase, which carries the same series of reactions, is a homodimer organized in a head-to-tail manner. Each of the identical polypeptides carry all of the above-mentioned enzymes (15).

2. Catalytic and Noncatalytic Functions may be Fused

In the case of cytochrome b_2 from calf liver **microsomes**, one domain of the protein represents the cytochrome b_2 proper, whereas another domain is responsible for an anchor function (16). The homodimeric mammalian meromyosin has a domain endowed with ATPase activity, whereas another domain has a structural function (forming **thick filaments**) (17). Diphtheria toxin is a monomer whose amino terminal part ribosylates the mammalian elongation factor, whereas the C-terminal part is responsible for transporting the catalytic part across the membrane (18). The biotin repressor is a very interesting bifunctional protein of 321 amino acid residues that acts at two different levels. In addition to its repressor function, it is endowed with acetyl CoA carboxylase holoenzyme synthetase activity (19).

3. Noncatalytic Functions can be Fused

Human and bovine serum albumins consist of three homologous domains. They are endowed with independent binding and transport functions for tryptophan, bilirubin, and long-chain fatty acids (20). The Lac repressor, a homotetramer, has two independent domains, a small N-terminal domain that recognizes the corresponding operator DNA and a core that binds the **inducer**. The amino terminal part of the constitutive monomer mediates the assembly into tetramers (21). Other repressors also have separate domains for ligand binding and for specific DNA binding. Mammalian **immunoglobulins** have separate antigen binding and **complement** fixation sites (22).

4. Structural Evidence for a Multifunctional Protein

1. There should be more than one function on a single polypeptide chain.
2. Autonomy of these functions must be demonstrated by the existence of distinct domains on this polypeptide chain. Genetic analysis may produce evidence if it is possible to isolate mutants that are defective in only one function. Single-point mutations may result in the loss of more than one function. In this case, however, pleiotropic effects should be excluded. Conclusive evidence may be obtained by constructing a detailed genetic map, as done for several enzymes from *E. coli* ((23),(24)).
3. A method providing convincing evidence is the isolation and characterization of fragments that have retained their individual function unimpaired. The N-terminal domain may be produced and isolated using nonsense mutants. Limited **proteolysis** is also useful because the hinge peptide that links individual domains is often very sensitive to proteolytic attack (25).
4. Chemical modification may affect one function without affecting another. For example, *E. coli* aspartate kinase I activity is destroyed by treating the enzyme with sulfhydryl reagents, whereas the other catalytic activity of the bifunctional protein, homoserine dehydrogenase, remains intact (26).

The proper physical methods are **ultracentrifugation**, **gel filtration**, and **PAGE** in with and without

denaturing agents to determine the molecular weight of the native protein and the number of its subunits. Isoelectric focusing may provide indirect evidence that the subunits are identical. The number of autonomous functions must exceed the number of separable protein bands. The protein band must be homogeneous. Final proof is evidently provided by the total sequence of the protein or of the coding gene (**cDNA** in the case of **eukaryotes**).

Multigene Family

When similar **nucleotide sequences** that code for protein and have been derived from a common

ancestor (**homologous**) exist in a repeated fashion in the genome, such a group is referred to as a multigene family, or gene family. For more detail, see Gene Families.

Multiple-Wavelength Anomalous Dispersion MAD

Anomalous dispersion gives information about the phases of the reflections measured in X-ray crystallography (see Phase Problem). In MAD measurements, isomorphous replacement is not necessary to solve the crystal structure of a macromolecule. Electrons in an atom are bound by the nucleus and are, in principle, not free electrons (see Anomalous Dispersion). However, they can be regarded as such if the wavelength of the incident radiation is short compared with the absorption edge wavelength. In X-ray diffraction this is normally true for the light atoms, but not for the heavy atoms. If the electrons in an atom can be regarded as free electrons, the atomic scattering factor is a real quantity f because the electron cloud is centrosymmetrical. If they are not free electrons, the atomic scattering factor becomes an imaginary quantity. This complex atomic scattering factor, $f_{\text{anomalous}}$, is separated into three parts: $f_{\text{anomalous}} = f+f'+if''$ where f is the contribution to the scattering if the electrons were free electrons, f' is the real part of the correction to be applied for non-free electrons, and f'' is the imaginary correction. The sum $f+f'$ is the total real part of the atomic scattering factor. Values for f, f', and f'' are always given in units equal to the scattering by one free electron and are listed in Ref. 1. Because the anomalous contribution to the atomic scattering factor is mainly due to the electrons close to the nucleus, the value of the correction factors diminishes only slowly as a function of the scattering angle, much slower than for f.

Anomalous scattering causes a violation of Friedel's law: $I(h\ k\ \ell)$ is no longer equal to $I(h\ k\ \ell)$. This fact can be used profitably to elucidate the absolute configuration of the structure determined, and it can assist in the phase angle determination in the single-wavelength isomorphous replacement method. It can also be exploited for phase angle determination by combining information from different wavelengths (MAD). The principle is based on the wavelength dependence of f' and f''.

Hendrickson was the first to apply this to a protein structural determination (2). The X-ray data can be processed in two different ways:

1. the classical way, advocated by Hendrickson
2. the simplified way in which the problem is treated as if it were isomorphous replacement.

Hendrickson split the anomalous from the nonanomalous scattering and derived relationships between them. With a minimum of two wavelengths (but in practice at least three), he can find the protein phase angles. In the simplified way, data are collected at three different wavelengths, l_1, l_2, and l_3 (3):

l_1 is regarded as the reference wavelength (remote from the absorption edge).

l2 has a maximum difference in f' compared with and this difference is used exactly as in isomorphous replacement. This results in two possible phase angles for the protein (see Isomorphous Replacement).

l_3 has a maximum difference in f'' and with this information the choice can be made between the two possible phase angles.

Multivalents

A multivalent occurs following the pairing in **meiosis** of more than one homologous chromosome. In meiosis, the chromosomes pair along their length during the **prophase** of the first meiotic division. This process of **synapsis** is associated with the assembly of a synaptonemal complex. When the synaptonemal complex extends from end to end of each of the paired chromosomal homologues, the final structure is called a **bivalent**. Multivalents that involve the pairing of more than two homologous chromosomes occur in polyploid organisms, especially in **plants**. If all of the chromosomes do not double in number during polyploidization, then partial pairing among homologous chromosomes occurs. Some bivalents form, but multivalents, containing three or more chromosomes connected by synaptonemal complexes and univalents with a single chromosome, also form. The aberrant distribution of chromosomal material at the end of the first meiotic division generates many **aneuploid** gametophytes. Thus many polyploid plants reproduce parthenogenetically because of the large number of inviable **gametes** that would otherwise result.

Mutagen

A mutagen is any chemical that increases the mutation rate above the spontaneous level in a cell. Few, if any, mutagens induce only one type of event, with all those mutagens that have been well-studied to date showing a spectrum of changes, sometimes considered diagnostic of that particular mutagen or mutagen class. The most extensively studied mutagens are agents that modify DNA by alkylation reactions, either directly or after metabolic conversion to reactive intermediates. This is a diverse group of chemicals for which carcinogenic potencies in rodents vary over a 10,000-fold dose range (1) (see Dimethyl Sulfate (DMS) and Ethyl Methane Sulfonate (EMS)). There is a wealth of literature on the chemistry of formation of DNA-carcinogen adducts, consideration of the potential of individual adducts for mutagenicity, and mechanisms of **DNA polymerase** fidelity and mutation in the presence of adducts. Whether or not a particular genetic lesion of DNA is mutagenic depends on the nature of the lesion, whether or not it is repaired, and, if so, whether the repair is accurate, the possibilities of replicating DNA at the lesion, and also the relative timing of DNA replication. An exogenous mutagen increases the number of lesions over the background rate of endogenous lesions,

which is known to be high already. Thus, Ames et al. (2) calculated that there are 10^6 oxidative lesions present in a normal rodent cell.

There is increasing recognition that certain chemicals can cause mutations through other types of mechanisms. Ferguson and Baguley (3, 4) reviewed the inhibition of topoisomerase enzymes as a mutagenicity mechanism (see DNA Topology). Turner and Denny (5) reviewed the mutagenic properties of ligands that can bind noncovalently to the minor groove of DNA and span a range of DNA sequence selectivities. Kunz et al. (6) considered the role of imbalances in the pools of the DNA precursors in the genotoxicity of certain DNA-damaging agents.

Mutagenesis

Mutagenesis is the study of mutation, which is classically defined as an abrupt and heritable genetic change, induced by chemical or physical agents known as **mutagens**. Practically, a mutation means any change in the **DNA** or the chromosomes that can be transmitted to descendant cells. These changes may affect a single **nucleotide**, several nucleotides in a **gene**, several genes, large chromosome segments, or whole chromosomes. Crow et al. (1) adopted the following terms:

1. *Gene mutation* affects a single gene. Heritable changes may be due to base-pair substitution mutations (*transitions* or *transversions*) or **frameshift** events in which deletions or additions of one or a few nucleotide base pairs leads to a change in the reading frame of the genetic code.
2. *Chromosomal mutation* affects blocks of genes in one or more chromosomes. Heritable changes may be due to large deletions, insertions, or translocations of blocks of DNA.
3. *Genome mutation* affects the number of chromosomes without altering the chromosomal structure.

Mutant

A mutant is an organism or cell with a mutation in its genome. Classically, a mutant was defined as an individual with an observable **phenotype**. For example, in **microorganisms**, if the **wild-type** is **prototrophic** (that is, it grows on a defined minimal medium), a mutant is an individual that needs a growth factor (such as an amino acid) added to the medium to support growth. The observable phenotype can be morphological or biochemical changes. However, modern molecular biological techniques detect changes in the nucleotide sequence that may or may not affect the metabolism or morphology of the organism. Thus, the phenotype may be detected only as a change in the **restriction enzyme's** digestion pattern or a change in the DNA or RNA sequence. When classifying an individual as a mutant, it is necessary to have a defined wild-type for comparison. Differences in the nucleotide sequence within a population that do not result in an altered phenotype are considered **polymorphisms**. The word mutant is also commonly used as an adjective, for example, in mutant protein and mutant plasmid.

Mutation Load

The mutation load represents the extent of genetic death in a population due to deleterious and . Genetic death can include (1) actual death of individuals before reproduction, (2) sterility, (3) lack of mating opportunities, and (4) other factors that reduce reproduction in comparison to other genotypes. Every population is exposed continuously to newly arising mutations, the average effect of which lowers the fitness of the population in the environment where it lives (1). This decrease in fitness can be considered as the price paid by a species for its capacity to evolve. Increases in mutation rates will result in an increased mutation load and higher rates of genetic death.

In general, the change of average fitness associated with maintaining the variability in a population has come to be called the “genetic load.” Muller first used the term “load” in assessing the impact of mutation on the human population (2). In population genetics and the study of molecular , it is used as a measure of the amount of natural selection associated with a certain amount of genetic variability. The mutation load is one of genetic loads. The operational definition of the genetic load (L) is given as $L = (W_{max} - W)/W_{max}$, where $W_{\max}$ is the fitness of the reference population, usually taken as the one with maximum fitness, and W is the average fitness over all individuals in the population. In a random-mating population, population genetics theory has shown that the mutation load can be expressed as $L = u$or $L = 2u/(1+u)$in the cases of complete recessive and no dominance, respectively, where u is the mutation rate.

Mutations

A mutation is a permanent change in the sequence of the heritable genetic material of a cell or organism. Any change in the sequence of the genome that is transmitted is a mutation. Transient changes to the genome that do not alter the primary sequence, such as **methylation** patterns, are transmittable, but are not mutations. To recognize a mutant, one must establish a wild-type **phenotype** or **genotype** . Forward mutations are changes from the wild-type phenotype, whereas **reversions** are changes that restore the wild-type. The organism that has a mutation is a mutant, and the process that leads to the mutation is mutagenesis. Mutations are rare events, but these rare events have provided scientists with the tools to dissect the inner working of cells. Mutations are usually thought of as deleterious because they cause diseases, such as birth defects and cancer, but mutations can be beneficial, and they provide the variation for evolution .

Mutations are generally grouped into the categories listed in Table 1. Point mutations refer to small changes, such as the substitution of one base for another or the insertion of one or two bases. A base change that converts a **purine** to the other purine, or a **pyrimidine** for the other pyrimidine, is a transition mutation. Transitions maintain the purine/pyrimidine axis of the nucleic acid **double helix**. Transversion mutations substitute a purine for a pyrimidine or a purine for a pyrimidine, thus reversing the purine/pyrimidine axis. Transitions are more common than transversions. When a point mutation occurs within the region of a gene coding for a protein, the mutation has one of three effects on the gene product. It can be a silent mutation, it can change the amino acid (missense mutation) or, it can cause a premature stop codon (nonsense mutation).

Table 1. Categories of Mutations

Mutation Class	Definition
Point mutations	
Base substitution	Any change in a single base of DNA (or RNA if an RNA genome)
Transition	Substitution of a purine for a purine or a pyrimidinefor a pyrimidine on the same strand
Transversion	Substitution of a purine for a pyrimidine ora pyrimidine for a purine on the same strand
Missense	A mutation that causes a change in the codon, substituting one amino acid for another
Nonsense	A mutation that changes a codon (sense) to astop codon (nonsense)
Frameshift	A mutation that changes the reading frame ofa transcript by insertion or deletion of [TEXnical Error]bases, where *n* is an

	integer
Large mutations	
Deletion	Loss of a large number of bases; generally used for loss of more than four bases
Insertion	Gain of a large number of bases; generally used for the gain of more than four bases
Duplication	Gain of an additional copy of a sequence already in the genome
Inversion	Reversal of a segment of DNA without the gain or loss of bases

The other classes of mutations are deletions, insertions, and inversions. Deletions are the loss of bases, as small as one or a few bases or as large as several kilobases encompassing several genes, which can have dramatic effects on the phenotype of the mutant. Small deletions and duplications can be the result of simple slippage during DNA replication, most likely mediated by repeated bases. Frameshift mutations are the insertion or deletion of [TEXnical Error]bases (where *n* is an integer), resulting in a shift in the translational reading frame. Technically, a frameshift occurs only within the coding region of a gene, but the term is commonly used for any insertion of [TEXnical Error] bases. Large deletions result from recombination between **homologous** or nonhomologous DNA sequences. Large rearrangements are also mediated by genetic mobile elements, such as **transposons**, **viruses** and **group I** or II **introns**. If a viral genome inserts at a specific point in the host genome (for example, at the **att site** for bacteriophage **lambda** in the *Escherichia coli* genome), the insertion is not considered a mutation. However, an illegitimate insertion of a viral genome is a mutation.

Mutations are either spontaneous or induced. One source of spontaneous mutations is replication errors. The fidelity of DNA replication is high because of the combination of base incorporation specificity, proofreading, and postreplicative repair. Most replicative **DNA polymerases** insert an incorrect base at the rate of one per 10^4 to 10^5 base pairs replicated. If a typical bacterial gene has 1000 bases, the rate of misincorporation would be 1 incorrect base per 10 to 100 genes. Most replicative DNA polymerases have associated **exonucleases** that are the "proofreading" function of the enzyme complex. If the polymerase incorporates an incorrect base, this misincorporated base is recognized by the proofreader, and the exonuclease degrades the nascent strand in the reverse order of polymerization. Then the polymerase has another chance to insert the correct base. Proofreading increases the fidelity of replication 10- to 200-fold. If misincorporated bases are not corrected by proofreading, postreplicative mismatch repair provides a third level of defense against mutation. Because DNA replication is **semiconservative**, a misincorporated base in the nascent strand creates a mismatch with the template strand. These mismatches are recognized by mismatch recognition proteins that correct the newly replicated strand in favor of the template strand. This postreplicative mismatch repair increases replication fidelity an additional 10- to 1000-fold (see Mismatch Repair). Spontaneous mutations also result from endogenous DNA damage. Cytosine spontaneously deaminates to uracil, and **5-methy-cytosine** deaminates to thymine. If not repaired, these deaminations cause a C to T transition mutation.

It is thought that most spontaneous mutations commonly arise as unavoidable replication errors during cell growth. However, in the 1950s Ryan reported the occurrence of mutations in *E. coli* cells that were not dividing or, apparently, replicating their genomes (1, 2). More recently, Cairns et al. (3) described other instances of mutations in nondividing *E. coli* under nonlethal selective conditions and presented evidence that the only mutations recovered were those that allow the cells to grow. This phenomenon has been called "directed," or "adaptive," or "postselection" mutation and has

been observed now in a variety of microorganisms (4). Although the cells undergoing adaptive mutation are not dividing, the mutations appear to be caused by DNA synthesis initiated independently of **chromosomal** replication. For example, recombination functions are required in one case, suggesting that recombination intermediates initiate at least some limited DNA synthesis in nondividing cells. In other cases, the mutations are caused by replication past endogenous DNA lesions (5). The "adaptiveness" of the mutations is not so clear, however, as recent evidence indicates that with sensitive tests nonselected mutations are found. One current theory is that a small subpopulation of the cells under selection undergo a period of transient mutation and that these give rise to the apparently adaptive mutations (6).

In addition to spontaneous mutations, genetic changes are also induced by exogenous chemical and physical agents that alter or damage bases (mutagens). Some mutagens covalently modify DNA. Alkylation is a common type of covalent modification, in which an alkyl group is attached to the base. Methylation of the N7 position of guanine is generally not mutagenic, whereas methylation of its O6 position disrupts the **hydrogen bonding**, allowing T to pair with G and giving rise to a G to A transition mutation. Physical agents, such as heat, UV light and radiation are also mutagens. UV light produces cyclobutane dimers between adjacent pyrimidine bases (see **Thymine dimer**). Cells have multiple systems to deal with these dimers, including (1) white-light **photoreactivating** enzymes that split the cyclobutane ring and (2) excision-repair enzymes that recognize the distortion of the helix and remove the dimer and adjacent bases, leaving a gap that is filled in by a DNA polymerase. Mutations in excision-repair genes in humans cause xeroderma pigmentosum, a skin disorder that makes people very sensitive to sunlight.

As mentioned above, genomic changes also occur by genetic recombination. Inappropriate recombination leads to deletions and duplications in the genome. Although these large alterations are devastating to the organism, gene duplications may allow evolution by providing "extra" gene copies in which a new genetic function can evolve. Homologous recombination between sister chromosomes changes the architecture of chromosomes in diploid organisms, changing the linkage of **alleles**.

Because mutations are rare, the study of mutagenic mechanisms is difficult. To increase the numbers of mutants, geneticists design selection procedures to find mutants of interests (see **Selection**). For example, if one is studying the types of mutations induced by a chemical mutagen, it would be helpful to know what change is being induced. Cupples and Miller (7, 8) developed a series of *E. coli* strains incapable of utilizing lactose as a carbon source but that revert to lactose utilization by a specific base substitution or frameshift mutation. If these strains are subjected to a mutagenic agent and then plated onto lactose minimal media, the number of mutations may be high in one strain, but low in the other strains. Because the base change needed to revert is known, the specificity of the mutagen can be determined. This is a brilliant example of how geneticists design selections to understand mutagenesis.

Mutator Genes

Defects in mutator genes lead to organisms with spontaneous mutation rates that are significantly elevated over the normal rate. The earliest report of this type of defect was from Treffers et al. (1), who discovered the *mutT Escherichia coli* mutator strain. This mutator is quite specific in increasing the frequency of A.T → G.Ctransversion mutations, even though these are only one of a number of mutation pathways that occur normally. The *mutT* strain frequently produces 10^3-fold increases in mutation rates. Similar genes have been described in many different organisms, each with their own spectrum of increased mutagenic activity. For example, the X-ray-sensitive yeast mutator strain described by von Borstel et al. (2) shows an increased frequency of frameshift mutations. Inactivation of the yeast RAD27 gene leads to a UV-sensitive phenotype and an elevated rate of duplications of 5–108 base pairs of DNA located between repeated sequences of 3–12 base pairs (3).

It has been argued that mutator genes play an important role in adaptive evolution (4). As many as 1% of natural bacterial isolates have defective mutator genes, some of them leading to very high mutation rates. Taddei et al. (4) developed models of clonal populations adapting to a new environment. Their results suggest that strong mutator genes (such as those that increase mutation rates by 10^3) will significantly accelerate adaptation to a changed environment. Although early studies on mutator genes focused on bacteria and yeast, mutator genes are increasingly being recognized as important in human cancer. Many of these mutants are defective in DNA repair systems, including DNA mismatch repair, a repair pathway for oxidative lesions and mistranslation (5). For example, the human MSH2 (hMSH2) protein is involved in the recognition of mismatched nucleotides during postreplication mismatch repair. Alterations to the hMSH2 gene are found in approximately 60% of hereditary nonpolyposis colon cancer cases. Loss of the function of this gene leads to a mutator phenotype and may be involved with the multiple mutations required for multistage carcinogenesis. (see Carcinogen).

Myb Oncogene

The *myb* oncogene, the transforming gene of the avian myeloblastosis virus, was isolated in 1941 from a chicken tumor (1). The normal cellular counterpart of this **oncogene**, c-*myb*, codes for a nuclear transcription factor that contains an amino-terminal **DNA-binding** domain, a central transactivation domain, and a C-terminal negative-regulatory domain (2, 3). Both the v-Myb and c-Myb proteins bind to DNA in a sequence-specific manner and transactivate the transcription of genes that contain Myb-binding sequences in their **promoter**/enhancer elements. A comparison of the v-*myb* and c-*myb* sequences showed that the viral oncogene arose as a result of deletions in the 5′ and 3′ portions of the coding sequences, which results in deleting a portion of the DNA-binding domain and the entire negative-regulatory domain (2). Although the deletion in the DNA-binding domain does not affect the viral protein's ability to bind to DNA, deleting the C-terminal negative-regulatory domain results in enhanced transcriptional transactivation by the v-Myb protein, which in turn enhances the proliferative activity of the virally infected myeloid cells (4).

c-*myb* is expressed predominantly in **hematopoietic** cells and is readily induced by treating these cells with interleukins or **mitogens**. Studies with **antisense** oligonucleotides demonstrate that expression of the c-*myb* gene product is essential for the proliferative potential of several myeloid and T-cell lines. In addition, studies with hematopoietic cell lines suggest that the terminal differentiation of these cells is accompanied by down-regulation of *myb* gene expression and constitutive expression of c-*myb* blocks their terminal differentiation. Homozygous null c-*myb* mutant mice die *in utero* because of defects in fetal hepatic hematopoiesis, confirming an essential role for c-*myb* in hematopoiesis (5).

Amplification of the c-myb gene has been observed in several human cancers, including the acute myelogenous leukemia (AML), chronic myelogenous leukemia (CML), acute lymphocytic leukemia (ALL), T-cell leukemias, melanomas, and colon carcinomas. Recent findings suggest that virtually all **estrogen receptor** -positive breast carcinomas express high levels of c- *myb*. This gene might also play a critical role in **estrogen**-induced proliferation of mammary epithelial cells, and its overexpression may be associated with the malignant growth of these cells.

The genomes of higher organisms contain two myb-related genes, which have been named A-myb and B-myb. B-myb is expressed ubiquitously, but A-myb is expressed almost exclusively in testis, pregnant breast, and the germinal centers of the spleen. These two genes are highly **homologous** to c-myb and contain virtually identical **DNA-binding** domains. Like c-Myb, they contain transactivation and C-terminal regulatory domains and act as activators of transcription. It is possible that these two proteins function similarly to c-Myb in tissues where they are expressed. Further evidence is that A-myb-null mutant mice exhibit defects in spermatogenesis, breast development, and spleen germinal center development (6).

Myc Oncogene

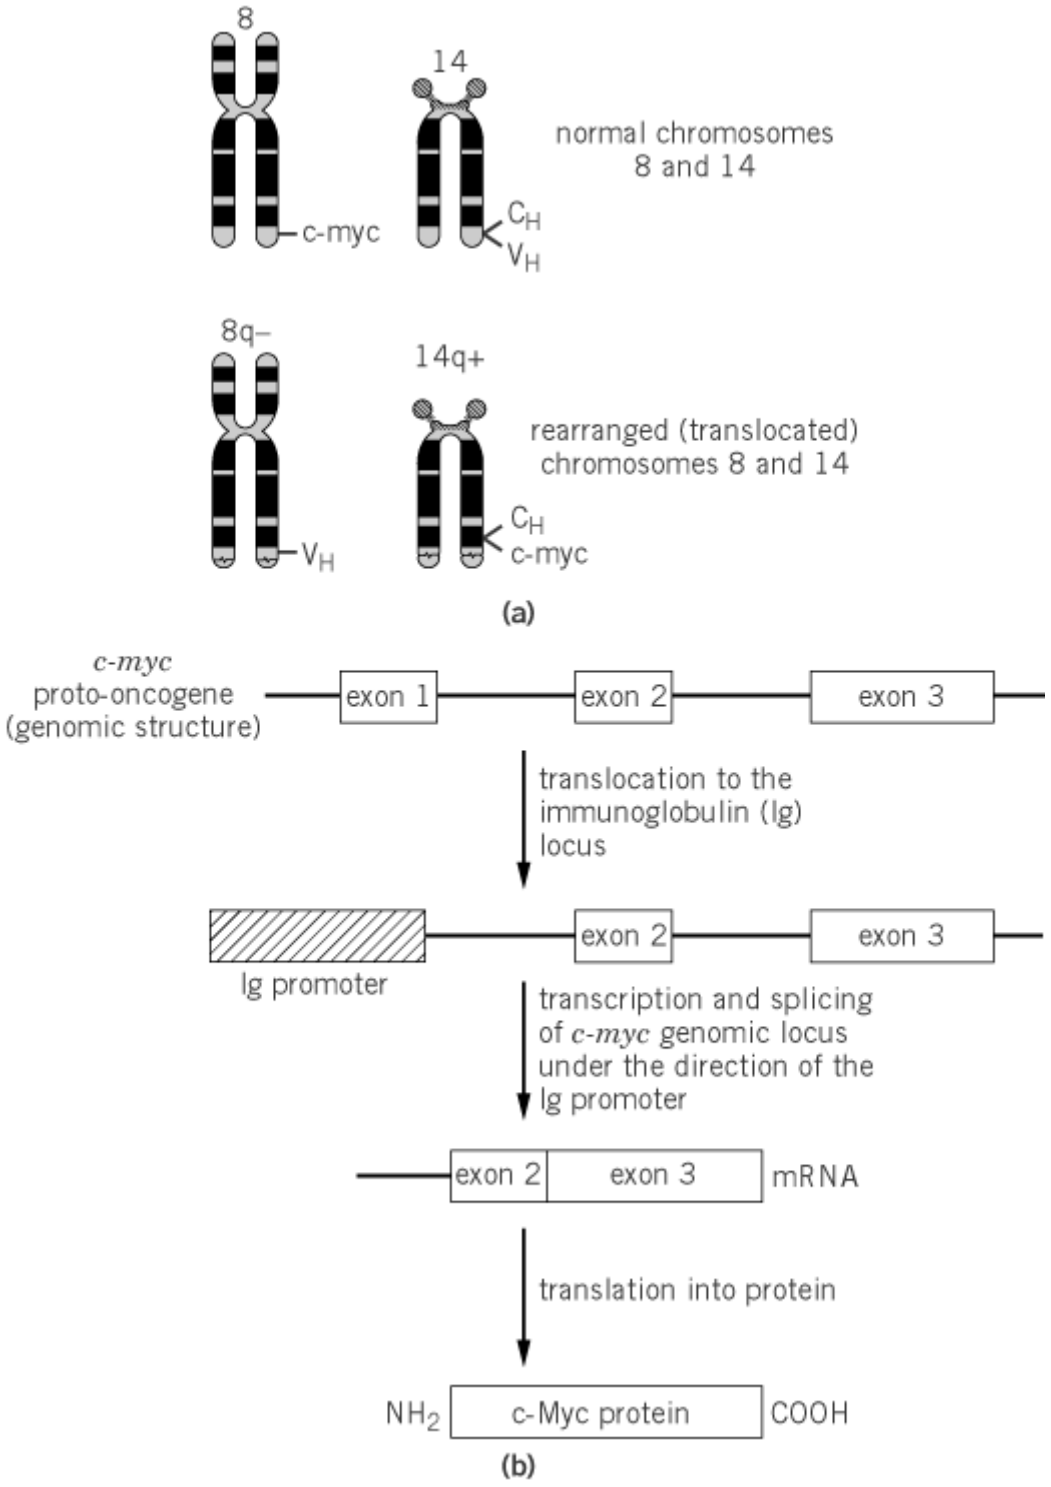
The *myc* oncogene was originally identified as the transforming gene of an acute transforming virus called MC29, which was isolated from a chicken that had spontaneous myelocytomatosis (1). The *myc*-related sequences were subsequently identified in three other independently derived chicken retroviral isolates called CMII, OK10, and MH2. Comparison of the MC29-derived v-*myc* and chicken c- *myc* sequences showed that the viral **oncogene** contains the entire coding sequence of the chicken c- *myc* gene fused to the viral gag sequence, thus producing a gag-*myc* fusion protein (2, 3). Although the fusion of the *myc* sequences to the gag gene results in elevated levels of Myc protein expression, deletion analysis of the proviral genome suggests that elevated expression of *myc* sequences alone is adequate for the transforming activity of this oncogenic virus. Thus, structural alterations play a less important role in the oncogenic activity of this gene than in other oncogenic viruses, and overexpression of the encoded protein product alone is adequate to induce transformation of appropriate target cells.

Avian and mammalian genomes code for three members of this family, which are known as c- *myc*, N-*myc*, and L-*myc* (4). All three genes code for approximately 50-kDa proteins, which belong to the **helix-loop-helix/leucine zipper** superfamily of proteins. The Myc proteins themselves do not bind to DNA with high affinity. However, they form heterodimers with a common partner termed Max, which has high affinity for the **consensus sequence** CACGTG, often referred to as the E Box. Myc-Max heterodimers bind to the E box sequence and transactivate transcription of the genes that contain this binding sequence.

c-*myc* expression in normal cells is induced by the interaction of growth factors with their cognate **receptors**, and this expression is essential for cell-cycle progression and cell proliferation. Downregulation of myc expression in **hematopoietic** cells, correlates with their terminal differentiation, and constitutive expression of *myc* often results in a block to the differentiation process. Studies with animal and human tumors show that the *myc* gene is frequently activated by one of three mechanisms: (1) proviral insertion; (2) gene amplification; and (3) chromosomal translocation. All three mechanisms result in elevated expression of the Myc protein. Although proviral insertion into the *myc* locus occurs in avian and murine tumors, activation of this gene in human tumors occurs predominantly by gene amplification and chromosomal translocation. Thus, several small-cell lung carcinomas, breast carcinomas, cervical carcinomas, and neuroblastomas have one of the three myc family members amplified. In Burkitts lymphomas, the chromosomal translocation between chromosomes 8 and 14 leads to juxtapositioning of the *c-myc* oncogene with the regulatory sequences of the immunoglobulin (Ig) genes (Fig. 1). Immunoglobulin loci code for **antibodies**, which are produced solely by B lymphocytes. When these genes are expressed, the Ig regulatory sequences direct high levels of mRNA transcription of the Ig genes located next to them. When the *c-myc* oncogene is placed under the transcriptional control of the Ig regulatory elements, however, the B cell abnormally produces extremely high levels of *c-myc* mRNA and protein (instead of antibody), which induces a malignant phenotype.

Figure 1. Activation of the *c-myc* oncogene as a consequence of translocation in Burkitt's lymphoma. (**a**) During translocation, the c-myc gene (located on chromosome 8) translocates to chromosome 14 at a site next to the immunoglobulin heavy chain (C_H) locus. (**b**) This translocation results in juxtaposing the immunoglobulin regulatory sequences upstream of the *c-myc* gene. Because the immunoglobulin promoter positively regulates high levels of

transcription in B lymphocytes, the *c-myc* gene (instead of the immunoglobulin gene) is constitutively transcribed and translated in the cell.



Recent studies have also implicated the *myc* gene in apoptosis (5). Thus, it has been found in hematopoietic cells that constitutive expression of myc during the withdrawal of **cytokines** leads to acceleration of apoptosis. Similarly, constitutive expression of *myc* in Rat-1 fibroblasts causes apoptosis when proliferation is inhibited by removing serum from the growth medium (see Serum Dependence) or by adding factors, such as tumor necrosis factor to the medium. Myc-mediated apoptosis is associated with elevated expression of cyclin A.

Mycoplasma

Mycoplasma is the vernacular name for the group of naturally occurring wall-less eubacteria. With one apparent exception, these are free-living microorganisms and part of the normal flora and significant pathogens of humans, animals, plants, and insects. The possible exception are the phytoplasmas (originally called “mycoplasma-like organisms”), which infect plants and insects and may be obligate intracellular parasites. Besides their clinical importance, mycoplasmas are of interest because of their small genomes: some mycoplasmas have the smallest known cellular genomes, perhaps defining the minimal number of genes a living cell can have.

The first isolation of a mycoplasma was in 1898 with the cultivation of the causative agent of bovine pleuropneumonia. This strain and subsequent similar isolates were named pleuropneumonia-like organisms (PPLO) and later renamed the genus *Mycoplasma*. Current mycoplasma taxonomy consists of a single class, *Mollicutes*, containing four orders (Table 1): *Mycoplasmatales*, sterol-requiring human and animal mycoplasmas; *Entomoplasmatales*, plant and insect mycoplasmas; *Acholeplasmatales*, non-sterol-requiring mycoplasmas that grow in a variety of habitats; and *Anaeroplasmatales*, obligate anaerobic mycoplasmas. There is also a group of plant and insect mycoplasmas, Phytoplasma, that cannot be given formal taxonomic status because it has not been possible to grow these microorganisms in axenic culture.

Table 1. Taxonomy of the Class *Mollicutes*[a]

Order: *Mycoplasmatales*
- Family: *Mycoplasmataceae*
  - Genus: *Mycoplasma* (102 recognized species)
  - Genus: *Ureaplasma* (6 recognized species)

Order: *Entomoplasmatales*
- Family: *Entomoplasmataceae*
  - Genus: *Entomoplasma* (5 recognized species)
  - Genus: *Mesoplasma* (12 recognized species)
- Family: *Spiroplasmataceae*

Genus: *Spiroplasma* (33 recognized species)
Order: *Acholeplasmatales*
Family: *Acholeplasmataceae*
Genus: *Acholeplasma* (13 recognized species)
Order: *Anaeroplasmatales*
Family: *Anaeroplasmataceae*
Genus: *Anaeroplasma* (4 recognized species)
Genus: *Asteroleplasma* (1 recognized species)
Undefined taxonomic status: Phytoplasma[b]

[a] Based on data in Ref. 2.
[b] There is no formal taxonomic classification for Phytoplasma. They were originally called mycoplasma-like organisms (MLOs).

The defining phenotype of members of the Class *Mollicutes* is the absence of any type of cell wall structure. Cell wall genes appear to have been lost during the degenerate evolution of mycoplasmas from Gram-positive eubacteria, and mycoplasmas are bounded only by a single cell membrane. The properties of the mycoplasma genera are shown in Table 2.

Table 2. Properties of mycoplasma genera[a]

Genus	Effect of Oxygen	Cholesterol Required	Genome Size	Habitat
Acholeplasma	Facultative anaerobe	No	1,500–1,650 kb	Animals, some plants and insects
Anaeroplasma	Obligate anaerobe	Yes	1,500–1,600 kb	Bovine and ovine rumens
Asteroleplasma	Obligate anaerobe	No	1,500 kb	Bovine and ovine rumens
Entomoplasma	Facultative anaerobe	Yes	790–1,140 kb	Plants and insects
Mesoplasma	Facultative anaerobe	No	870–1,100 kb	Plants and insects
Mycoplasma	Facultative anaerobe	Yes	580–1,350 kb	Animals and humans
Phytoplasma	—[b]	—[b]	640–1,185[c]	Plants and insects[d]
Spiroplasma	Facultative anaerobe	Yes	780–2,200 kb	Plants and insects
Ureaplasma	Facultative anaerobe	Yes	760–1,170 kb	Animals and humans

[a] Based on data in Ref. 2.

[b] No data available.

[c] These genome sizes are based on DNAs in phytoplasma-infected plant and insect tissues (21).

[d] Phytoplasma may be obligate intracellular parasites.

1. Phylogeny

Mycoplasmas arose from the *Streptococcus* branch of the Gram-positive eubacterial phylogenetic tree of species with low DNA G+C contents (1). There was an early split in the mycoplasma branch into two major branches, with the ancestral branch leading to *Acholeplasma, Asteroleplasma, Anaeroplasma*, and Phytoplasma branches. The more recent major branch led to *Spiroplasma, Entomoplasma, Mesoplasma, Mycoplasma*, and *Ureaplasma* branches.

The ancestral mycoplasma branch arose from bacteria with relatively small genomes (*Streptococcus* genome sizes are 2,100 kb to 2,300 kb) and probably consisted of microorganisms with 1,500 kb to 1,700 kb genomes. It is likely that these earliest mycoplasmas were similar to *Acholeplasma*, ie, non-sterol-requiring, facultative anaerobes. Further evolution must have led to branches of obligate anaerobes (*Asteroleplasma* and *Anaeroplasma*) and, more recently, to a Phytoplasma branch with 640 kb to 1,185 kb genomes. Phylogeny of the more recent major branch produced *Spiroplasma, Entomoplasma, Mesoplasma*, and *Mycoplasma* branches with 580 kb to 2,200 kb genomes. *Ureaplasma* is a urea-requiring branch of *Mycoplasma*. Surprisingly, the smallest genomes (about 600 kb) have evolved on several independent phylogenetic branches, meaning that mycoplasmas have been under selective pressure for genome reductions and repeatedly have explored the lower limit for the genome complexity for free-living organisms.

2. Viruses

Mycoplasma viruses have been found infecting *Acholeplasma, Spiroplasma*, and *Mycoplasma* species (2). Several viruses infecting *Acholeplasma* and *Spiroplasma* have been propagated and characterized. However, a virus infecting *My. pulmonis* is the only virus infecting a *Mycoplasma* that has been propagated and characterized.

Filamentous Acholeplasma and Spiroplasma viruses have circular, single-stranded DNA genomes. Their replication appears similar to bacterial filamentous phages, with a nonlytic infection cycle and progeny virus release by extrusion through infected cell membranes. The Acholeplasma viruses are short, bullet-shaped virions with genomes about 4.4 kb, and the Spiroplasma viruses are long, filamentous virions with genomes about 8.3 kb. The Spiroplasma virus SpV1 genome sequence (8,272 bases) has been determined (3).

The only known isometric mycoplasma virus is Spiroplasma virus SpV4, with a genome of 4,421 bases (4).

Two enveloped, quasi-spherical, Acholeplasma viruses have been reported: L172 with a circular single-stranded DNA genome (about 14.0 kb) and L2 with a circular double-stranded DNA genome. The L2 genome sequence (11,965 bases) has been analyzed (5). L2 is a temperate virus with an unusual infection cycle: productive infection is noncytocidal with enveloped progeny virions released by budding through infected host cell membranes followed by establishment of lysogeny in most, if not all, infected cells.

Viruses with tailed phage morphology have been reported infecting *Acholeplasma, Spiroplasma*, and *Mycoplasma* species. Those that have been propagated all have isometric heads and short tails and contain linear double-stranded DNA ranging in size from 11.3 kb for Mycoplasma virus P1 (6) to 39.4 kb for Acholeplasma virus L3 (7), with circular permutation and terminal redundancy, cohesive

ends, or terminal inverted repeats and 5′-terminal proteins (2, 6, 7). The genome sequence of Mycoplasma virus P1 (11,660 bases), which infects *My. pulmonis*, has been determined (8).

In addition, the genome sequence of Mycoplasma virus MAV1 (15,644 bases), which infects *My. arthritidis*, has been analyzed (9), although the morphology of this virus is unknown.

3. Genome Structure and Organization

3.1. Genome Structure

Mycoplasma genomes have low G + C contents and small sizes (2). The DNA G + C content ranges from 25 to 35 mol%, with the exception of the 40 mol% G + C *My. pneumoniae* genome. In general, coding regions have a higher G + C content than non-coding regions.

Mycoplasma genome sizes range from 580 kb to 2,200 kb. The larger genome sizes are found in organisms on the oldest phylogenetic branches and smaller genome sizes in organisms on more recent phylogenetic branches (Table 2). Physical and genetic genome maps have been constructed for several Mycoplasma species, *U. urealyticum*, and *S. citri* (2).

The *My. genitalium, My. pneumoniae, My. pulmonis*, and *U. urealyticum* genome sequences have been determined and are 580 (10), 816 (11), 964 (12), and 751 kb (13), respectively. Analyses of these data show that genome reductions during evolution of mycoplasmas from Gram-positive bacteria mostly involved losses of genes for cell wall synthesis and anabolic pathways.

3.2. Repetitive Sequences, Transposable Elements, and Genome Rearrangements

Several types of genetic elements have been reported in *Mycoplasma* (14). The repetitive sequences that have been found are related to insertion sequences (IS) and are involved in adhesin and antigenic variation. Mycoplasma IS elements have significant sequence similarity to the IS3 class of insertion sequences, but only *My. pulmonis* IS1138 has been shown to transpose. Besides transposition, other types of genome rearrangements (ie, insertions, deletions, and DNA inversions) have been reported in *Mycoplasma* and associated with variations in antigen expression and size. A novel type of phenotypic switching in *My. pulmonis* involves regulation of restriction and modification by DNA inversion.

3.3. Plasmids

Mycoplasma plasmids have been reported in *My. mycoides* (14). Two cryptic *My. mycoides* plasmids have been sequenced (1,717 and 1,875 bases) and found to have regions of similarity to each other and to a family of Gram-positive bacterial plasmids that replicate via single-stranded DNA intermediates.

Extrachromosomal DNAs have been reported in *Spiroplasma*. However, it has not been possible to determine which (if any) are plasmids because most *Spiroplasma* cultures contain viruses and many *Spiroplasma* extrachromosomal DNAs have been shown to be Spiroplasma virus replicative forms.

4. DNA Replication

4.1. Biochemistry

Mycoplasma DNA replication resembles that of eubacteria: the DNA replication complex is membrane-associated (15), and replication is bidirectional from a replication origin (oriC) (2). Mycoplasma oriC sites contain DnaA boxes, and genes in this region have organizational and sequence similarity to Gram-positive bacterial oriC sites.

Three DNA polymerases have been identified in *Acholeplasma* and *Spiroplasma*, as in eubacteria, but the number of DNA polymerases in *Mycoplasma* and *Ureaplasma* is uncertain (2). One of the *Acholeplasma* and *Spiroplasma* polymerases has properties similar to eubacterial DNA polymerase I (Pol I), and another has properties similar to eubacterial DNA polymerase III (Pol III). However, it is

not known if the exonuclease activity in mycoplasma Pol III preparations is part of the DNA polymerase holoenzyme or a contaminant. In contrast, genome sequence analyses of *Mycoplasma* have identified two DNA polymerase genes, both with sequence similarity to Gram-positive bacterial Pol III. The larger encodes both DNA polymerase and 3′-5′ exonuclease activities, but the smaller only encodes DNA polymerase activity. Other gene products required for DNA replication have been identified in *Mycoplasma* genome sequence analyses.

4.2. Repair

Acholeplasma, but not *Spiroplasma* or *Mycoplasma*, has a photoreactivation (light-dependent DNA repair) system (2). In addition, *Acholeplasma* and some *Mycoplasma* species have excision (dark) DNA repair systems, but *Spiroplasma* and other *Mycoplasma* species do not. *Acholeplasma* and *Mycoplasma* are also expected to have RecA-dependent (recombinational) DNA repair because they have functional recA genes and active recombination systems (2). However, no recombinational DNA repair could be demonstrated in *Spiroplasma*, and the recA gene in *Spiroplasma* has been shown to be either truncated or to contain an internal stop codon. Some of the gene products required for DNA repair have been identified in *Mycoplasma* genome sequence analyses, but the number of DNA repair gene products appears much smaller than it does in eubacteria.

4.3. Restriction and Modification

As in eubacteria, mycoplasma restriction and modification were first observed as host-controlled variation in virus plating efficiencies. Type II restriction and modification systems (with relatively simple endonuclease and modification enzymes and cleavage at or near a small palindromic site) have been reported in *Acholeplasma, Spiroplasma, Mycoplasma,* and *Ureaplasma* (14). In general, these resemble typical bacterial restriction and modification systems. A novel specificity is that of *A. laidlawii* strain JA1, in which DNA containing m^5Cyt is restricted, independent of the m^5Cyt-containing sequence, and host cell DNA is protected by the absence of m^5Cyt nucleotides.

The only mycoplasma Type I restriction and modification system (with multimeric endonuclease and modification enzymes and cleavage at a random site far from the recognition site) has been reported in *My. pulmonis* (16). However, restriction and modification in *My. pulmonis* is regulated in a way not found in other microorganisms; regulation is via DNA inversions that change the cells' restriction and modification properties. A similar genome sequence has been found in *My. pneumoniae*, suggesting this type of system may be common in *Mycoplasma* species.

5. Transcription

5.1. Biochemistry

Mycoplasma RNA polymerases resemble eubacterial RNA polymerases, with a core enzyme of a, b, and b′ subunits and a s initiation factor (2). However, Mycoplasma genome sequence analyses show only one s gene, in contrast to the six or more s genes in eubacteria.

Mycoplasma transcription is not inhibited by rifampin, an antibiotic that binds the RNA polymerase b subunit and blocks eubacterial transcription, and purified *Acholeplasma* and *Spiroplasma* RNA polymerases are not inhibited by rifampin. Hence, the mutation to rifampin resistance must have occurred early in mycoplasma phylogeny, before the ancestral mycoplasma branch split.

5.2. Promoters, Terminators, and Antiterminators

Mycoplasma promoters are similar to eubacterial promoters (2): -35 and -10 hexamers separated by a 15 to 17 base spacer, and transcription initiation 6 to 8 bases downstream from the -10 site. The mycoplasma -10 sequence is close to the eubacterial -10 consensus sequence (TATAAT), but there is significant diversity between mycoplasma -35 sequences and the eubacterial -35 consensus sequence (TTGACA). A novel type of transcriptional regulation has been found in *My. hyorhinis*, in which the spacer between the promoter -10 and -35 sites for a family of surface proteins is a poly(A) tract, and changes in the number of adenine residues in this tract correlate with changes in surface

protein gene expression and consequent antigenic variation (17).

Mycoplasma studies show transcription termination is at r-independent termination sites (2). Although several termination and antitermination factors have been identified in Mycoplasma genome sequence analyses, no r termination factor has been found, suggesting only r-independent termination is present. Antitermination sequences have been found in the spacer regions between genes in *Mycoplasma* rRNA and tRNA operons.

5.3. RNA processing and RNase P

Mycoplasma rRNA operons have putative stem-loop structures in the spacer region between 16S and 23S rRNA genes (2). In eubacteria, such structures are substrates for processing by RNase III. Mycoplasma genome sequence analyses have identified an RNase III gene, indicating processing of rRNA primary transcripts in mycoplasmas.

The RNase P gene or RNA have been identified in *Mycoplasma* (2) and found to have ribozyme activity as a tRNA-processing endonuclease. Comparative analyses of mycoplasma and bacterial RNase P RNAs are being used to investigate RNase P structure and function.

6. Translation

6.1. Biochemistry

Mycoplasma translation resembles that of Gram-positive bacteria (2). The only reported exception is the *My. genitalium tuf* gene, which uses a very different ribosome binding sequence from the Shine-Dalgarno sequences in other mycoplasma mRNAs (18). In small *Mycoplasma* genomes, about 15% of total open reading frames encode gene products needed for translation.

An interesting aspect of mycoplasma translation is the recent finding of a gene encoding 10Sa RNA in *My. pneumoniae* (11). This type of bacterial RNA appears to have both mRNA and tRNA functions and has been proposed to mediate a novel type of “trans translation” protein synthesis.

6.2. Codon Usage

Mycoplasma translation initiation is generally at UGA codons, although initiation at GUG and UUG codons also has been found (2). There is extensive codon bias in mycoplasmas, reflecting the low G+C contents of mycoplasma DNAs. Variations in codon usage in *My. pneumoniae* also has been found as a function of G+C content and frequency of expression (11).

There is an exception to the universal genetic code in some mycoplasmas. *Acholeplasma*, like other microorganisms, uses UGG as the tryptophan (trp) codon and UGA as a termination codon, has no tRNA with anticodon CCA, and has a trp-tRNA with anticodon UCA. However, *Spiroplasma, Mesoplasma, Mycoplasma*, and *Ureaplasma* use both UGG and UGA as trp codons and contain two trp-tRNAs, one with anticodon CCA and one with anticodon UCA. Hence, during mycoplasma phylogeny, the ancestral branch that arose from the Gram-positive bacteria retained the typical bacterial codon usage, with UGG as the only trp codon and UGA as a termination codon. The change in codon usage must have occurred on the more recent phylogenetic branch soon after it diverged from the ancestral branch and presumably involved duplication of the trp-tRNA gene with anticodon CCA and mutation of the anticodon in one of these genes to UCA.

6.3. Post-translational Modification

Studies of post-translational processing have involved mycoplasma membrane proteins (2). Many of these proteins have typical Gram-positive bacterial signal peptides, and cleavage processing has been confirmed in a few cases. Mycoplasma membrane proteins also may be modified by covalent addition of fatty acids, phosphorylation, and isoprenylation.

6.4. Heat Shock Proteins

Mycoplasmas have a heat shock response similar to that of other eubacteria: increased synthesis of a

specific subset of proteins after a shift-up in temperature (2). Two mycoplasma heat shock proteins have been identified as homologs of eubacterial DnaK and GroEL proteins, two of the most conserved heat shock proteins. The fact that a heat shock system has been conserved in mycoplasmas during their degenerate evolution from eubacteria indicates significant selective advantage for this system for adapting to environmental stress.

7. Genetics

7.1. Genetic Transfer

Mycoplasma can transfer genetic information by transformation and cell-to-cell contact (14). Many *Acholeplasma, Spiroplasma*, and *Mycoplasma* species have been transformed with viral and plasmids DNAs using polyethylene glycol-mediated and electroporation protocols. Both methods are successful in some mycoplasmas, but other mycoplasmas can be transformed by only one of these methods, and there are a few mycoplasmas in which transformation has not been successful.

Two types of genetic transfer in mycoplasmas requiring cell-to-cell contact have been observed: intraspecies transfer in *Spiroplasma* and *Acholeplasma*, but not *Mycoplasma*; and interspecies transfer from the Gram-positive bacterium *Enterococcus faecalis* to *Mycoplasma*. The interspecies studies involved transfer of the conjugal transposon Tn916 carrying the *tetm* selectable marker. This type of transfer probably occurs in nature, to explain the prevalence of the *tetm* gene in *Mycoplasma* and *Ureaplasma* clinical isolates. Both conjugation-like and cell fusion models have been proposed for the mechanism of cell-to-cell gene transfer in mycoplasmas.

7.2. Genetic Recombination

Homologous, site-specific, and illegitimate recombination have been found in mycoplasmas (14). As in bacteria, homologous recombination in *Acholeplasma* and *Mycoplasma* probably occurs via RecA-dependent pathways. These mycoplasmas have recA genes, and the enzymes required for homologous recombination have been identified in *Mycoplasma* genome sequence analyses. However, homologous recombination in *Spiroplasma* may involve a non-RecA-dependent pathway because *Spiroplasma* may not have complete recA genes. Mycoplasma site-specific recombination occurs in integration of Acholeplasma and Spiroplasma viruses during lysogenization, movement of transposable elements in *Acholeplasma* and *Mycoplasma* genomes, and DNA inversions regulating expression of restriction and modification and phase-variable surface antigens in *My. pulmonis*. Illegitimate recombination has been suggested to explain the deletions and genetic rearrangements in plasmids maintained in *Acholeplasma*.

7.3. Antigen and Phase Variation

Mycoplasma and *Ureaplasma* surface antigens can undergo high frequency variation (14). This variation may be important in pathogenesis by enabling mycoplasmas to adhere to different tissue receptors or evade a host immune response. Variation in two mycoplasmas has been studied in detail. The vlp gene family in *My. hyorhinis* contains three to six genes that can be expressed either individually or in combination. Regulation is via changes in the number of adenine residues in the poly(A) spacer between the promoter -35 and -10 sites for each vlp gene, which somehow affects vlp gene expression. In contrast, the vsa gene family in *My. pulmonis* contains at least seven genes, only one of which is expressed in any cell, and regulation among vsa genes is via DNA inversions. Similar DNA inversions also regulate restriction and modification in *My. pulmonis*.

7.4. Mycoplasmas and the Minimal Cell Genome

The small size of mycoplasma genomes led to interest in them as models for a minimal cell genome, perhaps the primordial cell genome. The increasing availability of mycoplasma and eubacterial genome sequences is enabling comparative sequence analyses to identify a putative minimal gene set (19). However, small mycoplasma genomes resulted from gene attrition during the degenerate evolution of mycoplasmas from larger eubacterial genomes in cells growing under moderate environmental conditions in niches with a variety of organic nutrient and metabolic precursors (20). In contrast, the primordial cell genome probably resulted from gene accretion in cells growing in an

environment of high temperature, reducing atmosphere, and sulfur metabolism. Therefore, a proposed minimal gene set extracted from nascent microbial genes is not expected to be a useful model for a primordial genome in early cell evolution.

Myeloma Proteins

Prior to the development and universal application of hybridoma methodology to generate monoclonal antibodies of defined specificity, immunologists relied on the existence of homogeneous pathological immunoglobulins called *myelomas*. Myeloma proteins are produced spontaneously in humans due to transformation of a lymphocyte to the malignant state. Myeloma proteins can also be generated in specific strains of mice through administration of various reagents, such as mineral oil, administered in the peritoneal cavity. However, for a long time, myeloma globulins produced during human and animal disease were considered to be devoid of functional properties and were classified along with normal immunoglobulins as nonspecific and lacking antigen binding capacity. With advent of the Clonal Selection Theory (1), homogeneous myeloma proteins become antibodies in search of antigen. Myeloma proteins in humans appear with a frequency that parallels their concentration in serum and, therefore, the respective number of lymphocytes synthesizing that class of antibody. Thus, human IgG myelomas appear most frequently (~90%) followed by IgM (10%). Myelomas in the other classes, such as IgA, IgD, and IgE, are quite rare in humans. In contrast, myelomas induced in mice are predominantly IgA, followed by IgG and IgM in incidence. The predominance of IgA reflects the administration of mineral oil into the peritoneal cavity, which is rich in IgA-producing lymphocytes.

Myeloma proteins proved homogeneous at the protein level and, because they were produced in high quantities, were easily purified to homogeneity. These homogeneous proteins provided the foundation upon which the first primary structures of immunoglobulins were based. Light chains of myeloma proteins in human patients exist in excess and are harvested from urine as monomers or stable dimers called Bence-Jones proteins. Because light chains are of lower molecular weight (~22 to 23 kDa) and lack carbohydrate moieties, they were used to obtain the first primary structures. Putnam et al. (2) published the first complete sequence analysis of a Bence-Jones protein called Ag, a sequence that became the standard by which all subsequent light chains primary structure analyses would be compared. Roy was the second completed sequence and was significant because it was the comparison of primary structures that yielded critical information. The comparison of several primary structures of heavy and light chains normalized for isotype revealed the existence of the variable and constant domains (3). Further comparisons within the variable domains showed that the H chain consisted of four hypervariable regions termed **complementarity determining regions** (CDRs). The L-chain variable domains consisted of 3 CDR segments. This finding, combined with similar results from analyses of hybridoma proteins, led to delineation of the molecular basis of immunological specificity.

Monoclonal antibodies proved to be the “tool of nature” whereby immunologists first learned of the structure–function relationship in antibody molecules. However, these basic relationships extended beyond the antibody molecule when it was determined that other members of the immunoglobulin superfamily of molecules (eg, T-cell receptors, **major histocompatibility** molecules, **T-cell** accessory proteins, and adhesion molecules) utilized the same basic motifs and canonical structures first determined in monoclonal antibodies (4).

Myoglobin

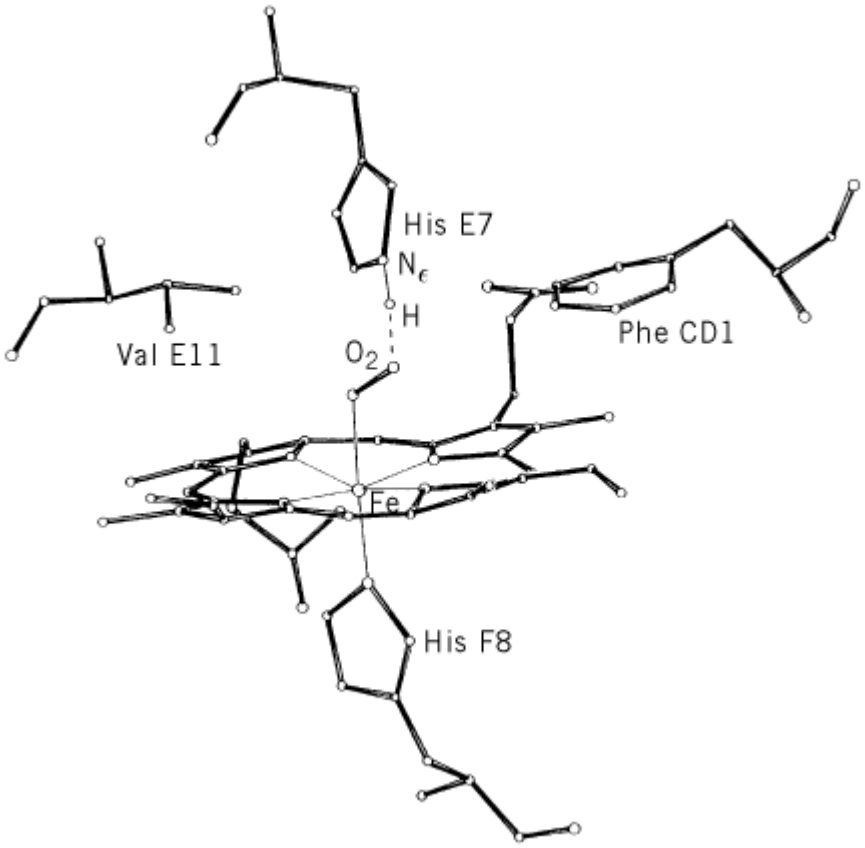
1. Distribution and Classification

Myoglobin (Mb) is one of hemoproteins, composed of globin and protoheme IX. It is found in cytoplasm of many vertebrate cardiac, skeletal and smooth muscles. Its fundamental function is intracellular oxygen store and transport. Vertebrate myoglobins are monomeric with a molecular mass of approximately 17 kDa. Myoglobin also occurs in invertebrates. It is found in body wall muscle of platyhelminthes, nemertea, nematoda, echiura and annelida, in radular muscle of amphineura, in buccal mass, radular muscle, pharyngeal muscle or triturative stomach of gastropods and in adductor muscle of bivalve. These invertebrate myoglobins are either monomeric or dimeric with a molecular mass of approximately 17 kDa per heme. Some species of gastropoda such as *Sulculus diversicolor* and *Nordotis madaka* (abalones) have a novel myoglobin in their radular muscle. It possesses one heme group but the polypeptide chain that has a molecular mass of approximately 40 kDa shows significant sequence homology with indoleamine dioxygenase (IDO), a tryptophan degrading enzyme carrying protoheme (1). The IDO-like myoglobin is considered to have evolved from a duplicated IDO gene through a pathway completely different from that for conventional globin (1).

2. Structure and Function

Skeletal muscle myoglobin of sperm whale is the first protein whose three-dimensional structure was solved by X-ray crystallography (2). Its structure is the origin for defining the "globin fold." Several amino acid residues surrounding the heme group are important for stabilizing of the heme-globin linkage and for reversible oxygen binding (Fig. 1). His-F8 (proximal His) and Phe-CD1 are strictly conserved. In most Mbs the site E7 is occupied by His but it is occasionally replaced by other residues such as Gln, Val, Leu, or Tyr. His-E7 stabilizes the oxygen-Iron bonding by forming a hydrogen bond with one of the oxygen atoms (Fig. 1). The amino acid residues at E7, E11, B10 and CD4 are known to make major contributions to control of ligand binding to Mb, as manifested in recombinant Mbs (3).

Figure 1. The heme group and key amino acid residues of sperm whale oxymyoglobin (14). His-F8 is the proximal His. His-E7 is the distal His, forming a hydrogen bond with the bound oxygen. Other key residues that control oxygen binding are Val-E11, Phe-CD1, Val-B10 and Leu-CD4 (the latter two are not shown).



Generally, the oxygen affinity of Mb is higher than that of hemoglobin within a single species. This enables oxygen transfer from the latter to the former. The oxygen dissociation curve of monomeric Mb is of hyperbolic shape whereas dimeric Mbs of annelida, amphineura and gastropoda often show sigmoid curves with Hill coefficient (see Hemoglobin) values greater than unity. Mb has no cofactor which modifies its oxygen binding properties. This feature is in striking contrast to that of Hb which shows the oxygen transport function allosterically regulated by several cofactors (see Hemoglobin). However, it is reported that lactate, a product of glycolysis, causes a marked lowering of oxygen affinity for sperm whale Mb and horse heart Mb (4).

The physiological functions of Mb are considered to be short-term or long-term store of oxygen (oxygen buffer) and facilitation of intracellular diffusion of oxygen from red cells to mitochondria. Mb serves as an oxygen store during temporary deficits in oxygen supply. In beating heart or exercising skeletal muscle Mb acts as a short-term oxygen store, tiding the muscle over from one contraction to the next (5). Long-term oxygen supply during diving supposed for aquatic mammals which have high concentrations of skeletal Mb is of small significance because the amount of oxygen bound to Mb is too little to ensure the long-term supply. There is a line of evidence supporting the validity of Mb-facilitated diffusion of oxygen in muscle cells. In this mechanism the amount of oxygen transported by translational diffusion of Mb makes a significant contribution to the total oxygen flux in the cell compared to spontaneous diffusion of free dissolved oxygen. However, for this mechanism to be proven to operate in vivo several discrepancies must be resolved (6).

Recently, new functional roles of Mb, most of which are not based on reversible oxygen binding but on enzymatic activities, were proposed. They include a defense mechanism against oxidative stress through a peroxidase activity of Mb (7), augmentation of mitochondrial oxidative phosphorylation (8), augmentation of signal transmittance by NO through a redox reaction with NO (9) and inhibition of the inactivation of cytochrome c oxidase by NO (i.e., protection of cellular respiration) through

NO scavenging by Mb (10). The recent observations that myoglobinless gene knockout mice are fertile and exhibit normal exercise capacity and a normal ventilatory response to low oxygen levels seemed to imply that Mb was not required to maintain the normal cardiovascular and musculoskeletal function in a terrestrial mammal (11). However, the later observations that the elimination of Mb was accompanied by the activation of multiple compensatory mechanisms in the circulatory system indicate that Mb is still important for the delivery of oxygen (12).

IDO-like Mbs have no sequence homology with conventional Mbs. Nevertheless, they show light absorption spectra similar to those of conventional Mbs and are capable of reversible oxygen binding, whereas they have completely lost IDO activity (13). Their oxygen affinity is lower than that of conventional Mbs (13). Their three-dimensional structure is not elucidated, and the amino acid residues corresponding to the proximal and distal residues of conventional Mb are not identified.

Myristoylation

N-Myristoylation is a cotranslational process in which eukaryotic or viral proteins become amide-linked to the 14-carbon saturated fatty acid, myristic acid (see Fig. 1 and Table 1). Myristoylation occurs on the a-**amino** group of the N-terminal glycine residue exposed after removal of the initiator methionine residue (see Translation). The reaction takes place in the cytosol, and is catalyzed by N-myristoyl transferase using myristoyl CoA as the myristic acid donor. Recent work suggests that N-

myristoylation may also occur post-translationally but as yet there is only one instance of this type of reaction (1). Myristoylation provides some proteins with a relatively weak membrane anchor, and is important for correctly localizing them within the cell. Myristoylation also occurs on many proteins that do not appear to associate with membranes. The role of the myristoyl group in these proteins is less clear, but may involve stabilizing the protein structure, facilitating protein–protein interactions by binding to a site on another protein, and viral assembly.

Figure 1. Modification of an N-terminal glycine residue by a myristoyl group. The N-terminal glycine residue of the protein (outlined by the dotted line) is amide-linked via its exposed a-amino group to the 14-carbon saturated fatty acid, myristic acid.

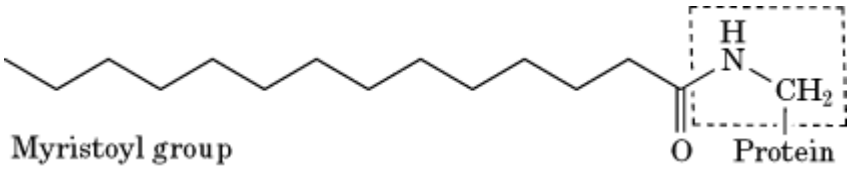

Table 1. Examples of Myristoylated Proteins

Src family tyrosine kinases (eg, $p60^{src}$, $p59^{fyn}$, $p56^{lck}$)
G-protein a subunits (eg, a_i, a_o)
MARCKS protein
ADP ribosylation factor
Endothelial nitric oxide synthase
Recoverin
NADH-Cytochrome b_5 reductase
cAMP dependent protein kinase (catalytic subunit)[a]
Calcineurin[a]
Retroviral *gag* polyproteins[a]
Viral coat proteins (eg, poliovirus VP4)[a]

[a] Not associated with membranes.

In studies with the purified N-myristoyl transferase and synthetic peptide substrates, the only amino acid that is absolutely required for myristoylation is the N-terminal glycine (2, 3). This observation agrees well with the known distribution of myristoylation among naturally occurring proteins. On the other hand, the identity of residues at positions 2–8 can also have some influence on the efficiency of myristoylation. For example, substitution of residue Ser5 (in **G-protein** a_s subunits) with an Asp residue may be the reason that a_s subunits are not myristoylated, in contrast to most other a subunits. A search of the yeast genome database suggests that about 1% of yeast ORFs will encode myristoylated proteins (4). Palmitoyl CoA is not a substrate for N-myristoyl transferase, which accounts for the relative lack of naturally occurring N-palmitoylated proteins. The transferase is less

selective for shorter acyl chain lengths (eg, C_{12}) or for degree of unsaturation (3). Detailed analysis of several myristoylated proteins reveals considerable acyl heterogeneity, and in some cases myristic acid is not even the most abundant molecular species.

That myristoylation occurs on proteins that do not bind to membranes suggests that the myristoyl group, unlike other lipid groups attached to proteins, may have functions other than membrane anchoring, but there is relatively little detailed information as to what these other functions might be. The amide linkage in N-myristoylated proteins is relatively resistant to hydrolysis, and is not degraded or turned over metabolically. Myristoylated and nonmyristoylated forms of the **cyclic AMP**-dependent protein kinase regulatory subunit have similar kinetic properties, and are equal in their ability to associate with the catalytic subunit. The myristate, however, does seem to increase thermal stability of the kinase, possibly by binding to an adjacent hydrophobic region of the protein (5). Myristoyl groups also seem to play a role in stabilizing interactions between protein molecules. This may be especially important for **viral** assembly, eg, the interaction between VP4 and VP3 on the inner surface of the polio virus capsid. The short length and lack of bulky side chains may make myristate particularly versatile and capable of binding to a membrane or to a protein site, a feature that is exploited for regulatory purposes as described below.

The myristoyl group has a relatively low affinity for membranes and by itself results only in weak and transient binding of proteins to membranes (6-8). It has been shown that membrane affinity of myristoylated proteins can be altered by three distinct mechanisms and may provide a way to regulate their distribution within the cell (for a general discussion of factors that affect membrane affinity of lipid-anchored proteins see Membrane Anchors):

1. Basic amino acid residues close to the N-terminus will bind to the negatively charged phospholipid bilayer and increase the membrane affinity, as proposed for the tyrosine kinase $p60^{src}$ and the MARCKS protein. The strength of these electrostatic interactions is reduced by **phosphorylation** of the MARCKS protein, causing it to redistribute within the cell (9).
2. Palmitoylation of a cysteine residue close to the amino terminus increases the affinity of myrisoylated proteins for intracellular membranes (10, 11). This occurs in some G protein a subunits (eg, a_o) and Src family tyrosine kinases (eg, $p59^{fyn}$ and $p56^{lck}$). Palmitoylation of these proteins also depends on prior myristoylation, because the palmitoyltransferase activities are localized in membranes (see Palmitoylation).
3. The myristoyl group may also bind to a site on the protein itself, which prevents it from acting as a membrane anchor. The myristoyl group might be extruded by a conformational change that "closes" the binding site, causing the protein to bind to the membrane. This mechanism has been proposed for recoverin and hippocalcin (Ca^{2+}-sensing proteins in the visual and nervous systems) and for **ADP ribosylation** factor, where the conformational changes occurs in response to Ca^{2+} and GTP, respectively (12).

N-End Rule

This term refers to a pathway for **protein degradation** that depends on the identity of the N-terminal amino acid residue of a protein. The N-end rule was originally elucidated in yeast by Varshavsky and coworkers, who studied the half-life of **beta-galactosidase** after genetically modifying its amino terminus. They found that if basic and large **hydrophobic** amino acids were placed, instead of the normal methionine residue at the N-terminus of b-galactosidase, the protein became very unstable. This degradative pathway requires the ubiquitin carrier protein $E2_{14}$ kDa (yeast UBC2/RAD6) and the Ub-protein ligase, E3a. The protein E3a (designated Ubr1 in yeast) recognizes such N-terminal protein substrates and forms a large complex with protein $E2_{14}$ kDa, an amidase (yeast NTA1), and an arginyl-tRNA-transferase (yeast ATE1). These additional enzymes appear to be important for modifying the N-terminus of substrates so they can be recognized by E3a. The rare cellular proteins with these abnormal amino termini can be degraded by this “N-end” pathway. The vast majority of cytosolic proteins, however, contain N-a-acetylated or methionyl amino termini, which should not be recognized by this system. Therefore, the functional importance of this pathway is uncertain. A number of recent observations suggest that this E2/E3 pair is responsible for a major portion of the protein breakdown in mammalian muscle.

n-Octyl-b-D-Glucoside

This detergent has a high critical micelle concentration (cmc) of 23 nM and has been used to solubilize and reconstitute many integral membrane proteins efficiently. The special advantage in using this detergent is in the efficient postsolubilization removal of the detergent by dialysis. It is only mildly **denaturing**, which makes it highly efficient in solubilizing integral membrane proteins, such as the nicotinic acetylcholine receptor and those for opioids, $\mathbf{GABA}_A$ (1-3), and the photoreceptor guanylate cyclase (4). However, the relative inefficiency of this detergent in solubilizing plasma membrane lipids (as compared to CHAPS and dodecylmaltoside, see Detergents), makes it inappropriate for solubilizing and reconstituting the heavily lipid-dependent serotonin 1A receptor (5, 6). Nevertheless, because of its weakly denaturing property, this detergent has been efficiently used to obtain active preparations of other solubilized membrane proteins, such as the **mitochondrial** membrane protein carnitine palmitoyltransferase I (7) or the **GPI-anchored** proteins (8). It is also a popular detergent in X-ray crystallography, where it is used to crystallize solubilized membrane proteins. Typical examples of such studies include the solubilization of the bifunctional enzyme fructose 6-phosphate, 2-kinase:fructose 2,6-bisphosphatase (9), and prostaglandin H synthase-1 (10).

N-Region Diversity

The existence of the N-region of **immunoglobulins** (Igs) was postulated when it was observed that nucleotide sequences of small, but variable, lengths identified at the VD and DJ junctions of Ig heavy chains had no counterpart in any of the **V gene, D gene**, or **J gene** segments in the germline. It turned out that these nucleotides were added at both the VD and the DJ junctions by the enzyme terminal deoxynucleotidyl transferase (TdT), which is specifically expressed in lymphocytes.

Direct evidence that N diversity was indeed the result of TdT activity was first obtained by

transfection of a non-Ig-producing fibroblast cell line with a DNA vector containing an insert of unrearranged D and J segments. Gene rearrangement was observed, provided that a co-transfection with the RAG1/RAG2 recombinase activating genes was made. In the absence of TdT, no additional nucleotides were inserted. When co-transfection also included the TdT gene, N diversity was observed in the rearranged substrate. The ultimate proof came from gene targeting experiments, because mice rendered $TdT^{-/-}$had heavy chains that no longer contained N diversity.

The results of these experiments are also in good agreement with analysis of B-cell differentiation that takes place in fetal liver and in bone marrow. In mouse fetal liver, TdT is not expressed and, as a result, no N diversity is seen in B cells that have differentiated in this organ. By contrast, TdT expression takes place in bone marrow, but only at precise steps of B-cell differentiation—that is, at the proB stage. This is the time when DJ rearrangements first take place, which correlates nicely with the major N diversity that accumulates at the D–J joint. It is still active whenever the V to DJ recombination takes place, but is then down-regulated. As a result, no or very limited N diversity is seen in the light chains. Recent data confirmed the presence of N diversity in some light chains and suggest that this occurs later in the periphery, whenever both the TdT gene and the RAG system are reactivated transiently, especially in the course of an antigenic stimulation. This is another example of the extraordinary plasticity of the mechanisms that ensure Ig diversity.

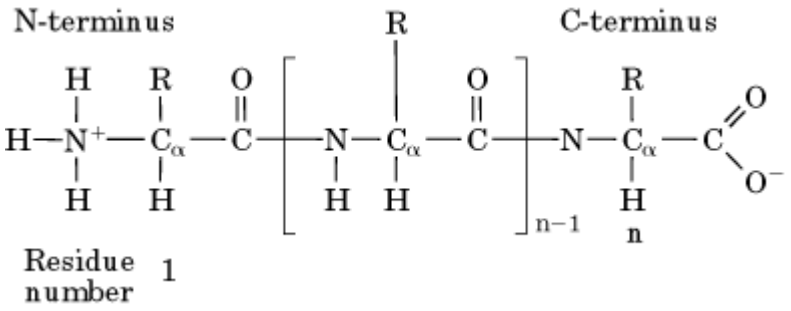
N-Terminus

The *N*-terminus is the term for one end of the polypeptide chain of a protein. Proteins are **polymers** formed by condensation of the amino groups and carboxyl groups of amino acids. That end of the polypeptide chain having an uncondensed or “free” amino group is called the amino terminus or *N*-terminus (Fig. 1). By convention, the *N*-terminus is the first residue in the protein sequence. Similarly, the other end of the polypeptide chain, having an uncondensed or free carboxyl group, is called the carboxyl terminus, or ***C*-terminus**, and by convention is the last residue in the protein sequence. The *N*-terminal amino group is usually positively charged at physiological pH.

Figure 1. Schematic representation of the covalent structure of a protein, showing the *N*-terminus as the first residue in the polypeptide chain. The square brackets indicate the repeating part of the chain (the backbone), and the R group denotes the variable side chain of each amino acid residue. The *C*-terminus is the last residue in the chain.



The *N*-terminal protein residue can be specifically and selectively modified *in vivo* (see Post-Translational Modifications). Proteins synthesized by the cell, as opposed to chemically synthesized by peptide synthesis, have an initiating **methionine residue** at the *N*-terminus. This *N*-terminal methionine residue is often removed by cellular enzymes. Also, **acetylation** of the amino group of the *N*-terminus can be catalyzed by enzymes.

The sequence of a protein can be determined experimentally using a process called the Edman Degradation. This process is based on successive removal and identification of the *N*-terminal residue of the protein.

[See also ***C*-Terminus** and Polypeptide Chain.]

NAD-Binding Proteins

NAD-binding proteins bind the dinucleotide NAD (nicotinamide adenine dinucleotide) and generally are enzymes that **catalyze** a **redox reaction** in which a proton is transferred from the carbon of a substrate alcohol group to NAD, thereby oxidizing the substrate and reducing NAD to NADH (Fig. 1). Examples of NAD-binding proteins include lactate dehydrogenase, alcohol dehydrogenase, and malate dehydrogenase. These different proteins catalyze the same basic reaction, but on different substrates, simply as a result of having differing substrate specificities.

Figure 1. The reaction catalyzed by the NAD-binding proteins. R_1 and R_2, vary depending on the substrate specificity of the enzyme. For malate dehydrogenase, the substrate malate has R_1 = COOH and R_2 = CH_2–COOH. For lactate dehydrogenase, the substrate lactate has R_1 = COOH and R_2 = CH_3. For alcohol dehydrogenase, the substrate ethanol has R_1 = CH_3 and R_2 = H.

The protein structures of these enzyme are composed of two **domains**; one domain binds the

substrate, and the other binds NAD. The substrate-binding domains of the different proteins are unrelated, but their NAD-binding domains have a common structural fold. The NAD-binding domain is a symmetrical 6-stranded **b-sheet** with **a-helices** on both sides, formed from two b–a–b–a–b protein motifs, called **mononucleotide-binding motifs** or Rossmann folds. Each of the two mononucleotide-binding motifs binds one-half of the dinucleotide; the adenine moiety of NAD binds to the first of these structural motifs, and nicotinamide binds to the second. The first three elements of secondary structure in the common adenine-binding motif, b1–aA–b2, have a similar sequence amongst the NAD-binding proteins (1). This fingerprint sequence has small **hydrophobic** residues conserved in b1, followed by a glycine-rich region (–Gly–X–Gly–X–X–Gly, where X is any residue), additional small hydrophobic residues in the aA-helix, and an Asp/Glu at the end of helix aA. The glycine residues adopt conformations forbidden to other residues and allow close packing of the strands and helix, plus a close approach between the adenine pyrophosphate and the *N*-terminal end of the aA-helix. The Asp/Glu residue interacts with the ribose hydroxyl. This signature sequence of ~30 residues was derived from the tertiary structures of known NAD-binding proteins and can be used to predict NAD-binding in proteins from simply their primary structure.

Nanos Gene

The *nanos* is a **maternal effect** gene required for the development of the fruit fly *Drosophila melanogaster*. *nanos* is required during oogenesis for the development and maintenance of the **germ line**, in the embryo for patterning of the abdomen, and in the primordial germ cells for their migration to the embryonic gonad. *nanos* messenger RNA is a model system for the study of RNA localization and translation mediated by the 3′-untranslated region (UTR), and the Nanos protein is studied for its ability to repress translation of mRNAs through sequences within their 3′-untranslated regions (see **Translational repressors**).

1. Protein and RNA Structure

The *nanos* gene encodes a 3-kb primary transcript, containing two **introns**, that is processed to a mature 2.4-kb mRNA (1). The 3′-untranslated region contains sequences required for localization and translational repression of the transcript (2). *nanos* mRNA is detected at high levels in ovaries, 0- to 8-hour embryos, and adult female flies (1). Low levels of the transcript are also detected in adult male flies, but there is no genetic evidence of a role for *nanos* in males. The Nanos protein is a 400-amino-acid-residue polypeptide chain with a predicted molecular weight of 43 kDa. It contains several polyglutamine and polyasparagine repeats, which are common to *Drosophila* proteins. Analysis of *nanos* mutants reveals that a small carboxyl-terminal **domain** is required for *nanos* function *in vivo*. Within this region are two Cys–Cys–His–Cys motifs that have been shown to bind metal *in vitro* and closely resemble the retroviral nucleocapsid class of **zinc-finger** proteins (3).

2. Oogenesis

A *Drosophila melanogaster* ovary consists of approximately 16 ovarioles, each representing an independent egg assembly line (for review see Ref. 4). Every ovariole is a linear array of developing egg chambers beginning at the anterior with the germarium, where the progeny of the germ-line and somatic stem cells are organized into egg chambers, and progressing to more mature egg chambers as they move toward the posterior. In the germarium, a germ-line stem cell produces a cystoblast by asymmetric division. The cystoblast undergoes four rounds of division with incomplete cytokinesis, resulting in 16 cells connected by cytoplasmic bridges; one of these cells becomes the oocyte while the other 15 become nurse cells. An egg chamber that has left the germarium consists of the oocyte and nurse cells surrounded by somatically derived follicle cells. As the egg chambers mature, the nurse cells synthesize and deposit factors into the oocyte that are required for the development of the oocyte and early embryo. Late in oogenesis, the nurse cells contract and dump the contents of their cytoplasm into the oocyte. Nanos protein is expressed at high levels in the germ-line cysts of the germarium and at lower levels in the germline stem cells and dividing cystoblasts.

Females **trans**-heterozygous for strong *nanos* **alleles** lay a few eggs, but rapidly become sterile due to a loss of germ-line stem cells from the ovary. Analysis of *nanos* mutant ovaries demonstrates a number of defects (5). In most instances, ovarioles completely lack germ line, suggesting that zygotic *nanos*, like ***pumilio***, is required for incorporation of germ-line cells into the developing ovarioles. Less frequently, germ-line cells appear to be incorporated into the ovariole. In some of these ovarioles, germ-line stem cells are absent and germ-line cells may develop directly into egg chambers, while in other cases stem cells seem to be established but the subsequent development of the cystoblast and maintenance of the stem cells are impaired. This suggests that *nanos* is required for the proliferation and viability of the germ-line stem cells and the developing germ-line cysts (5).

Once developing egg chambers leave the germarium, Nanos protein is no longer detectable until late in oogenesis, when Nanos protein is expressed at high levels in the nurse cells, but not the oocyte (6). The function of *nanos* at this stage is not clear, because egg chambers that lack this expression develop normally. *nanos* does not appear to play a role in spermatogenesis.

3. Embryonic Patterning

In *Drosophila melanogaster*, the anterior–posterior axis is defined by three independent systems: the terminal group of genes that controls the formation of the unsegmented termini at the anterior and posterior ends of the embryo; the anterior group of genes that controls development of the head and thorax; and the posterior group of genes that determines the abdomen (for review see Ref. 7). Each system requires the localized activity of a maternally supplied factor that functions as a spatial signal resulting in a **morphogenetic** gradient. The terminal and anterior systems require the activities of *torso* and bicoid, respectively. *nanos* is the posterior determinant; in the absence of *nanos*, embryos fail to form abdominal segments. *nanos* mRNA is localized to the posterior pole, where its translation results in a gradient of Nanos protein from the posterior pole to approximately 50% of the egg length (8). Mislocalization of *nanos* RNA to an ectopic site leads to ectopic abdomen formation (8). The only required function for *nanos* in abdomen formation is the repression of maternal *hunchback* translation at the posterior—resulting in a gradient of Hunchback protein, with its high point at the anterior pole (9-11). Hunchback is a zinc-finger containing transcription factor that represses translation of abdominal gap genes; consequently, repressing *hunchback* in the posterior allows the ordered expression of the abdominal gap genes and abdomen formation.

3.1. Regulation of *nanos* mRNA Localization and Translation

Throughout oogenesis, *nanos* RNA is synthesized in the nurse cells and deposited in the developing oocyte (6). Late in oogenesis, *nanos* RNA becomes enriched at the posterior pole of the embryo (1). This process requires a localization control element located within the first 400 nucleotides of *nanos* 3′-untranslated region and the ordered activity of the posterior group genes including **oskar**, a gene necessary for organization of the pole plasm (12, 13). *oskar* mutant embryos lack pole plasm and fail

to localize *nanos* mRNA to the posterior pole (14). Ectopic expression of *oskar* at the anterior pole results in ectopic pole plasm formation and in *nanos* mRNA being mislocalized to the anterior (14). *nanos* mRNA that is localized to the posterior pole plasm is translated, whereas unlocalized *nanos* mRNA is translationally repressed, suggesting that *nanos* mRNA localization and translation are linked (2). A 90-nucleotide translational control element in the 3′UTR of *nanos* is both necessary and sufficient for translational repression of *nanos*. The translational control element can function independently of the localization element, and RNA localization can occur in the absence of the translational control element (12, 13, 15). Translational repression can be overcome by removing the 3′-UTR, localizing the transcript to the anterior pole via heterologous RNA localization sequences from the *bicoid* 3′UTR, or by specifically mutating the translational control element. A 135-kDa protein, Smaug, has been shown to bind to the translational control element *in vitro* (15). Mutational analysis of the translational-control-element indicates that failure to bind Smaug *in vitro* correlates with lack of translational repression *in vivo* (15). It is not yet understood how the translational control element and Smaug mediate repression, or how this repression is relieved at the posterior pole.

3.2. Function of *nanos* in Embryonic Patterning

Although the maternal *hunchback* transcript is distributed throughout the early embryo, it is only translated in the anterior half of the embryo (16). Repression of maternal *hunchback* translation in the posterior requires sequences within the *hunchback* 3′-untranslated region (termed *nanos* response elements or NREs) and the activity of *nanos* and *pumilio* (17). Mutation of the NRE, or loss of *nanos* or *pumilio* activity, results in a loss of abdominal segmentation (17). Recently it has been shown that Pumilio is an RNA-binding protein that interacts specifically with the NRE (18-20). Although Nanos can bind RNA with high affinity, it does so with low specificity (3). It has therefore been proposed that Pumilio acts as a sequence-specific adaptor for Nanos that provides the spatial aspects of *hunchback* translational regulation (19). The mechanisms by which Pumilio and Nanos regulate *hunchback* translation are unclear. Maternally supplied *hunchback* RNA is deadenylated in the presence of Nanos and Pumilio (21) which suggests that NRE-directed removal of the poly (A) tail may lead to translational repression. Ectopic expression of *nanos* in the eye imaginal disc results in disruption of the development of the adult eye (20). This activity requires endogenous *pumilio* expression. Furthermore, ectopic *nanos* can repress the expression of reporter genes bearing the NREs, suggesting that the machinery needed for *nanos* -mediated repression may be present in all cells (20). Finally, ectopic *nanos* mediates repression of a reporter gene containing internal ribosome entry sites. This suggests that *nanos*-mediated translational repression may occur in a **5′-cap**-independent manner (20).

When Nanos is ectopically localized to the anterior pole of the embryo, in addition to *hunchback*, translation of the homeodomain transcription factor *bicoid* is also repressed (8). Repression of *bicoid* translation results in the loss of head structures, while repression of *hunchback* translation at the anterior causes a mirror image duplication of the abdomen, resulting in a bicaudal phenotype (8). As with *hunchback*, translational repression of *bicoid* RNA is mediated by a NRE in the *bicoid* 3′-untranslated region, and the poly (A) tail of *bicoid* mRNA is shortened in the presence of *nanos* and *pumilio* (21).

Cyclin B also contains a sequence in its 3′-untranslated region that is similar to the nanos response element. *cyclin B* is not translated at the posterior pole, and removal of this element is sufficient to activate translation of *cyclin B* mRNA at the posterior pole. The role of *nanos* and *pumilio* in the regulation of *cyclin B* translation has not been demonstrated (22).

4. Germ Cell Migration

After fertilization, the *Drosophila* embryo develops as a syncytium where nuclear rather than cellular divisions follow each other rapidly and in synchrony. The primordial germ cells are the first cells to form. They cellularize at the posterior pole of the embryo, encapsulating the pole plasm in the

process (reviewed in Ref. 23). During gastrulation, the germ cells are carried along the dorsal surface of the embryo inside the invaginating posterior midgut pocket. Subsequently, the primordial germ cells migrate through the posterior midgut and move toward the somatic component of the gonad, the gonadal mesoderm. Finally, the germ cells align with the gonadal mesoderm and coalesce to form the embryonic gonad.

Nanos protein and RNA are incorporated into the germ cells as they form at the posterior pole (6). Nanos protein is present in the germ cells until gonad coalescence (6). *nanos* is not expressed in the soma, and wild-type germ cells transplanted into *nanos* mutant embryos migrate to and populate the gonad. In *nanos* mutant embryos, the germ cells form normally and are carried into the midgut pocket. However, while wild-type germ cells migrate from the midgut to the mesoderm, *nanos* mutant germ cells fail to migrate appropriately and often remain associated with the midgut (5). Analysis of *nanos* mutant germ cells demonstrates that several germ-cell markers, which are normally expressed within the gonad, are transcribed prematurely during germ-cell migration (24). These data suggest a role for *nanos* in the specification or maintenance of the germ-cell identity during migration. Although Pumilio protein is also encapsulated in the germ cells when they form, it is not known if *pumilio* and *nanos* share a common function in the germ cells as they do in abdomen formation.

5. Homologues

Based on similarity to the carboxyl-terminal domain, *nanos* homologues have been identified from three other Dipteran species (*Drosophila virilis*, the housefly *Musca domestica*, and the midge *Chironomous samoensis*), the leech *Helobdella robusta*, the African clawed frog *Xenopus laevis*, and the nematode *Caenorhabditis elegans* (25-27). Analysis of the distribution of the homologues that have been studied so far suggests that *nanos* is a localized factor important for establishing embryonic polarity and/or development of the germ line. The expression pattern of *nanos* RNA is virtually indistinguishable among the different Dipteran species analyzed (25). Injection of *nanos* RNA isolated from the different Dipteran species into *D. melanogaster* embryos is able to rescue the abdominal defects associated with loss of *nanos* in *D. melanogaster*, suggesting that these homologues share a common, conserved function (25).

Natural Selection

Natural selection is defined as the differential fitness of genetically distinct individuals or genotypes within a given population. The fitness is defined as the number of offspring per parent who are capable of producing the next generation (1). Differential fitness is caused by differences among individuals in ways such as mortality, fertility, fecundity, mating success, and viability of offspring (2).

In population genetics, natural selection is classified into positive and negative selection, depending on whether the fitness is greater or less than 1. When the fitness is larger than 1, a selective advantage is conferred to the individuals or genotype. It follows that Darwinian evolution is operating; this is positive selection. On the other hand, when the fitness is less than 1, the individuals or genotype have a selective disadvantage. This means that deleterious mutations are selected out; this type of selection is negative selection, or purifying selection. When the fitness is just 1, this means selectively neutral (see Neutral Mutation).

Three major factors make important contributions to the genetic changes of a population, namely, evolution: mutation, natural selection, and genetic drift. Selectionists believed that natural selection

is the most important because it acts like an "editor" of genetic variation; that is, it eliminates deleterious **alleles** and captures advantageous ones. On the other hand, neutralists contend that the effect of genetic drift is substantial, particularly at the molecular level (see Genetic Drift) (3). Both selectionists and neutralists agree that natural selection is the most important for morphological evolution. Both groups implicitly agree that neither natural selection nor genetic drift is effective without mutation, because mutation is the only way to produce genetic variability.

Near-Field Scanning Optical Microscopy

Near-field scanning optical microscopy (NSOM) is a relatively new subfield of microscopy that allows visualization with sub-wavelength resolution, also called super-resolution (1). NSOM is a combination of optical microscopy with scanning probe techniques. The principle is based on a probe consisting of an aperture smaller than the wavelength of light that is positioned in close proximity (near field; < 10nm) to the specimen. By laterally scanning the specimen. By laterally scanning the specimen with near-field optics, one can generate an image at a resolution dependent on only the probe size and the probe-to-specimen separation, each of which can be pushed into the nanometer regime. Thus, NSOM extends light microscopy to a higher spatial resolution. Since the achievable resolution degrades with increasing distance from the probe, it is possible to obtain super-resolution information in three dimensions only within a few tens of nanometers from the surface. NSOM therefore falls into the class of surface probe microscopies, eg, atomic force microscopy. However, the surface-penetrating power is sufficient to map cytoskeletal structures in addition to cell membranes (2) and membrane proteins (3). Super-resolution surface features can be obtained from thick as well as thin specimens by filtering (4), although subsurface structures are usually better studied with complementary 3-D microscopies such as confocal light or transmission electron microscopies. Resolution as fine as 30–50 nm has been obtained on biological specimens using NSOM (2). Another important aspect of NSOM is the possibility of sensitive mapping of dynamic events between two fluorophores, eg, connected by a short DNA strand, by using fluorescence resonance energy transfer (FRET; (5)).

An advantage of NSOM over microscopies that offer higher resolution, such as STEM, STM, and AFM, is the wide range of contrast mechanisms available. Contrast in NSOM can be accomplished by absorption, polarization, refractive index, fluorescence, and reflectivity (1). From the perspective of molecular biology, fluorescence may be the most powerful contrast mechanism because a wide variety of fluorescent probes have previously been developed for light microscopy. A powerful application of NSOM coupled with fluorescence was demonstrated through the mapping of multiple fluorescent probes for *in situ* hybridization on a single human metaphase chromosome (6). In another study, dual-color immunofluorescence labeling coupled with NSOM was used to detect colocalized proteins and to simultaneously map membrane proteins to membrane topography (3). The power of NSOM was also shown by resolving previously unreported structural details of biological membranes including gradual domain boundaries between various lipids and a fine web structure,

which might reflect nanoscale lipid crystals (2).

Necrosis

Necrosis was the classically accepted form of cell death and occurs in response to any *severe* physiological or environmental deviation ie, change in temperature, change in pH, or disruption of the plasma membrane (1-3). Such environmental deviations lead to a loss of homeostatic control by the cell, causing an influx of ions into the cell and loss of **mitochondrial** function, which results in a reduction of ATP levels (see Adenylate Charge) and loss of membrane integrity.

Unlike apoptosis or programmed cell death, necrosis is a passive process that ends with cell rupture and induction of an immune response. The latter is an undesirable outcome. The recruitment of inflammatory **macrophages** to the site of necrotic cells can also lead to damage within otherwise healthy surrounding tissues. Thus, when considering therapeutic treatments that trigger cell death, such as cancer treatment, it is desirable to trigger apoptosis and not necrosis, so as to minimize tissue damage. It is still unclear whether cells *in vivo* do necrose, or whether the necrosis observed is actually secondary necrosis in cells that have undergone apoptosis but have not been phagocytosed, due to the extent of cell death occurring. In areas where necrotic cells are prevalent—ie, centers of solid tumors, sites of infarcts, stroke damage, and rupturing of atherosclerotic plaques—apoptosis also occurs (2, 4-6). It is important to determine whether apoptotic cell death occurs initially, because this pathway, unlike necrosis, is subject to genetic regulation, making inappropriate cell death by apoptosis treatable. Moreover, if apoptosis does occur initially, it may be possible to increase the phagocytic capacity of the surrounding cells, such that all the apoptotic cells are phagocytosed prior to the onset of secondary necrosis. This would then prevent any unnecessary damage to the surrounding tissues through an inflammatory-mediated response.

The distinction between necrosis and apoptosis has been somewhat blurred by the demonstration that the anti-apoptotic gene*Bcl-2* can suppress death in response to signals that are considered to induce only necrotic death, such as cyanide (7, 8). Because cyanide damages the mitochondria, the cell is no longer able to maintain its internal environment, leading to rapid cell lysis. It has been suggested that Bcl-2 primarily functions in regulating both ion fluxes and **cytochrome *c*** release in apoptotic cells (9, 10), and it may be because of its localization at the mitochondrial membrane that it has some protective effect against necrosis. Whether for the reasons mentioned above this observation is therapeutically relevant remains to be determined.

Morphologically, cells dying by necrosis show a distinct pattern of cellular breakdown [see Apoptosis, Fig. 1], which consists of two stages, one reversible, the other irreversible (1). In the reversible stage, cells are able to adapt to environmental changes. Morphologically, this is characterized by the dilation of the endoplasmic reticulum, along with a slight clumping of the

nuclear chromatin. Other changes in the cell include cytoplasmic swelling and mitochondrial condensation due to the inner membrane shrinking from the outer. The irreversible stage is reached once the cell is unable to adapt further to the environmental change. This stage can be identified by the mitochondria undergoing "high amplitude swelling," characterized by the appearance of dense lipid-rich aggregates within the inner membrane. The cell continues to swell, and chromatin takes on the appearance of flocculent masses, which eventually disappear, leaving a nuclear ghost (2). Finally, all membranes rupture and the cell undergoes autolysis and denaturation. Areas of tissue affected by the initial toxic insult often involve large numbers of necrotic cells, and this can result in exudative inflammation in viable tissue nearby, damaging this also. Cellular debris resulting from necrosis is phagocytosed by monocytes.

Overall, necrosis can be viewed as a relatively unhelpful process. Necrotic death results in an inflammatory response that can cause considerable damage to surrounding healthy tissues. From a clinical perspective, necrosis is difficult to prevent, unless it is the result of apoptotic cells that have not been phagocytosed.

Negative Stain

Negative staining is an excellent method for the preservation and contrast enhancement of objects

ranging in size from **macromolecules** to entire organisms, such as bacteria. This method is outstanding among electron microscopy preparation methods for its easy and rapid procedure (1). In addition to increasing the contrast, negative stain (i) also protects the specimen from distortion caused by dehydration as the stain displaces the water surrounding the specimen, and (ii) stabilizes against collapse in the vacuum of the electron microscope. However, care must be observed when choosing a stain since the preparation protocol and choice of stain can produce different results. Furthermore, the wrong stain can disorder the structure.

Staining is achieved by using heavy metal salts which have the property of drying from an aqueous solution to an amorphous "glass." The metal salt solution is able to occupy the hydrated regions in and around the particle, and as the solution dries it forms an amorphous electron-dense replica of the particle. The image formed is light in areas occupied by biological structure (said to be stain-excluding) and dark in areas occupied by stain. Hence, the technique is called "negative" staining, since the image has the appearance of a photographic negative. The degree of permeation for a particular stain may be influenced by local charge distributions and variations in the degree of hydrophilicity of the specimen (2). A number of heavy metal stains have been employed, but uranyl acetate, phosphotungstic acid, and ammonium molybdate are the most commonly used because they exhibit excellent structural detail. The high contrast of negatively stained preparations even permits the visualization of individual protein molecules (Fig. 1) that are relatively small (>20 Kdal). Negative stain embedment also reduces the problem of radiation damage, since the negative stain replica, which is more resistant to electron radiation, supports the biological specimen. However, at higher electron doses, stain redistribution can cause a loss of resolution (3).

Figure 1. Molecules of *E. coli* glutamine synthetase negatively stained with uranyl acetate. This enzyme is composed of 12 identical subunits of 50,000 MW each arranged at the vertices of two eclipsed hexagons to produce a structure with 622 symmetry with dimensions of 145 Å by 95 Å. Notice the well-defined features of isolated molecules many of which show six-fold symmetry or two-fold symmetry depending on orientation. Glutamine synthetase molecules have a tendency to aggregate along the six-fold axes forming stacks of molecules which can be seen in this image.

Negative stain is most useful for revealing (i) the molecular envelope in projection and in 3-D reconstruction, (ii) the orientation of resolvable subunits in complexes, and (iii) the interactions and interfaces between molecules in assemblies and crystals. One of the downfalls of negative staining is that the resolution limit for most specimens is ~1.5 nm, even when the structure possesses higher order. This limit is probably set by the grain size of the stain. However, there have been reports of images of negatively stained specimens with a resolution of 1.0 nm or better. This increased resolution is usually accomplished at cryotemperatures and with mixtures of negative stain and sugars or aurothioglucose (4-6), although a resolution of 0.8 nm has also been reported in negative stain without adding sugar or resorting to cryotemperature (7). In limited cases, negative stain can produce higher resolution than vitreous ice embedment, as shown for crystals of cytochrome *c* oxidase (6) in which 0.7 nm resolution was achieved in negative stain, while only 1.0 nm resolution was achieved with ice-embedded crystals. The lower resolution in ice may be ascribed to beam-induced specimen movement or specimen charging. The ease of negative stain makes it useful for surveying crystallization conditions and the degree of order of newly grown crystals, which may be used to ascertain if a higher resolution medium is warranted (8). When judging between the relative merits of negative stain and of a higher resolution medium, at times it is important to ask, “What level of structural detail will answer the research question?” For example, negative stain was chosen over ice embedment for crystals of biochemically split gap junctions as the best medium to enhance the contrast in order to visualize the extracellular domains that had been previously unseen (9).

Nematodes

Nematodes, commonly known as roundworms, are one of the most successful groups of animals on earth. It is estimated that they represent several percent of the total biomass, and that 80% of all living metazoans are nematodes (1). Their phylum, the Nematoda, includes free-living, plant-parasitic, and animal-parasitic species (see ***Ascaris***). Adult nematodes range in length from less than 1 mm for some plant and free-living species to greater than 4 m for a whale intestinal parasite.

1. Lifestyles

Parasitic nematodes cause extensive economic loss and human suffering. Crop damage from the plant parasites in the United States alone is estimated at more than $5 billion annually. Livestock production is adversely affected by the animal parasites, which also are present in about 25% of the human population. Hookworm, pinworm, and filarial infections such as African river blindness and elephantiasis are common human diseases caused by parasitic nematodes, primarily in developing countries.

The majority of nematode species are free-living, found worldwide in soil as well as marine and aquatic environments, and generally harmless. One free-living soil species, *Caenorhabditis elegans*, has become one of the best understood "model organisms" for biological research, through extensive study of its genetics, anatomy, physiology, and development (see ***Caenorhabditis***).

2. Anatomy and Physiology

In spite of their widely differing sizes and lifestyles, all nematodes are similar in their anatomy and physiology. All are simple animals with relatively few cells, and this phylum is one of only a very few that include species with fixed cell numbers and an invariant pattern of cell divisions during development. The basic nematode body plan can be simply described as a tube within a tube. The outer tube is an epidermal layer of cells (hypodermis), which secretes a tough, flexible **collagenous** cuticle covering the animal's exterior. Associated with the inside of this tube are neurons and body-wall muscles. The inner tube is the digestive tract, including a muscular pharynx as well as the intestine, which runs from the posterior end of the pharynx to the anus. Between the two tubes is a space called the pseudocoelom, which is occupied by the gonad in adults. In free-living species, the pharynx is used to ingest and crush bacteria; in plant parasites it is specialized for boring into root tissue. Nematodes lack skeletal components and maintain their body shape by hydrostatic pressure.

3. Life Cycle and Development

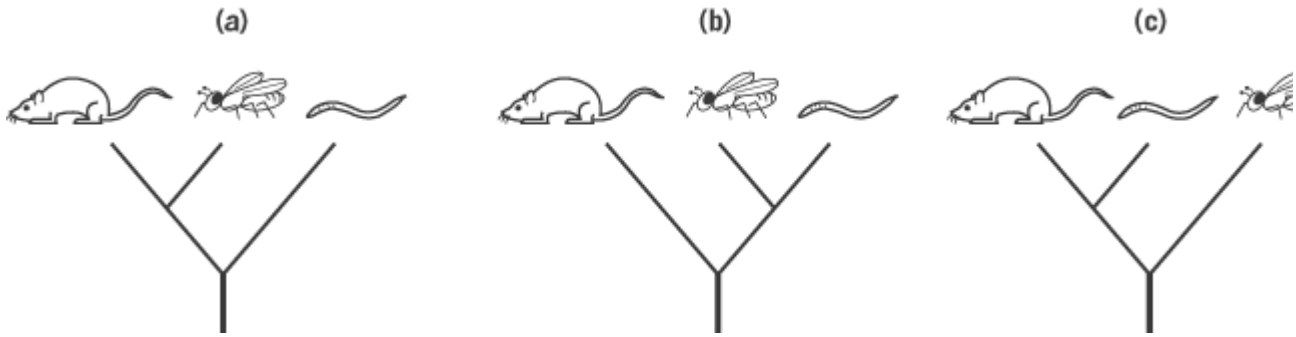
Nematode embryos develop inside a chitinous egg shell, which forms shortly after fertilization. After

hatching as first-stage juveniles, the worms grow through three more juvenile stages, separated by molts at which a new cuticle forms and the old one is shed. The fourth-stage juveniles molt to sexually mature adults, which continue growth to varying extents in different species. The four juvenile stages are commonly referred to as larval stages (L1–L4), although this nomenclature is not strictly correct because there is no metamorphosis to adulthood. In parasitic species, particular stages are often specialized for growth in a different host or host tissue. Free-living species are capable of molting under adverse conditions to an alternative form of the L3, called a *dauer* (enduring) larva, which is resistant to environmental stress, does not feed, and can survive for much longer than the normal lifespan. When conditions improve, the dauer larva can molt to the L4 and resume the normal life cycle (see *Caenorhabditis*).

4. Evolution

The evolutionary relationship of nematodes to other animal phyla is still a subject of debate. It has been difficult to establish, partly because there is no nematode fossil record. Figure 1 shows the three possible evolutionary relationships between nematodes, arthropods (represented by **Drosophila**), and chordates (represented by the mouse). Based on present evidence, Figure 1a seems most likely and Figure 1c least likely; however, an argument has been made for Figure 1b based on molting as a common character of nematodes and arthropods (2).

Figure 1. The three possible evolutionary relationships between chordates, represented by the mouse, arthropods, represented by the fruit fly *Drosophila*, and nematodes. Vertical axis represents evolutionary time. See text for further explanation.(Modified from Ref. 3.)



Within the phylum Nematoda, there are two major classes, termed Adenophorea and Secernentea. Figure 2 shows one possibility, based primarily on morphological characters, for the relationships of the various nematode orders, with their habitats and free-living or parasitic lifestyles indicated (3). A new classification based on ribosomal RNA sequences, currently in progress, suggests somewhat different relationships (M. Blaxter, personal communication).

Figure 2. Possible evolutionary relationships of nematode orders and their principal ecological niches. Multifurcations represent not simultaneous divergence events but rather uncertainty regarding sequences of divergence. Not indicated under “Marine” are several orders of the Secernentea that are parasites of marine vertebrates. (From Ref. 3, with permission.)

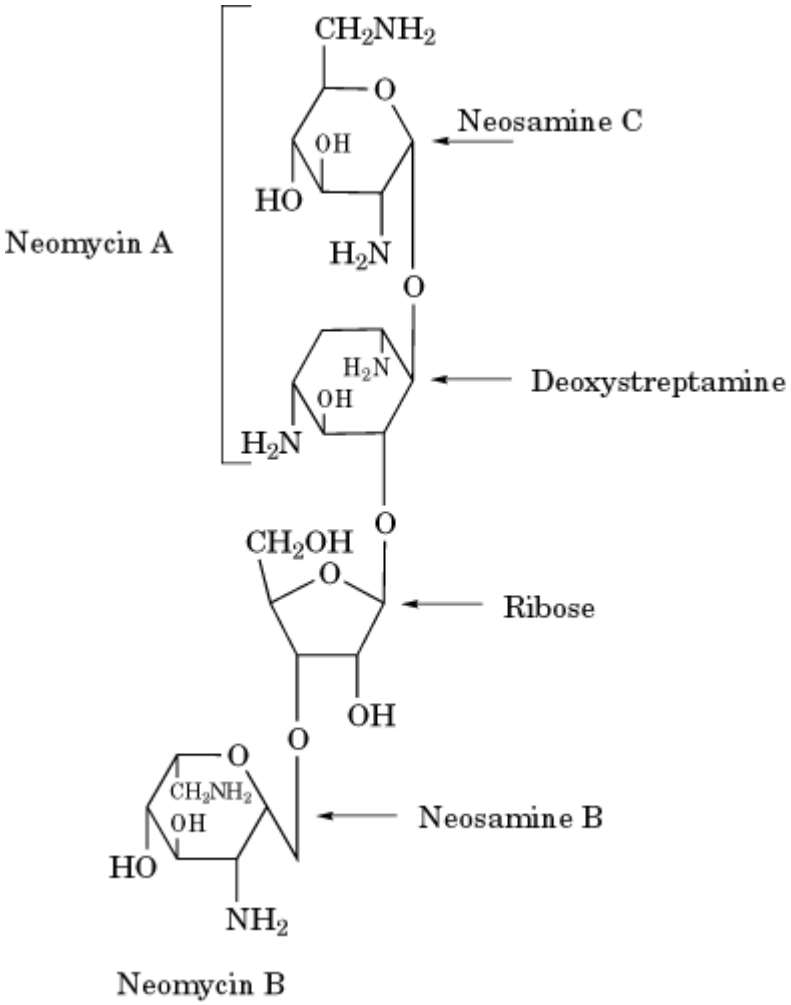
Neomycin

Neomycin is a polycationic aminoglycoside produced by actinomycetes that was first isolated in 1949 from the soil-dwelling microbe *Streptomyces fradiae* by Waksman and Lechevalier (1). As isolated, neomycin is a mixture composed primarily of two stereoisomers, neomycin B and C (Fig. 1), both of which possess antibacterial activity. In addition, there is a third component, neomycin A, that is generated by the hydrolysis of neomycins B and C. There are a number of other antibiotics which fall into the same class as neomycin, including streptomycin, gentamycin, kanamycin, tobramycin, and netilmicin.

Figure 1. Neomycins A, B, and C. The structure of neomycin B is shown in full. Neomycin C is the same, except that a second neosamine C moiety replaces the neosamine B. Neomycin A is produced by hydrolysis of neomycins B and C and consists of just the neosamine C and deoxystreptamine units.



1. Clinical Uses

Neomycin has been used as both an oral and a topical antibiotic and is effective against most

clinically important aerobic **gram-negative** bacteria. It has, however, only minor effects on *Streptococci* and gram-positive *Bacilli*. It was used originally to treat tuberculosis. This treatment was discontinued when it was realized that there were serious side effects (discussed below). Neomycin has also been given in combination with niacin to decrease serum cholesterol and lipoprotein A concentrations (2). Again, side effects have prevented it from being used clinically as a cholesterol-lowering agent. Neomycin sulfate is, however, widely used both as an over-the-counter topical agent for cuts and wounds and microbial skin infections and as a preparative treatment in bowel surgery.

2. Mechanisms of Toxicity

The side effects of neomycin administration in humans have included both nephrotoxicity and ototoxicity (involving the auditory and vestibular functions of the eighth cranial nerve). Neomycin has been found to inhibit both the renal and cochlear forms of ornithine decarboxylase, enzymes important for polyamine biosynthesis (3). Use of neomycin as a cholesterol-lowering drug was discontinued due to its side effects of ototoxicity and diarrhea (2). Neomycin also induces acute neuromuscular blockade, perhaps by displacing bound calcium and inhibiting the prejunctional release of the neurotransmitter **acetylcholine** (4).

3. Neoresistant Gene and Use in Molecular Biology

Although limited in its clinical usefulness, neomycin has in recent years become a major tool in molecular biology. Neomycin inhibits the initiation of **protein biosynthesis** by binding to the 30S ribosome, thereby blocking translation . The real usefulness of neomycin as a tool in molecular biology came with the discovery of the mammalian antibiotic resistance gene (*NeoR*) (5). This gene codes for an enzyme, aminoglycoside phosphotransferase, that catalyzes the phosphorylation of neomycin, gentamycin, and kanamycin, which inactivates them as inhibitors of protein synthesis. Expression of the *NeoR* gene, therefore, blocks the toxic effects of the aminoglycosides. Growth of transfected cells in the presence of neomycin allows for selection of cells that are expressing *NeoR* coupled to other genes of interest. *NeoR* and other drug-resistant genes are being considered for use in gene therapy to protect patients from the hematological side effects of chemotherapy (6). This new approach involves the use of a chimeric **vector** that fuses the antibiotic resistance genes with the genes of therapeutic value.

4. Interaction with Ribosomes and Protein Synthesis

Aminoglycosides such as neomycin B are bactericidal in that they prevent translation of messenger RNA by prokaryotic ribosomes. RNA molecules that recognize neomycin share a common stem-loop structural motif (7) (see RNA Structure). Recent studies have suggested that aminoglycosides inhibit protein synthesis by direct interaction with the ribosomal RNA (8). The nuclear magnetic resonance (NMR) structure of paromycin (a member of the neomycin family) bound to the A site of *E. coli* 16S rRNA has been analyzed. Aminoglycosides such as neomycin bind to the A site of rRNA (9), which is the entry site for aminoacyl tRNAs. Binding of the aminoglycoside interferes with protein synthesis by causing **codon** misreading (10). The translational block may arise from stabilization of a unique high-affinity conformation of rRNA in the tRNA–mRNA complex, thereby perturbing the accuracy of protein synthesis (11).

5. Interaction with Lipids

Neomycin also appears to inhibit the phosphatidyl inositol (PI) cycle (12, 13). Platelet-Derived Growth Factor (14), thrombin (12), and a number of other molecules that bind to certain surface **receptors** mediate their cellular effects through activation of phospholipase C (PLC), leading to the cleavage of phosphatidylinositol 4,5-bis-phosphate (PIP_2). Neomycin B indirectly inhibits the activity of PLC. PLC normally cleaves PIP_2 to generate 1,4,5-triphosphate (IP_3) and 1,2-

diacylglycerol (DAG), which are involved in activation of the IP_3 receptor and protein kinase C (PKC), respectively. Neomycin binds to PIP_2 and blocks the cleavage of PIP_2 by PLC. Because PIP_2 is a cofactor in the activation of phospholipase D, neomycin also inhibits its activity and the subsequent production of phosphatidic acid (15).

6. Ion Channels and Calcium

Neomycin has been shown to inhibit a number of **ion channels**, including surface membrane Ca^{2+} channels (16, 17), two intracellular Ca^{2+} release channels, the ryanodine receptor (RyR) (18, 19), and the IP_3 receptor (20). K^+ channels, such as the ATP-sensitive K^+ channel (21) and the Ca^{2+}-activated maxi-K^+ channel (22), also appear to be inhibited by neomycin.

The specific interaction of neomycin with an ion channel has probably been most thoroughly studied with the skeletal muscle Ca^{2+}-release channel, also known as RYR1. Neomycin has been suggested to inhibit the Ca^{2+}-release channel by enhancing its rate of inactivation (23), and it appears to bind to a location in the carboxy-terminal 20% of the molecule (19). There may actually be multiple binding sites for neomycin on RYR1 (18). Neomycin has been used as a tool to transfer a **fluorescent** label to its binding site on RYR1 to determine whether this region of the protein is involved in the conformational changes induced by various channel activators (24).

A specific binding motif for neomycin on the target proteins has not yet been identified. Neomycin may be binding to the binding sites for either Ca^{2+} or Mg^{2+}-ATP (25) on its target proteins. The identities of the actual binding sites and the specificities of these sites are unknown. Nevertheless, neomycin is thought to mediate its effect through direct interaction with ion channels and continues to be used as a tool to study ion channel properties.

7. Summary

Although of limited clinical value, neomycin has been an extremely valuable tool for basic science research. Its use as an inhibitor of ion channels and of the PI cycle has helped to elucidate the molecular events involved in these processes. The discovery of the antibiotic resistant genes has led to the widespread usage of neomycin and other aminoglycosides to select cells containing exogenous genes. The success of the neomycin selection technique in molecular biology and in the generation of **transgenic** mice has led to the possibility of using this approach in gene therapy (6).

Neoplastic Transformation

The term neoplastic transformation first came into common use in the 1950s to refer to changes in cell morphology and growth behavior in **cell culture** related to those described for tumors in animals. The changes in culture came about either spontaneously during long-term culture of mouse embryo cells or as a result of infection of chicken embryo cells with Rous sarcoma virus (RSV). The term was then applied retrospectively to the changes occurring in the development of cancer itself in animals and to a lesser degree in **plants**. During the 1970s, individual transforming **genes** were identified with different **RNA**-containing tumor-inducing **viruses**, including RSV, known collectively as retroviruses. The RNA of these viruses was **transcribed** during infection into **DNA** and integrated into the genome of the host cell, where it brought about its transforming action. The DNA of the transforming genes, or **oncogenes**, was used to "**transfect**" normal chicken embryo cells and mouse embryo cells and to transform them into neoplastic cells in the same way as the virus itself did. The DNA of normal vertebrate cells contains nucleotide sequences similar to those of the retrovirus oncogenes, and a mutated form of one of these was isolated from the DNA of a cell culture derived from a human bladder cancer. It was inferred that oncogenes were mutated forms of cellular genes related to viral oncogenes, and they played an important part in the development of human cancer. This inference was related to much earlier results in chemical **carcinogenesis** in experimental animals, particularly mice, which suggested that the primary event in the development of a tumor was a mutation that then required a series of other events to bring the tumor to full expression. A later development was the concept of tumor suppressor genes. As methods are refined for detecting genetic changes in tumors, large numbers of such changes can be found in a single tumor, particularly in solid cancers of humans, and the role of any particular genetic change in

development of the cancer is uncertain. The sum of these observations indicates that the development of cancer is an extremely complex process involving many genetic, as well as epigenetic, changes in the host.

1. Experimental Carcinogenesis in Animals

The first strong experimental indication that mutation plays a primary role in neoplastic development came from the application of polycyclic aromatic hydrocarbons (PAHs) to the skin of mice. The earliest work in rabbits and mice indicated that repeated application of a PAH was necessary to induce a tumor. In the 1940s, it was discovered that the combined application of a PAH and a non-**carcinogenic** substance (ie, croton oil) was more effective than the PAH alone. In fact, a single application of a PAH to the skin of a mouse produced no tumors, unless it was followed by repeated applications of croton oil over many weeks. If the repeated application of the croton oil was made before the PAH, no tumor resulted. A key finding was that the interval between the single PAH application and the croton oil could be as long as 10 months and a positive result would still be obtained. It was therefore concluded that the single dose of the PAH induced a permanent genetic change, called *initiation*, that required the promoting action of croton oil or further PAH application to produce a tumor. Because the croton oil was itself noncarcinogenic, *promotion* was considered an epigenetic or physiological effect. The most active ingredient of croton oil was 12-*O*-tetradecanoyl-phorbol-13-acetate (TPA), more recently termed phorbol-13-myristate-12-acetate (PMA) (see **Phorbol esters**).

The actions of initiators and promoters are subsumed under the rubric of the two-stage theory of carcinogenesis. While the two-stage theory has gained wide acceptance, it is not without its critics who interpret results such as the seeming unidirectional action of initiators and promoters in a quite different way, that is, “carcinogenesis is most probably composed of a multifarious combination of both genetic and epigenetic phenomena” (1).

The two-stage theory of carcinogenesis is based largely on studies of carcinogenesis of mouse skin. Another carefully studied model of carcinogenesis is in the rat liver. There a carcinogenic procedure consisting of systemically inoculating a carcinogen, such as dimethylhydrazine or 2-acetylaminofluorine, that does not initiate in the same way as the PAHs do in the skin, but inhibits proliferation of the vast majority of hepatocytes and selects a few resistant hepatocytes for proliferation. When coupled with mitotic stimulation, such as removal of part of the liver (partial hepatectomy), many nodules of altered, proliferating cells are formed. If the hepatectomy is delayed for 48 h or longer, the number of nodules is greatly reduced. In any case, 90% to 98% of the nodules redifferentiate into normal-appearing liver tissue. Changes typical of cancer appear only in a small fraction of the nodules. The rapid decrease in the number of nodules with increasing delay in applying the mitotic stimulation, along with the subsequent redifferentiation of most of the nodules, has suggested that the initiating treatment does not directly result in mutational change but is a physiological adaptation resulting in hepatocytes that resist growth-inhibitory toxic material. The cells in these nodules have an increased probability of undergoing the genetic changes that eventually result in liver cancer (2). It is apparent therefore that the simple relation between initiation/mutation and promotion that arose from PAH carcinogenesis in mouse skin is inadequate as a generalization for all forms of cancer.

2. Mutagenic Action of Carcinogens

The two-stage model of carcinogenesis led to attempts to demonstrate the mutagenic action of known carcinogens, particularly the PAH compounds, which were the only ones that regularly caused neoplastic transformation when painted on the skin. Attempts to demonstrate their mutagenicity in the fruit fly ***Drosophila*** *melanogaster*, a favorite organism for genetic studies, were largely negative or indecisive. Beginning in the 1950s, however, genetic studies turned increasingly to the use of **microorganisms**, which would provide many millions of dividing organisms that would exhibit mutational change within a day or two. A test was developed for mutations in the

bacterium *Salmonella typhimurium* that seemed capable of detecting about 90% of the animal carcinogens (see Ames Test). The small number of presumed nongenotoxic, epigenetic carcinogens were considered a negligible problem. Broader studies later reduced the sensitivity of the assay to 53%, and they also reported that about 30% of noncarcinogens were mutagenic in the test. Further study confirmed these results and recommended dividing carcinogens into genotoxic and nongenotoxic categories (3). The picture is further complicated by the fact that a diet deficient in choline or methionine is carcinogenic. Some interpretations of these results could be used to question the significance of genetic change in the origin of cancer. However, such doubts are countered by the fact that the *Salmonella* test detects only base pair substitutions and frameshift mutations and therefore would not detect large-scale chromosome rearrangements and deletions. Such changes are, in fact, considered to be the most important ones in the origin of human cancer (4) and will be discussed further in the text below.

There is an efficient assay that detects larger-scale changes in the genome and that had identified many carcinogens that were negative in the *Salmonella* test. It uses a line of mouse lymphoma cells that are heterozygous for a gene that phosphorylates thymidine (5). When the active allele becomes inactive as a result of genetic alteration, the cell can survive under certain conditions that kill the unaltered cells containing the active allele. The inactivation can occur either by local (intragenic) changes in base sequence or by large-scale deletions or rearrangements of chromosomes. The latter types of change can be distinguished from the former because they also cause an inheritable reduction in growth rate of the altered cells. Probably because of the dual response, this assay has detected several important carcinogens (such as the hormone diethylstilbesterol) that were negative in the *Salmonella* test, and it exhibits a good quantitative correlation between mutagenicity and carcinogenicity in experimental animals (5). Many of the compounds that are positive in this assay do not interact directly with DNA, but their ultimate effect is to alter the genome regardless of their initial target. These would be termed epigenetic or *dysgenetic* agents (6).

3. Viral Transformation of Cells

The first clear-cut demonstration that some viruses could induce neoplastic transformation was the induction of sarcomas in chickens by inoculation of filtrates from a naturally occurring connective tissue tumor of chickens that had first been transplanted serially by intact cells in closely related chickens. The virus was later named Rous sarcoma virus (RSV) after its discoverer and was the source of most of the quantitative work done on viral carcinogenesis in animals for many years. Single infectious particles of RSV could initiate epithelial tumors on the chorioallantoic membrane of the developing chicken embryo, and progeny virus particles from the epithelial tumors initiated sarcomas or connective tissue tumors in the tissue underlying the epithelial tumors, or when inoculated into adult chickens. Every infected cell gave rise to a tumor, and unlike the cytocidal or cell-killing viruses, all the infected cells could proliferate. It was therefore obvious that a small amount of genetic material could initiate neoplastic transformation, the first clear indication that genetic change *could* cause cancer. There was as yet, however, no evidence that some change in the host cell genome itself could induce transformation. The viral genome was made of RNA instead of DNA. However, it was discovered that the virus contained an enzyme, **reverse transcriptase**, that converted the viral RNA into DNA, which would then integrate into the genome of the cell, where the protein readout of the viral oncogene would transform the cell. This confirmed experiments on radiation of cells before infection with RSV which showed that loss of ability of cells to reproduce prevented the establishment of virus infection and suggested that the viral genome had to integrate into cellular DNA before the virus could multiply. Because there was a nucleotide sequence in the normal cellular DNA that was very similar to that of the viral RNA oncogene, the idea arose that a simple mutation in the cellular gene would lead to neoplastic transformation.

The opportunity for precise quantification of viral transformation arose when a method for infecting and transforming chicken embryo cells in culture was developed. Infection resulted in morphological transformation of spindle-shaped fibroblastic or connective tissue cells into a more rounded sarcoma cell. More significant than the morphological change, however, was the altered growth behavior of

the cell. Normal fibroblasts multiply rapidly in culture when they are sparsely distributed on the floor of the dish, but when they become crowded the cell-to-cell contact results in a marked decrease in growth rate (see Contact Inhibition). Net growth ceases when the cells multiply enough to form a confluent sheet. However, the cells transformed by RSV continue to multiply after they come in contact with other cells. If there is one transformed cell surrounded by normal cells, the latter form a single sheet of cells, but the former continues to multiply into several layers and form what is called a *transformed focus*. If the cells from the focus are dispersed from one another and transferred to a new culture dish along with a large majority of non-transformed cells, many neoplastically transformed foci result, each one like a small tumor.

Some strains of RSV are defective in the sense that they require coinfection of the same cell by a helper virus in order to produce new infectious virus. The reason for the defect is that the defective strains lack the information to produce the outer coat of the virus, which is required to adsorb to and penetrate into another cell. However, the defective virus can transform the cell to which it has gained entry even when no new infectious virus is produced. Clearly the coat protein does not participate in the transformation itself.

Just as there are a number of transforming retroviruses, there are a number of transforming viral oncogenes, and their protein translation products are associated with different functions in the cell. The transforming ***src* gene** of RSV codes for a protein kinase (an enzyme that **phosphorylates** protein), and considerable effort has been expended to find the cellular target of phosphorylation that causes transformation. However, the enzyme is promiscuous in the proteins it phosphorylates, and no single target protein has been found that transforms upon phosphorylation.

There is another oncogene called the ***ras* gene**, which stands for *rat sarcoma* virus from which it was isolated. A particular substrain, the *Harvey*- or *H-ras* gene, was the first gene from a human tumor shown to have transforming activity on transfection into a mouse cell culture line. Actually, the gene was only isolated from the tumor cells after they had been several years in culture, and the mutation could have occurred during that period. Later work showed that the *H-ras* gene, even when mutated, did not transform the target mouse cells directly but had first to recombine with a strong **promoter**, which led to a 100-fold increase in the protein product of the gene (7). Because there was no indication of a significant overproduction of the *ras* protein in the original tumor, it is unlikely the mutated gene played a major role in tumor development. It is also noteworthy that recombining the *normal* cellular *ras* gene with a strong promoter also leads to transformation, though with a lower efficiency than the recombined mutant *ras* gene does. The transfection assay in murine cells therefore leads to the questionable conclusion that the mutated *ras* gene derived from human tumor cells was the cause of the tumor, when it was in fact the artifact of recombination that produced the transformation in the test system. The results, however, do point up the potential significance of chromosome rearrangements in producing new gene combinations that are carcinogenic.

4. Induction of Neoplastic Transformation by Chemical and Physical Carcinogens

Although several unsuccessful attempts were made to transform mouse embryo cells in culture with carcinogenic PAHs (see **Spontaneous transformation** below), the first success was achieved with Syrian hamster embryo cells in 1965. The untreated hamster embryo cells became large, flat, and vacuolated about 3 weeks after they were explanted to culture from the embryo, slowed down in growth, and finally stopped multiplying after 6 to 7 weeks. The main body of PAH-treated cells exhibited the same early degenerative changes as the controls, but there were also foci of criss-crossing slender, spindle-shaped proliferative cells. Upon isolation, these early-appearing proliferative foci could not be subcultured. Their number and size increased with time of incubation in the original culture. The later transformed cells had a random pattern of organization, in contrast to the flattened, degenerating nontransformed cells of the background, and they continued to multiply on subculture. After about 10 weeks in culture, the cells produced slow-growing sarcomas when inoculated into hamsters. Longer periods in culture resulted in faster growing tumors in hamsters. When single cells were treated with PAH, even if only for a few hours, a significant

fraction (2% to 26%) developed into transformed foci after they grew into full colonies. This would constitute a remarkably high frequency of transformation if it were the result of mutation in one or a few genes. There was considerable variation in cell morphology, both within and between the transformed foci. A fairly close relationship existed between the concentration of carcinogen that produced transformation and that which caused an initial inhibition of growth. Noncarcinogenic and weakly carcinogenic PAH produced neither growth inhibition nor transformation. The results suggest a relationship between a degree of cell damage and subsequent transformation, as had been proposed many years earlier. They suggest that PAH treatment introduces genetic instability into cells that results in varied forms of transformation among a fraction of the progeny. Attempts to transform primary or secondary cultures of mouse embryo cells were difficult to interpret, because even the untreated mouse cells underwent transformation. (See **Spontaneous transformation** below.)

Following the success in chemically transforming hamster embryo cells in culture, efforts were renewed with mouse embryo cells, only this time cell lines were used that had been adapted to grow in culture continuously. Single cells from a permanent line of fibroblasts derived from mouse prostate glands were exposed to a carcinogenic PAH. Under optimal conditions of treatment, 100% of the treated cells that could form a clone exhibited morphologic evidence of transformation and produced tumors upon inoculation into hamsters, while only 5% of the untreated clones did so.

Despite this remarkable result, further work with the prostate fibroblasts was discontinued, possibly because they developed higher frequencies of spontaneous transformation. Instead, a permanent line of fibroblasts was developed from embryonic body wall fibroblasts of the C3H mouse strain. These cells formed a stable, flat monolayer of cells when they reached confluence and did not appear to undergo spontaneous transformation. Brief exposure to a carcinogenic PAH led to the formation of transformed foci after a 6-week period of incubation. A peculiar feature of clonally isolated transformed cells was that they grew at a *lower* rate than their parental normal cells when seeded at low population density. This again indicates that transformation is associated with cell damage and will be considered further in the text below. The efficiency of chemically induced transformation in mass populations of the C3H cell line appeared much lower than had been obtained with clones of the prostate fibroblasts. However, later PAH treatments of low densities of the C3H cells resulted in transformation at high but variable frequencies. The same cell line was used to study the transforming effect of exposure to X-rays. These experiments gave the surprising result that the number of transformed foci produced by the X-rayed cells when they reached confluence was independent of the number of cells that was used to start the culture after the irradiation. The authors proposed that X-rays induce an ill-defined change in many or all of the surviving cells that is transmitted to their progeny. This change increases the probability of a second step, overt transformation, when the cells are maintained under the growth inhibitory conditions of confluence. The fraction of confluent cells that undergo transformation is small, but almost all the survivors of X-irradiation give rise to progeny that produce some transformed foci. As in the case of the hamster cells treated with PAH, it appears that the carcinogenic treatment induces a genetic instability in most of the cells that can result in transformation in a small fraction of their progeny.

The very high frequency of the first change, while surprising when contrasted with the rarity of specific genetic mutations, is correlated with several other findings. A similarly high proportion of X-rayed cells suffers a heterogeneous, heritable reduction in growth rate signaled by the formation of small colonies. The X-rayed cells and their progeny also display an increased frequency of mutations and an increased sensitivity to mutagenic treatment. The lesions that produce the instability appear to be related to double-strand breaks in DNA and to the elimination of chromosome fragments. Another corollary is the finding that chromosome aberrations are produced in a high proportion of cells by doses of X-rays only one-tenth the mean lethal dose. The aberrations consist mainly of chromatid and chromosome gaps and are found in several copies per cell as the X-ray dose approaches the mean lethal dose. Thus the genetic lesions at the chromosomal level are likely to be associated with the instability induced by X-rays in whole populations that increases the likelihood of neoplastic transformation.

Another example of a high-frequency transformation occurs when either thyroid or mammary cells are removed from rats, X-irradiated in culture, and reinoculated into rats made susceptible to tumor development. As many as one irradiated thyroid cell out of seven will produce a thyroid cancer, and about 1 in 100 irradiated mammary epithelia produce mammary cancer. Similar results are obtained in this procedure when the cells are treated with the chemical carcinogen and mutagen *methylnitrosourea*. It is likely that the same sequence of changes is produced in these cells as in those that produce transformed foci in culture, namely a pervasive chromosomal destabilization in a cell population that results in much rarer genetic lesions in the progeny that produce tumors.

Exposure of normal fibroblasts from baby mouse skin to white fluorescent light produced a marked increase in the number of transformed foci that appeared in the culture. A conspicuous feature of this treatment was the variation in morphology of cells between foci, contrasted with their relative similarity within a focus. Many combinations of sparse or dense growth, isometric or spindle shape of cells, and large or small, narrow or wide, flat or refractile cells were observed. Also observed were one or more characters commonly associated with spontaneous neoplastic transformation in culture, such as clumping, "cording" in linear arrays, poor spreading, criss-cross or disorderly orientation, multilayering, small cytoplasm, and variable shape. A similar effect was produced by exposing the cells to drugs, such as colchicine, that combine with tubulin and prevent the formation of spindles that are necessary for chromosome segregation during cell division. In the first few divisions after removal of the antitubulin drugs, many cells became **tetraploid** (double the normal **diploid** number of chromosomes). There was also widespread asymmetric nuclear division, which creates the potential for chromosome loss. The authors felt that the resultant abnormal chromosome composition of cells (aneuploidy or heteroploidy) along with DNA damage were responsible for transformation of the cells. A large number of the transformed foci were isolated and continued for long-term culture. Although the resulting cultures grew quickly at first, this was followed by slower growth, accompanied by many dying cells. Some of the cultures died out, some grew slowly, and about one out of five became an established cell line. All of them were entirely or mostly polyploid. There appeared to be a continuing but random genetic reshuffling process, with some cell death and selection of viable gene sets. The long-term survival of isolated foci of 20% was orders of magnitude greater than the bulk of the original culture, from which only about one in 10^5 cells survived. The surviving cells retained some of the features of neoplastic cells but did not produce tumors when inoculated into mice. The cell lines eventually became aneuploid (mainly subtetraploid), resembling in chromosome distribution the preneoplastic cells described in cultures of mouse salivary gland epithelium. Because focus formation is maximized by fluorescent light irradiation plus antitubulin treatment, the authors conclude that DNA damage, as well as chromosome reshuffling, is a significant factor in the neoplastic transformation (8).

5. Spontaneous Neoplastic Transformation in Newly Explanted Cells

When connective tissue is removed from the mouse embryo and the cells separated from one another in culture, they will multiply in a nutrient medium containing animal serum. They can be subcultured at 3-day intervals, but the growth rate decreases at each subculture until they reach a point of crisis. At that point, a new cell type appears that can grow indefinitely in culture. If the subcultures are kept at low population densities, the permanent cell line stops growing at confluence, behaving like normal cells. If the subcultures are made at high density, the ensuing cell line gains the capacity to multiply at high density, a characteristic of neoplastic and preneoplastic cells. Such cells produce tumors when inoculated into the same strain of mice from which the cells originated. This transforming effect of high population density also occurs in the normally behaving established lines of mouse cells. For example, if the cells are grown to confluence before subculture, transformed foci appear on a background of normal cells. These transformed cells can be maintained in culture indefinitely, and they will eventually gain the capacity to produce tumors in mice (9). This process was termed *spontaneous malignant* or *spontaneous neoplastic transformation* because it occurred in the absence of deliberate carcinogenic treatment. There was a trend toward a marked increase in

chromosome abnormalities at about the time of neoplastic transformation. The abnormalities were chromosomal breaks and minute and biarmed chromosomes. The frequency of transformation depended on the type of serum used in the medium, and it could be increased by exposure to fluorescent light or high concentrations of oxygen.

Chinese hamster embryo fibroblasts also undergo spontaneous neoplastic transformation in culture. A sequence of changes in growth behavior preceding transformation occurs in these cells, beginning with a crisis followed by establishment of permanent growth. The early preneoplastic changes consist of growth to higher population densities in crowded cultures and increased capacity to multiply in low concentrations of protein growth factors. The capacity for isolated cells to multiply and form colonies increases, the cells gain the capacity to grow in suspension, and colonies with transformed morphology appear. After many more subcultures, the cells are able to produce tumors when inoculated into gelatin sponges that had been implanted into the subcutaneous space of the hamsters. Still later, the cells gain the capacity to produce tumors when inoculated in suspension directly into the subcutaneous space. Chromosome studies were conducted during sequential subcultures. After only six passages, about half the cells had an abnormal chromosome composition, with almost every abnormal cell having a unique karyotype (10). By the 19th passage, all the karyotypes were abnormal; about half of them were of the same type, and the others were quite variable. The presence of individual marker chromosomes increased with passage level. Despite the presence of diverse chromosome abnormalities in the early passages, the cells did not produce tumors in gelfoam sponges until about the 30th passage, nor in direct subcutaneous injection until the 54th passage. It is apparent, therefore, that only a small fraction of the total number of abnormal chromosomal combinations are associated with tumor-producing capacity, but many more combinations are associated with preneoplastic growth behavior of the cells in culture. No specific chromosome combination could be definitively linked to tumor formation, although trisomy of chromosome 5 seemed to play an important role. The sequence of changes in culture leading to tumor-forming capacity can be considered a form of progression similar to that which occurs during the development of tumors in animals.

6. Spontaneous Transformation in Established Cell Lines

A problem in using newly explanted or primary cultures of cells in studying spontaneous neoplastic transformation is that the growth properties of the cells are in a constant state of decline. There is an increasing rate of death with each passage, and the growth rate of the survivors steadily declines. Cells of rodent species go through a crisis period of minimal cell growth before a new cell type emerges that can grow indefinitely in culture, but normal human and chicken cells eventually expire. It is possible to study spontaneous transformation systematically in long-established cell lines of mouse embryo fibroblasts, such as the NIH 3T3 line. These can be kept in a nontransformed state, capable of forming a flat monolayer of regularly arranged cells at confluence, if they are subcultured every few days at low population density. If they are kept under the growth constraint of confluence for 2 weeks or longer, foci of transformed cells begin to appear. These foci are just like those produced in C3H10T1/2 cells after exposure to carcinogenic PAH, consisting of closely packed, multilayered criss-crossing cells. The number and size of the transformed foci depends on the length of the incubation period and on the concentration of animal serum in the medium. If a low concentration of serum is used, the confluent cells have to be subcultured and grown again to confluence for foci to appear. Each cell from a transformed focus can initiate a new focus if subcultured on a background of nontransformed cells. The continued capacity for nontransformed cells to undergo transformation depends on the type of serum and the frequency of subculture. After many low-density passages in medium containing a high concentration of calf serum, followed by growth to confluence in a low concentration of serum, the foci produced at first are small and light-staining, but they become larger and darker staining on further passages. Cells from the larger foci produce sarcomas within a few weeks when inoculated subcutaneously into immune-deficient mice. There are many types of morphologically distinct foci in a spontaneously transformed, established cell line, just as there are in primary cultures of baby mouse skin, indicating that there are many pathways to transformation in both cases. Unlike the foci from the primary cultures, however, those

from the NIH 3T3 cells are tumorigenic. There is also evidence that incipient, or unapparent, changes are occurring in the cells before they produce morphologically distinct foci (11). The progressive development of the foci has parallels to the progressively malignant stages of naturally occurring cancer in animals and humans.

The characteristic of cells in culture that correlates most closely with tumorigenesis in animals is known as *anchorage independence* , and it signifies the capacity to multiply while suspended in a soft agar or methylcellulose. Such growth in suspension demonstrates an escape from the requirement of normal cells to attach to and spread on a solid substratum in order to multiply. Oddly enough, repeated seeding of large numbers of nontransformed cells in soft agar suspension, which inhibits their growth, sometimes results in a transformation that permits a cell to multiply in suspension; this does not happen when the cells are growing at a maximal rate attached to the surface of a culture dish. Each of the transformed clones isolated from the agar is morphologically unique, just as each human cancer is unique. Inoculation of large numbers of cells from an anchorage-independent colony into immune-deficient mice results in a rapidly growing tumor within 2 to 3 weeks, but smaller numbers of inoculated cells may produce a disproportionate delay before a tumor appears. Cells from the early tumors grow as well as the original cell culture line when placed in cell culture, but very few cells from the delayed tumors grow in culture, and most of these grow at a low rate. This indicates that the cells have undergone a selection for ability to grow in the mouse during their long incubation and thereby have reduced their capacity for growth in culture. Furthermore, there is great heterogeneity in capacity to produce colonies in agar suspension among individual cells from the delayed tumors. Such variation indicates that a continuous, progressive evolution is occurring in the delayed tumor for improved capacity for continuous growth in the mouse. The great complexity of these growth dynamics has parallels in the great diversity of genetic lesions in human cancers, as will be discussed in the next section.

An unexpected feature of the work with spontaneous transformation is that the procedure of long-term confluence that evokes it also results in some cell death in the confluent culture and in a heritable reduction in growth rate at low population density of the surviving population that later produces transformed foci. It will be recalled that mouse cells transformed by treatment with carcinogenic PAHs also multiply at a lower rate at low density than the parental nontransformed cells. This appears to be true of most, but not all, clones of transformed cells, whether induced by chemicals or spontaneously. These are the same cells that continue to multiply and form transformed foci at high population density when the surrounding nontransformed cells have ceased net multiplication. The reduction in growth rate at low density of the cells is heritable, indicating that genetic damage has occurred (12). It occurs both in transformed and nontransformed cells after prolonged incubation at confluence, indicating that the genetic damage is widespread in the population, but the extent of growth reduction is highly variable, and only certain damage results in transformation. In another cell system, a wide variety of mutagenic chemicals cause a heritable reduction in growth rate of the mutated cells, and the slowdown is related to chromosomal rearrangements and deletions. Because most of these compounds are also carcinogenic, the implication is that neoplastic transformation is frequently the result of chromosomal changes rather than point mutations.

The chromosomal changes, however, are not necessarily visible at the level of the light microscope. For example, two fibroblast cell lines were isolated from a Chinese hamster embryo. Both lines have a stable diploid mode of chromosomes that are apparently normal in appearance. By the criteria of growth in suspension, colony morphology, and tumorigenicity, one of the lines is transformed and the other is not. On prolonged exposure to the cytotoxic drug methotrexate (see Aminopterin, Methotrexate, Trimethoprim, and Folic Acid), the transformed line develops resistance three times faster than the nontransformed line. A major part of the resistance to methotrexate is the result of gene amplification (increase in gene copy number) of the gene that codes for the enzyme blocked by methotrexate. In this treatment, large-scale changes in chromosome composition are seen. The implication is that chromosomal changes occur much more readily in neoplastic than in normal cells, with the further implication that those changes underlie the progressive increases in malignant

behavior (invasiveness, metastasis) that occur in tumors.

The same biochemical effect that is induced by treating cells with methotrexate can be achieved by depriving the cells of the vitamin folic acid, which is the substrate of the enzyme blocked by methotrexate. Either treatment causes single- and double-strand breaks in DNA. Folic acid deficiency also increases the metastatic capacity of cancer cells and causes a heritable decrease in the growth rate of cells. It has been suggested that dietary deficiency in folic acid may contribute to the onset of cancer in humans. It may be recalled that a deficiency of choline or methionine results in cancer in experimental animals. Therefore, a part of the damaging and transforming effect of prolonged incubation of cells at the high population density of confluence could be due to depletion of vitamins or amino acids from the medium. Heritable reduction in growth rate of cells is also a hallmark of cell aging in animals and could be the result of accumulated chromosomal damage below the resolution of the light microscope. The relation between the genetic damage, age, and neoplastic transformation will be discussed below.

7. Summary of Findings in Experimental Cancer and Cell Transformation

Injection of a single RNA tumor virus particle can initiate a tumor in animals or transformation in culture. Molecular analysis has shown that a single transforming gene in the viral RNA is the responsible agent. However, such transforming viruses are of little importance in nature, and the tumors they produce in adult animals usually regress. Cellular counterparts of viral transforming genes do not transform cells unless associated with strong retroviral promoters. Transformation initiated spontaneously or by physical and chemical carcinogens is a much more complex and multistaged affair than viral infection, and in many cases it involves large-scale changes at the chromosomal level. A single initiating treatment of cultured cells with a carcinogenic PAH or X-rays genetically alters most or all of the cells in a population in a manner that increases the probability of transformation in their descendants, but the transformation itself only occurs in a small fraction of descendants of each altered cell. The population-wide alteration induced by carcinogens was at first thought by many to be epigenetic or physiological in nature. However, it has been shown to be heritable, and there is evidenc that treatments such as X-irradiation, chemical carcinogens, or prolonged periods of crowding and nutritional deficiency cause genetic damage that apparently differs from cell to cell, but genetically destabilizes most of them. There is a general association of transformation with chromosome changes in these treatments. Some of the carcinogens interact directly with DNA, but many do not, indicating that the genetic changes in the latter case are indirect. Such indirect effects have been called epigenetic or dysgenetic, but the ultimate effect is on DNA structure. Many of the indirectly acting agents are clastogenic or disruptive at the chromosomal level, causing recombination, deletion, or asymmetric distribution of chromosomes at **mitosis**. Such changes are not detected in the *Salmonella* test for mutagenesis, which depends on local base substitution or frameshifts in DNA. They can, however, be detected in animal cell culture. There is great diversity in the morphology of transformation, indicating a very large variety of transforming genetic changes. But there are many more chromosomal changes that do not transform cells, so the transforming changes can be considered a selection from among many possibilities. This indicates that it may not be possible to predict which chromosomal changes will cause transformation. This is all the more true because the sensitivity of cells to transformation varies with the initial state of the cells and the methods and materials used in subculturing the cells. Cells thawed from different frozen vials of the same stock of tumor cells will exhibit different growth properties, especially when those properties are repeatedly measured in serial subcultures over an extended period of time. The unpredictable details of the long-term growth behavior of cells, combined with its general dependence on the conditions of culture, are not dissimilar from the extreme heterogeneity and unpredictability of tumors in animals, and tumors are in stark contrast with the relative constancy of function and behavior of normal tissues over extended periods of time. *In vitro* transformation reveals great sensitivity to environmental conditions, such as cell density, serum type, and frequency of subculture, which therefore reflect an epigenetic or conditional aspect of transformation.

8. Neoplastic Transformation in Humans

The concerted application of molecular genetics to human cancer began with the transformation of NIH 3T3 cells in culture by DNA from a long-term cell population that had been cultured from a human bladder cancer and with the demonstration that the transforming gene was a mutant form of the cellular *ras* gene. (See section on **Viral transformation** .) Given the common occurrence of genetic variation in cell culture, especially that of human tumors, there is reason to question the conclusion that the mutation caused, or even existed in, the tumor. Those doubts are reinforced by the finding that the gene has to recombine with a strong mouse promoter in order to transform the NIH 3T3 cell. Nevertheless, the finding set off attempts to detect the altered gene in other human cancers. The mutation was reported in the benign tumors (adenomas) that precede colon cancers. Other genetic changes were found in early stages of colon cancer, and it was concluded that five to seven mutations were required to produce advanced stages of cancer. However, it was then found that more than 20% of the alleles of heterozygous genetic loci were lost in the average sporadic colon cancer, which casts doubt on the estimates of the number of mutations needed to produce the cancer. Indeed, the estimates of the number of altered genes in the average case of sporadic colon cancer is now estimated at greater than 25% of the entire genome (13), which implies many thousands of genetic changes during development of the cancer. It should be kept in mind, however, that *ras* mutations found in mutagen-induced rat mammary tumors actually arose from preexisting *ras* mutants. That raises the question of how many of the mutations reported in tumors arose before the tumor, and what role, if any, they had in development of the tumor. Another finding that raises specific questions about the role of *ras* mutations is that *N-ras* gene function of mice can be knocked out entirely in the earliest stages of development without affecting either the growth or development to adulthood. As methods for detecting genetic changes improve, the number of such changes in tumors increases. When the technique of comparative genomic hybridization was introduced into studies of human mammary cancer, 21 new chromosomal subregions of gene amplification were added to the five already known. The same methodology applied to prostate cancer detected about 30% of the chromosomal regions with a significant increase or decrease in gene copy number in the average case, and some of the cancers had such alterations in more than 50% of the sites (14). These changes involve large chunks of chromosomes, indicating rearrangements and large deletions or amplifications. Although some particular sites were altered in a high percentage of the prostate cancers, no two cancers had the same distribution of altered sites. This confirms what had been reported earlier, that the karyotype of glial tumors was different in every case and, furthermore, that it rapidly changed when the cells were placed in culture. The very large number of copy number changes in genes of prostate cancer seems surprising in view of evidence that nearly 50% of metastatic prostate cancers have a diploid DNA content. The diploid DNA content in so many advanced prostate cancers shows that equal proportions of the genome can be lost or gained, resulting in an overall balance of genetic material. The large number of genetic alterations in cancers indicate great instability in the tumors, but it also creates problems in determining which of the alterations bear a causal relation to development of the tumor, and how many are required to produce its progressive growth. It also raises questions about the source of such instability. One possibility is that an epigenetic change in methylation might lead to defects in chromosome disjunction and distribution at mitosis. Marked decreases are found in **methylation** among each of four genes tested in benign and malignant colonic neoplasms. Because the hypomethylation is prevalent in the benign tumors, the great majority of which have been reported to have no genetic alterations, it is possible that the altered methylation patterns drive the chromosomal changes. In support of such a possibility is the finding that experimentally induced hypomethylation induces transformation in a diploid line of Chinese hamster cells at a high frequency and that the transformation is in every case associated with DNA hypomethylation and the presence of an extra copy of part of a single chromosome. Hence, there may also be a relation between methylation and fragility of chromosome sites, which determines the likelihood of chromosome breaks in particular tissues.

A percentage of human tumors occur in dominantly inherited patterns in families. About 15% of colorectal cancers fall into this pattern (12). Hereditary nonpolyposis colorectal cancer (HNPCC) is one such familial cancer. It is related to germ-line mutations of mismatch repair genes. This results

in changes in short repeated sequences of DNA (**microsatellites**) in colorectal cancers. The question arose whether similar changes occur in normal tissues of HNPCC patients who had few tumors. Using special amplification methods, it was found that the normal tissues of these patients had a high incidence of these mutations. This shows that the existence of many mutations in cells of tissues throughout the body is not sufficient to initiate cancer, nor is the presence of the mutations in the tumor proof of their causative role. This moved a prominent geneticist to recommend a more rigorous look at the evidence that mutation induction constitutes a rate-limiting step in carcinogenesis (15). Other factors that contribute to carcinogenesis will now be considered.

9. The Role of the Tissue Environment in the Origin of Tumors

Teratocarcinoma is a malignant tumor derived from **germ cells** and consists of many different cell types. It can be induced experimentally in mice by transplanting 6-day-old mouse embryos under the testis capsule of adult male mice. The normal diploid tumors can be grown in culture and will produce malignant growth when a single cell is inoculated under the skin of mice. When the same cells are inoculated into the very early embryo (blastocyst stage) of mice, normal development occurs, and redifferentiated teratocarcinoma cells contribute to normal development of many tissues, including some never seen in the original tumors (16). They also contribute to the germ line, which produces normal progeny mice from **gametes** of the teratocarcinoma line. The authors of this work concluded that the conversion to malignancy in all likelihood did not involve mutational events and was completely reversible to normal function and appearance. While it has not been proven unequivocally that there were no mutations involved in causing the teratocarcinoma, it is apparent that the local environment was the determining factor in the origin and in the reversal of this malignant behavior.

A related situation exists in the newt *Triturus cristatus* . Inoculation of carcinogenic PAHs in nonregenerative regions of the newt induced metastasizing tumors that killed the host. Tumors induced in regenerating regions healed spontaneously and differentiated to normal tissues. The malignant behavior of these tumors, therefore, is dependent on the lack of regenerative potential of the surrounding tissue.

There is evidence that the local environment of tissues changes with age. For example, there is a 50-fold increase in the activation of the “inactive” X-chromosome in the liver of aging female mice, and there is a sixfold decrease in the transcription of a certain globulin gene in liver cells. The expression of genes is related to their state of methylation, which may serve as a surveillance mechanism for chromosome loss. The 5-methylcytosine content of tissues decreases with age in mammals, including humans, and the rate of loss of these methylated nucleotides correlates inversely with age in two rodent species that differ in lifespan by a factor of two. This suggests a tie-in between aging, tissue organization, methylation, and chromosomal alterations underlying cancer. The incidence of cancer in humans increases sharply with age (17), and the susceptibility of tissues to carcinogenesis also increases with age. If lung tissue of mice is damaged by X-irradiation or certain cytotoxic chemicals, there is a large increase in the number of metastases that occur in the lung when metastatic cells are inoculated intravenously. Inoculation of rat liver cancer cells into the liver of old rats is much more likely to produce a progressively growing tumor there than if the cells are inoculated into the liver of young mice. In contrast, the liver cancer cells inoculated into the liver of young mice are much more likely to differentiate into normal liver cells. It is apparent that the local environment of the liver in old mice is more favorable for tumor growth than the liver of young mice.

The tissue environment in which human cancers develop appears to be different from that of normal tissues. In cancer of the bladder, there is a gradient of biochemical and cytological abnormality extending for some distance from the edge of the tumor. Loss of **alleles** of some genes occurs in morphologically normal tissue adjacent to breast cancers. Cancer of the esophagus in patients with predisposing conditions is preceded by chromosome changes in large areas of the esophagus in which cancer later arises. The transitional mucosa immediately adjacent to colorectal cancers

contains a variety of biological abnormalities but no evidence of genetic change. There is a 15-fold increase in transcripts of the methyltransferase enzyme catalyzing DNA methylation in normal colonic mucosa from patients with either polyps or cancer of the colon. It is generally believed that tumors progress by a sequence of genetic changes. As each new mutation appears that selectively favors the mutated cell, the microenvironment of altered cells in which the newly mutated cell is growing may be more favorable for further tumor development than normal tissue. These are all factors that must be taken into consideration in understanding the growth of tumors, and particularly their high degree of genetic instability. A comparable instability is seen when normal rodent cells are dissociated from one another and grown in monolayer culture. Human cells under the same conditions remain largely diploid but lose reiterated sequences of DNA, including **telomeric** DNA. Chromosomal instability persists after the cells have established themselves as a cell line, as indicated by the report that no two cells of a line of rat hepatoma cells were found to be karyotypically identical. Hence, it is possible that the high degree of genetic instability found in human cancer is due not only to the intrinsic instability of the cells, but to the loss of normal organization within and adjacent to the tumor.

10. Overview

There are many ways of producing neoplastic transformation: with high efficiency by RNA tumor viruses, with low efficiency by carcinogens, and by dependence on the environment, as in prolonged crowding in certain cell lines in culture. The resultant transformed cells are usually genetically altered, as indicated by the irreversibility of the altered state and the demonstration of altered gene and chromosome composition of the cells (except for exceptional cases like teratocarcinoma, which exhibits in its very origin and reversibility the importance of the surroundings in which cells grow). The idea that transformation could result from mutation in one or a few genes arose first from transformation by RNA tumor viruses and seemed to receive confirmation by transforming especially sensitive NIH 3T3 cells with an altered *ras* gene isolated from an established cell line that originated from a human bladder cancer. Attempts to generate the same kind of transformation with other genes from tumors were unsuccessful. It was then shown that the transformation by the *ras* gene depended on recombination with strong promoter elements, with no indication that it had such a relation in the original tumor. Furthermore, the NIH 3T3 target cells were shown to transform by themselves without transfection, by long-term incubation under growth constraining conditions. There is also the likelihood that the *ras* mutation in chemically induced tumors of rats occurred during normal development.

Despite these reservations, the idea grew that cellular genes with nucleotide sequences like those of RNA tumor viruses were potential “oncogenes” if activated (mutated). It was then found that some genetic loci that were heterozygous in normal tissues of an individual with cancer were homozygous in the tumor. These “loss of heterozygosity” (LOH) genes were then considered to be tumor suppressors in the heterozygous state in normal tissue, although there was no direct evidence for such a role aside from the clonal occurrence of the homozygous state in tumors. There were mathematical arguments that the development of solid cancers required five or more steps; and mutational analysis, particularly of colorectal cancers, was taken as support of the argument. As methods detecting genetic changes were refined, however, more and more of them were found in cancers. Chromosome counting evolved to banding of chromosomes, methods were developed for **allelotyping** DNA, and comparative genomic **hybridization** could detect changes in gene copy number in any region of the genome. These methods then detected changes in some common cancers at an average of 25% to 30% of the chromosomal sites per case, and in more than 50% of the sites in a few cases. This indicated a great instability in the cancers, with alterations in thousands of genes. It is well known from classic genetics that the expression of any multigenic phenomenon is very dependent on the genotypic milieu, so that a given mutation may be deleterious in one genetic milieu and advantageous in another. Thus, the combination of mutagenic changes in genotypic milieus that are different in every human, plus the sensitivity of multigenic phenotypes to the surrounding environment, account for the difficulty in predicting the likelihood of nonfamilial or sporadic cancers or their outcome once they appear. Such a high degree of complexity and the problems of

establishing causal chains in organisms were anticipated in the theoretical work of Walter Elsasser (18). Even where there is a dominant germ-line mutation that favors development of cancer with a probability approaching unity, the time of onset cannot be predicted, and only a very small fraction of the cells, all of which carry the mutation, become transformed; to do so, additional mutations are required, but they can be found in normal tissue as well. To achieve a better understanding of cancer, it will be necessary to take into account the genome of the transformed cell, the state of the surrounding tissue, the age of the organism, its diet, and the environment in which it lives.

The reader should also consult the entries on **Antioncogenes, Cell cycle, Contact inhibition, Oncogenes, Protooncogenes**, ***ras* genes, Rous sarcoma virus, Somatic mutation, Tumor necrosis factor, Tumor promoters**, and Tumor suppressor genes for further information on neoplastic transformation.

Nerve Growth Factor and Related Neurotrophins

The neurotrophins are a family of dimeric proteins that control key neuronal behaviors, including growth, differentiation, function, and survival. These proteins are structurally similar molecules that are expressed in greatest abundance within the nervous system and various target sites of innervation. Nerve growth factor (NGF) was the first member of the neurotrophin family, having been discovered over 40 years ago by Rita Levi-Montalcini, to whom (along with Stanley Cohen) the Nobel Prize in Medicine was awarded in 1986. Studies of this protein have been at the frontier of many life sciences, particularly protein chemistry, molecular biology, structural biology, and the neurosciences.

The neurotrophins interact with membrane-spanning surface receptors of responsive cells, thereby activating signal transduction cascades that trigger distinct biological responses. The dysfunction of neurotrophic mechanisms has been implicated in the pathogenesis of a number of neurological disorders, thereby creating considerable interest in targeting them for therapeutic development. A tremendous effort is currently underway to define novel biological actions of neurotrophins and the mechanisms of their receptor interactions and signal transduction pathways, as well as to develop novel agents mimicking their biological activities.

1. The Discovery of NGF

The concept of a “trophic” substance guiding the growth of axons was formulated by Ramón y Cajal, at the beginning of this century. This proposal was developed to explain an exciting observation made when peripheral nerve grafts were implanted in the central nervous system (CNS). Cajal and colleagues noted that peripheral nerve grafts were able to support and direct the growth of damaged nerve fibers of the central nervous system. In the late 1940s, Rita Levi-Montalcini and collaborator Viktor Hamburger began to study the development of the nervous system, including the mechanisms whereby the correct number of peripheral neurons innervate the correct peripheral target. Using the chick embryo as a model system, these investigators demonstrated that development of the nervous system was accompanied by a steady increase in the number of neurons; as they reached their target, however, the number decreased to the final population. This discovery provided the basis for the “neurotrophic hypothesis” of neuronal development. This model states that an excess number of neurons innervate the target tissue during development. As the target produces a limited amount of neurotrophic substance, the excess neurons are deprived of trophic support and die off, presumably as a result of competitive mechanisms. It is now recognized that the excess neurons die via apoptosis (or programmed cell death), leaving the optimal number of intact connections.

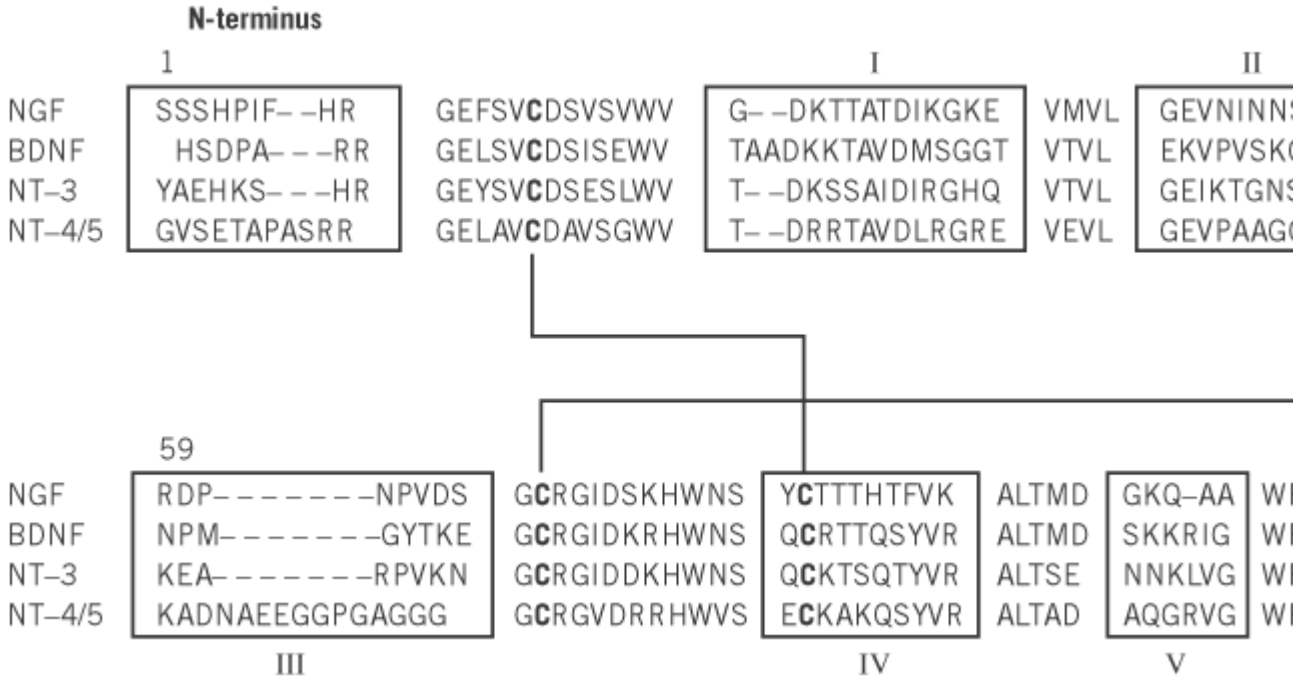
The biochemical characterization of this factor began in the early 1950s with the discovery that a sarcoma tumor cell line implanted into embryos promoted the growth of ganglia neurons, suggesting that a chemical substance was mediating the effect. Levi-Montalcini and Cohen identified a

nucleoprotein fraction obtained from the sarcoma tumor that promoted neurite outgrowth. A “nerve growth promoting factor” was purified by the late 1950s, which has subsequently become known as NGF. The biochemical characterization of this protein was greatly facilitated by the observation that the male mouse salivary gland was a very rich source of the protein. The subsequent 30 years of investigation provided the purification and amino acid sequencing of this and similar proteins, along with the cloning of the **genes** for the human neurotrophins. More recent years have witnessed the identification of additional neurotrophin family members, their receptor proteins, and a host of novel biological activities of the neurotrophins.

2. Structures of Neurotrophins

The mammalian family of neurotrophins is now comprised of four members. In addition to NGF, brain-derived neurotrophic factor (BDNF) was discovered using classical biochemical purification of the protein from pig brain. More recently, neurotrophin-3 (NT-3) and neurotrophin-4/5 (NT-4/5) have been identified using molecular biology techniques and DNA sequencing. All four members of this family share striking sequence homology (Fig. 1). The illustrated pattern of disulfide bonds is identical in all neurotrophins. It is apparent from the alignment of the primary structures of the neurotrophins that the conserved regions of all family members are located in the same regions, leaving a series of variable regions at the amino and carboxyl termini and interspersed within the primary structure at regular intervals. It was hypothesized early in the characterization of these proteins that the conserved domains maintain the structural features of the neurotrophins, whereas the variable regions mediate the interactions with the specific receptors.

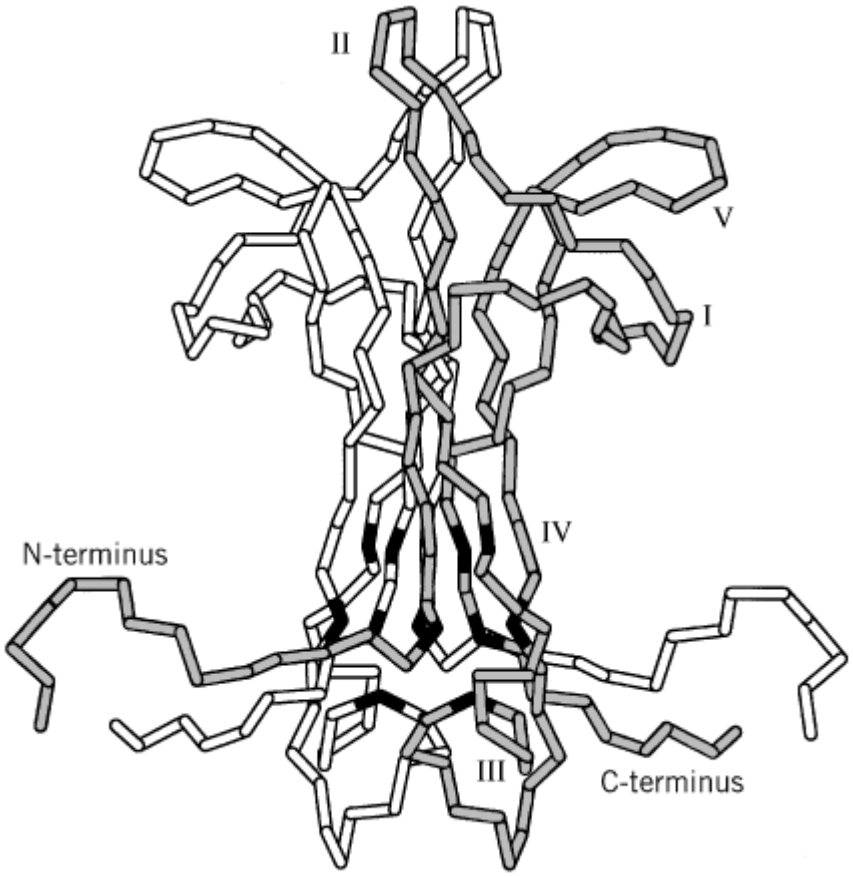
Figure 1. The amino acid sequences of the human neurotrophins NGF, BDNF, NT-3, and NT-4/5. The regions with the ; boxes; their general location within the neurotrophins is depicted in Figure 2. Cysteine residues are shown in bold, with t bonds (which form a cystine knot) indicated by the single lines.



The structure of NGF was solved by X-ray crystallography in the early 1990s (1). The structure of this protein (Fig. 2) turned out to be remarkable, most notably with respect to a unique folding pattern and a novel cystine knot motif. This structure consists of three antiparallel pairs of b-strands that form a flat surface, with two polypeptide chains of NGF associating through this surface. The

three disulfide bonds that form the cystine knot link these strands and help to stabilize the unique tertiary conformation of NGF. Most of the variable regions (namely I, II, III, and V) are located within the exposed loops, which probably represent the parts that dock with receptor (Fig. 2). The crystal structure of other members of the neurotrophin family have now been determined, and the general conformation depicted for NGF appears to be common for all the neurotrophins.

Figure 2. The conformation of NGF as determined by X-ray crystallography (1) and molecular modeling (for the flexible amino and carboxyl termini only, ref. 11). This a-carbon trace demonstrates the way two identical polypeptide chains of NGF (indicated in white and gray) associate to form a dimeric protein. Cysteine residues that define the cystine knots are illustrated in black. The variable regions of the neurotrophins are indicated by Roman numerals, as in Figure 1, for one protomer; they represent areas that are accessible, possibly for receptor binding. The amino- and carboxyl-terminal regions of NGF are involved in binding to TrkA receptor, whereas loop regions I and V are recognized by $p75^{NTR}$.



3. Neurotrophin Receptors

Each of the mammalian neurotrophins binds to two distinct receptor types. All four neurotrophins bind to the common neurotrophin receptor designated here as $p75^{NTR}$ (which is also known in the literature as p75, $p75^{NGFR}$, and p75LNGFR). The **dissociation constants** of the neurotrophins for $p75^{NTR}$ are similar (in the nanomolar concentration range), while there are subtle differences in the rates of binding. Conversely, each of the neurotrophins interacts rather specifically with a member of the Trk **tyrosine kinase** receptor family: NGF binds TrkA, BDNF and NT-4/5 bind TrkB, and NT-3 binds preferentially to TrkC. Binding of the neurotrophins to the Trk receptors is generally of higher affinity (occurring at picomolar concentrations) than that to $p75^{NTR}$, so the receptors are often referred to as the high-affinity (Trk) and low-affinity ($p75^{NTR}$) binding sites. Over the past decade,

significant efforts have been focused on (a) the activation of signal transduction pathways, (b) biological outcomes, and (c) the comodulation of this two-receptor system (2, 3).

4. The Common Neurotrophin Receptor $p75^{NTR}$

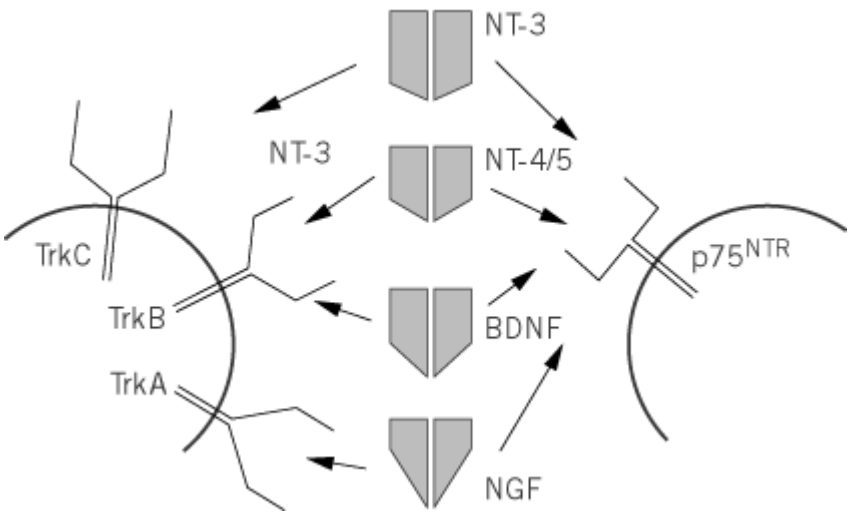
The first receptor identified for neurotrophins, $p75^{NTR}$, was recognized in the early 1970s as a cell-surface receptor for NGF. The common neurotrophin receptor plays a variety of roles in neurotrophin signaling, including the enhancement of Trk activity as well as Trk-independent signaling. Signal transduction cascades induced by $p75^{NTR}$ include the production of ceramide as a result of activation of sphingomyelinase, activation of JNK (c-JUN amino-terminal protein kinase), and the translocation of nuclear factor kB (NFkB). Interestingly, while all of the neurotrophins bind to $p75^{NTR}$ with similar affinities, the resulting signaling cascades are neurotrophin-specific. Binding of NGF to the common neurotrophin receptor enhances Trk activity, while pathways that are independent of Trk activation may, under appropriate conditions, lead to an apoptotic cell death (4).

The common neurotrophin receptor is one member of what has come to be known as the "death domain" family of receptor proteins. This family (which includes Fas receptor, tumor necrosis factor receptor, and others) share specific sequence homologies, including an intracellular "death domain" sequence. In addition to the conserved intracellular domains, $p75^{NTR}$ and the tumor necrosis factor receptor $p55^{TNFR}$ also share conserved extracellular features, particularly the cysteine-rich domains (5).

5. The Trk Family of Neurotrophin Receptors

A major breakthrough in the study of neurotrophins occurred in the early 1990s with the discovery that the *trk* proto-**oncogene** encoded a 140-kDa protein ($p140^{protoTrk}$) that was shown to be a receptor for NGF (6). This protein was initially called Trk, but later became known as TrkA as more neurotrophin receptors of the Trk family were identified. Each of the Trk receptors is relatively specific for each neurotrophin (Fig. 3). It is now well established that the Trk receptors mediate most of the biological actions of the neurotrophins, particularly with regard to cell survival, differentiation, and growth.

Figure 3. Neurotrophin receptor selectivity. All neurotrophins bind to $p75^{NTR}$ with similar affinities. Selective receptor interactions are observed with the Trk tyrosine kinase receptors: NGF binds TrkA, BDNF and NT-4/5 bind selectively to TrkB, and NT-3 binds preferentially to TrkC. In general, the Trk receptors possess higher affinity for neurotrophins than does $p75^{NTR}$.

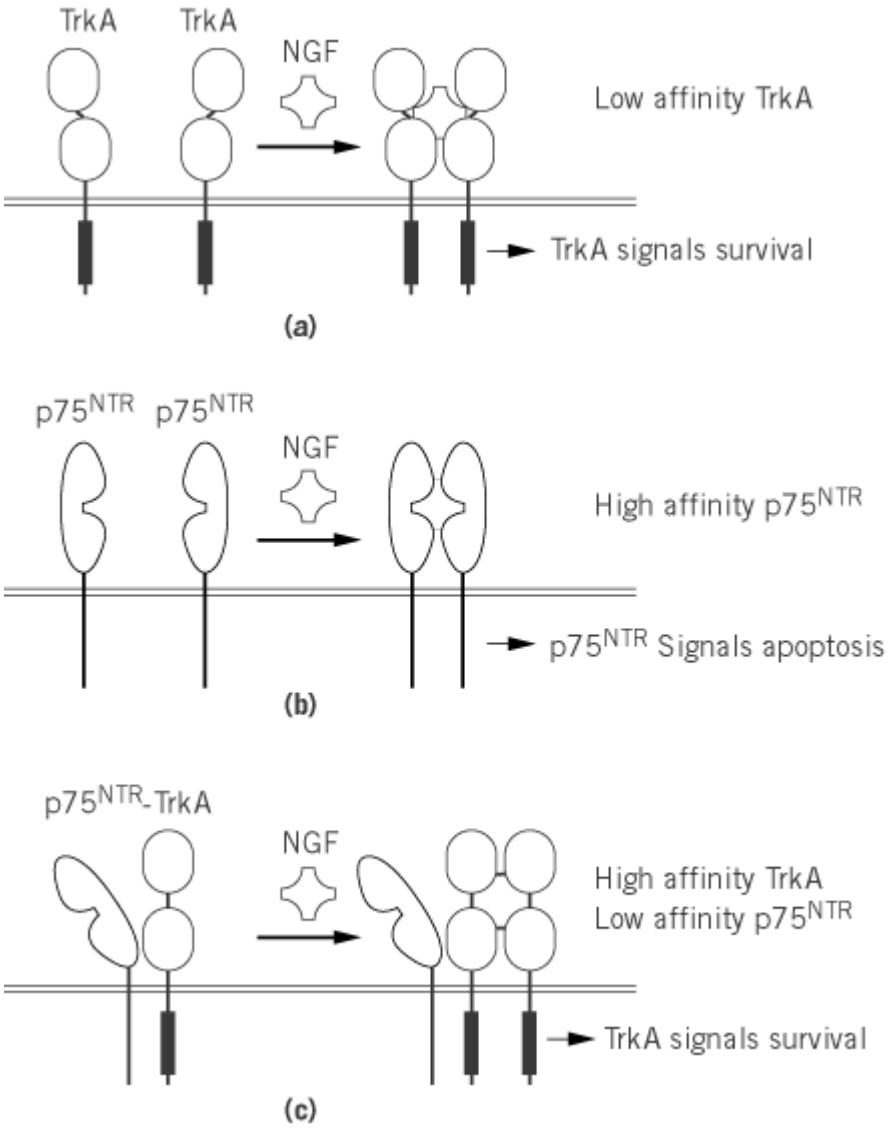


Activation of TrkA receptors is initiated by a ligand-induced dimerization that leads to activation of the receptor's tyrosine kinase activity and autophosphorylation of tyrosine residues within the intracellular domain of the receptor. Once phosphorylated, the Trk receptors interact with a number of cytoplasmic proteins. These interactions can activate multiple intracellular signaling pathways, including **phospholipase C**-1, PI3-kinase, **Ras**, MEK, and others. The signaling mechanisms of TrkB and TrkC have not been sufficiently investigated, but these receptors are also known to dimerize and to autophosphorylate upon ligand binding, and they probably share many of the transduction pathways with TrkA (7).

6. Interactions Between $p75^{NTR}$ and TrkA

Considerable experimental data accumulated over the past decade suggest that $p75^{NTR}$ modulates the activity of TrkA. As such, it has long been proposed that there is probably a direct interaction between these two receptors, although such an interaction has been difficult to demonstrate directly. The importance of demonstrating such an interaction has increased recently with the recognition that $p75^{NTR}$ can induce cell death, but only in the absence of TrkA. These observations led to the conclusion that the receptor modulation is reciprocal, and they provide further evidence that a direct interaction exists. Several recent reports provide direct evidence for an interaction between these two receptors, and it has been suggested that a transient TrkA-$p75^{NTR}$ complex exists in the absence of NGF. It appears that $p75^{NTR}$ has the ability to enhance the effects of TrkA, while the TrkA receptor can inhibit the activity of $p75^{NTR}$ (8). In the context of receptor expression on a neuronal cell, this situation could ensure neurotrophin-mediated survival of Trk-expressing cells, while the apoptotic death of cells expressing Trk receptors would be inhibited. The possible receptor expression patterns and examples of cellular outcomes in response to NGF are illustrated in Fig. 4.

Figure 4. Potential cellular responses to NGF. The direct interactions of neurotrophin receptors TrkA and $p75^{NTR}$ is an emerging concept. Cells that express TrkA only (**a**) will undergo typical responses to NGF, including growth, survival, or differentiation. Cells expressing only $p75^{NTR}$ have the potential to undergo apoptosis in response to NGF (**b**). Where both receptors are present, an enhanced TrkA outcome is observed, such that cells respond to NGF more efficiently and by a TrkA-mediated mechanism (**c**). In the presence of TrkA, $p75^{NTR}$ does not induce an apoptotic signal. Experimental data indicate that these receptors interact allosterically, such that TrkA induces a lower affinity state in $p75^{NTR}$, while $p75^{NTR}$ induces a higher affinity state in TrkA.



7. Biological Actions of Neurotrophins

Many different biological outcomes have been demonstrated to result from the treatment of a responsive cell with a neurotrophin. Most were identified originally using cultured cells obtained from the developing nervous system. With respect to nerve cells (neurons), the most studied effects of the neurotrophins are on differentiation, growth, and survival. Neuronal differentiation is a process wherein a precursor cell differentiates into a neuron (perhaps, with a specific neurotransmitter **phenotype**). The growth of neurons may include features such as the length and the number of branches of neurites. These features may be quite distinct depending on, for example, whether the neuron is developing or has been damaged (as in nerve regeneration). With regard to survival, the roles of neurotrophins are turning out to be quite complex. While the neurotrophins have classically been considered to be survival factors, it is now apparent that some cells can under certain conditions undergo NGF-mediated cell death. Apoptotic cell death appears to be mediated solely by $p75^{NTR}$, because NGF-mediated cell death is generally restricted to cells that are $p75^{NTR}$-positive and Trk-negative (4).

The biological actions of neurotrophins are not limited to neurons or to cells of the nervous system. Many non-neuronal nervous system cells (such as Schwann cells, oligodendrocytes, etc.) respond to neurotrophins, which may mediate such biological outcomes as cell migration and proliferation.

Outside of the nervous system, the neurotrophins influence the activity of several cellular members of the immune system, including B lymphocytes and mast cells. NGF causes degranulation and histamine release from mast cells, which can alter neuronal function by indirect mechanisms (9).

8. Emerging Concepts

Consistent with the recognition of expanding roles and multiple actions of the neurotrophins, new concepts of their influence on biological systems are being developed. It is now recognized that the neurotrophins can modulate specific behaviors of nerve cells. With respect to pain mechanisms, the neurotrophins can influence the phenotype of neurons, and they may play a key role in the perception of normally innocuous stimuli as painful ones. The neurotrophins have also been shown to alter the functions of neurons in acute conditions, acting to alter **ion channel** function and neurotransmitter actions within fractions of a second. These actions are quite discrete from the slower activities of their modulating functions, such as growth and survival, which generally involve the biosynthesis of new proteins and occur over a much longer time scale.

With the recognition that NGF may trigger immediate cellular responses, in contrast with active cell death versus survival, there is now considerable focus on the multiple receptors for NGF and their interactions. Specifically, the way that direct interactions of these receptor proteins may lead to such dramatically different outcomes is of tremendous interest. It is now becoming apparent that how a cell will respond to NGF is a function of the exact receptor expression pattern (including the receptor ratios) and also the signaling pathways that the cell is able to recruit. Given the complexity of a system with interacting receptors and the possibility of selective recruitment of multiple signaling pathways, it is understandable how so many different cellular outcomes could result from exposure to neurotrophins.

9. Therapeutic Potential of Neurotrophin Agonists and Antagonists

A number of neurological diseases are characterized by neuronal death and loss of connectivity within the nervous system. The recognition that neurotrophins represent potent survival factors and modulate neuronal plasticity has generated considerable expectations for the potential use of the agents for therapeutic development. In particular, a significant effort has been mounted to identify Trk receptor agonists that would mimic the effects of neurotrophins. The neurotrophins themselves, while the focus of much activity, will probably have limited therapeutic efficacy due to their inability to penetrate the blood–brain barrier. The identification of small organic compounds that are Trk agonists and likely to gain access to the CNS has been disappointing thus far. Clinical trials on the neurotrophins themselves have provided some encouraging results, particularly for peripheral indications, but none of them are currently approved for clinical use in humans (10). Several new approaches to modulation of neurotrophin biology are underway, including the identification of agents that alter signal transduction pathways and receptor–ligand and receptor–receptor interactions. As new roles for neurotrophin activities are being defined, most notably with regard to pain mechanisms and immune function, the clinical utility of neurotrophin antagonists may prove to be highly significant. Such compounds have been identified, and development of new therapeutic agents that block the deleterious actions of neurotrophins may emerge.

Neural Crest

The neural crest is a mass of cells that initially forms between the neural tube and the ectoderm (1). The neural crest then forms two long masses of cells along the dorsolateral side of the neural tube. Soon after forming the neural crest, the neural crest cells begin migrating laterally and ventrally. The migration spreads the neural crest cells throughout the body, coming to lie between the mesoderm and the epidermis and between the organ rudiments. During differentiation, the neural crest cells give rise to pigment cells, the visceral skeleton, subcutaneous connective tissue, and some of the peripheral nervous system.

Neural Networks and Genetic Algorithms

The information about the behavior of biological molecules can be evaluated and classified by different **computer simulation** approaches and can then be used to predict the properties of related systems. Effective ways of performing such tasks are provided by neural networks (1) and genetic algorithms. Commonly used types of neural nets contain input and output layers connected by a hidden layer. The network is first trained to perform the desired task by being presented with a set of sample input and output. During the training period, the network optimizes the strength of the connections that give the best agreement between the input and output. The trained network can now be used for predictive purposes. Neural networks have been applied to a wide range of problems including predictions of protein **secondary structure**, (2) structure–activity correlation (3), and side-chain conformations (4).

Genetic algorithms can also be used to predict molecular properties. These methods are designed to find optimal solutions to problems using strategies based on biological evolution (5). The first step creates a population of possible solutions whose "fitness" is calculated. Finally, a new population is generated with a bias toward a better fit. Genetic algorithms were originally developed as a technique for global optimization. However, this aim has not been accomplished, and the method is used primarily as an effective way of generating a large number of reasonable solutions (6).

Neural Tube

The neural tube is a structure formed in vertebrate **embryos** that gives rise to the brain and spinal chord. After gastrulation, the neural folds arise as paired structures from the blastopore to the top of the embryo. The neural folds soon fuse to form the hollow neural tube. The anterior portion of the neural tube gives rise to the brain, the posterior portion to the spinal chord.

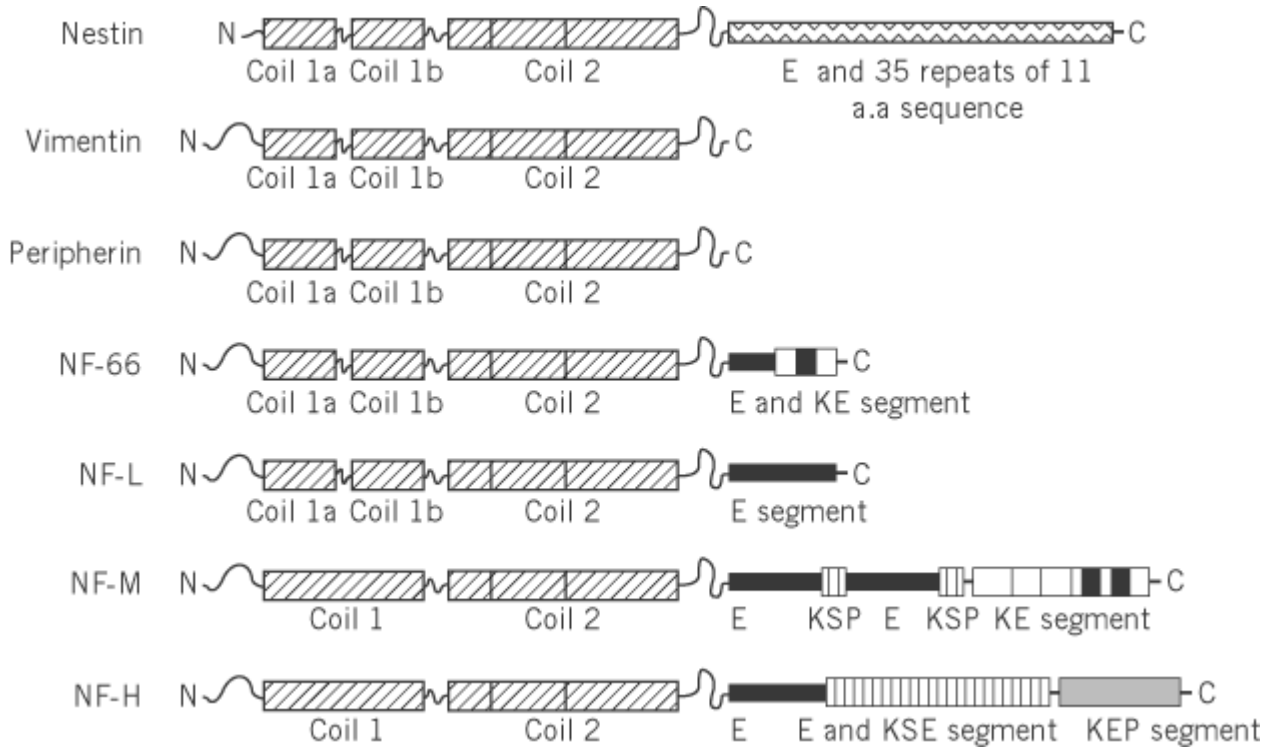
Neurofilaments

Neurofilaments are the intermediate filaments of mature neurons. They are obligate heteropolymers composed of three different subunits, the neurofilament "triplet proteins," designated NF-H ("heavy"), NF-M ("medium"), and NF-L ("light"), reflecting their apparent molecular masses of 200, 145 to 160, and 70 kDa, respectively, as determined by SDS-PAGE (Fig. 1). Unique charge characteristics and extensive phosphorylation of NF-M and NF-H cause these subunits to migrate anomalously on SDS-containing gels, and their true molecular masses are smaller (1). Neurofilament triplet proteins are members of one of the five classes of intermediate filament (IF) proteins, which are tissue-specific proteins distinguished by their amino acid sequences and intron placement. Exclusively localized to neurons, the neurofilament subunit triplet proteins have distinctive amino- and carboxyl-terminal domains that characterize them as class IV IF proteins (2).

Figure 1. Domains of the individual polypeptide chains of neuronal intermediate filaments. Coil 1 and coil 2 regions are conserved a-helical domains containing heptad repeats of hydrophobic amino acids that probably adopt coiled-coil conformations in the trimer. These regions are separated by nonhelical "links" (represented by separation of boxes) and, within coil 2, by single-residue breaks in the heptad repeats (represented by vertical lines). Note that NF-M and NF-H possess a unique, single, elongated coil 1 region, which may restrict their ability to form filaments in the absence of a "backbone" subunit, such as NF-L. The initial segment of the carboxy terminus, which constitutes the tail region of vimentin and peripherin, is followed by the following specialized domains in the other neuronal intermediate filament species. The carboxy terminus of nestin contains glutamic acid-rich segments ("E") and about 35 repeats of an 11 amino acid (a.a.) sequence. Nestin also possesses a relatively short N-terminus. NF-66 and the neurofilament triplet proteins NF-L, NF-M, and NF-H each contain one or more glutamic acid-rich regions ("E segments"). NF-66 also contains a region rich in lysine and glutamic acid residues ("KE segment"). NF-M and NF-H contain repeating regions of the sequence Lys-Ser-Pro ("KSP2 segments"), which represent the sites of extensive phosphorylation of these two species. The extreme termini of NF-M and NF-H possess unique regions rich in lysine and glutamic acid residues ("KE segment") and in lysine, glutamic acid, and proline ("KEP segment"), respectively. [Adapted from Ref. 7 with permission of the publisher.]



Neurofilaments are the most abundant cytoskeletal components in large myelinated axons. Like other IF proteins, individual neurofilaments are discrete, linear structures that extend for distances of at least 10 µm. They are often curved, indicating a flexibility inherent in their construction. Arranged in parallel in axons, they maintain minimal distances of 25 to 30 nm from neighboring filaments, even in pathological states when neurofilaments accumulate. Their regular spacing and parallel alignment stem, in part, from their most unique feature, lateral sidearms that project perpendicularly from the filament backbone.

1. Domain Structure, Assembly, and Developmental Expression of Neurofilament Proteins

As expected for a multigene family evolving from a single ancestral gene (see Gene Families), all intermediate filaments display a similar domain organization, consisting of a central a-helical rod domain of highly conserved size and a secondary structure, flanked by strongly basic domains that are highly variable in sequence. (Fig. 1) (2). The rod domain of every IF subunit is composed of four distinct tracks (IA, 1B, 2A, and 2B) that contain characteristic repeating sequences of seven hydrophobic amino acids. This “heptad repeat” strongly predicts that the rod sequence would form a parallel coiled-coil dimer-the first step in the formation of 10-nm filaments. The constant length of these four tracts across all classes of IF proteins suggests that these regions may be critical components in the assembly of the basic filament.

In contrast to the rod domain, the amino-terminal head domains of IF proteins have diverged considerably during evolution. The head domains assume predominantly b-sheet and b-turn conformations and vary in both size and charge. These regions of neurofilament subunits and other nonepithelial intermediate filaments range in molecular weight from 4.5 to 9 kDa. An excess of positively charged amino acids, particularly arginine residues, confers a highly basic charge to the head domain of neurofilament subunits and to the class III intermediate proteins. The head domain, rich in serine and threonine residues, some of which are phosphorylated or glycosylated, is believed to be important in regulating neurofilament assembly (3-5, 93).

The carboxy-terminal tail region of neurofilament subunits is quite distinctive (6-8) (Fig. 1).

Although the tail domains of class III IF proteins are relatively small (5 to 9 kDa) and similar in structure, neurofilament subunits have large and complex carboxyl termini. By *immunoelectron* microscopy, the NF-H and NF-M tail domains appear as long, thin, fibrous protrusions, or "sidearms," that extend from the cores of axonal neurofilaments. They are largely random coil (6), and four subdivisions can be defined. Each subunit contains a neutral or slightly basic, proline-containing region 3.5 to 5.5 kDa in size, flanked by a 50 to 60-residue glutamate-rich region that may be the homologue of the entire tail domain of other intermediate filament proteins. In NF-H, this segment is followed by a region that consists of multiple repeats of the sequence–Lys-Ser-Pro-("KSP repeats"). These KSP sequences, embedded within motifs of 6 or 8 residues, are arranged in nearly tandem repeats and range in number from 39 to 51, depending on the species. A common polymorphism of human NF-H generates either 43 or 44 KSP repeats (9) although the functional significance is unclear. The corresponding region of NF-M is shorter and contains 4 to 13 KSP repeats and a variable number of repeated sequences characterized by the consensus sequences KXSP or KXXSP, where X is any residue (10). Only serine residues located in KSP and KSP-like repeats are phosphorylated (11) and, at least in axonal neurofilaments, most are phosphorylated in *vivo* (8, 12, 13). NF-H terminates at the carboxy end with a variable, glutamic acid-rich region about 20 kDa in size (14, 15). Its counterpart in NF-M is a 24-kDa region rich in lysine and glutamic acid residues, but virtually no proline, which is very highly conserved in sequence among different species. This latter feature is not shared by any other known proteins, suggesting that it may serve a unique neuronal function (10).

Similar to other intermediate filaments, neurofilaments are believed to assemble from dimer, tetramer, and octamer intermediates of two or more subunits (16-21). Each NF triplet protein has an a-helical rod domain and heptad repeat regions that can initiate the first stage of assembly-coiled coil dimer formation-implying that each subunit may be integral to the neurofilament. Once assembled, neurofilaments usually assume a parallel arrangement within the axonal cytoskeleton. Although single neurofilaments in *vitro* are flexible and tend to curl up (22), under appropriate conditions they can form bundles complete with cross-bridges resembling those seen in *vivo* (23). The carboxy-terminal domain of NF-M is crucial to this interaction (24).

The appearance of NF-L and NF-M in the rodent central nervous system a few days after birth is followed several days later by the appearance of NF-H, a marked up-regulation of NF-L and NF-M expression, and extensive NF-H and NF-M phosphorylation (25-28) –events associated with major axonal caliber expansion. Thus, as neurons develop, the plastic, intermediate networks, composed of the class III intermediate filaments, (e.g. vimentin and a-internexin) are replaced by more stable class IV IF networks to support the highly polar morphologies of mature neurons, especially those with large caliber axons. The cDNA sequences that encode the entire protein sequences of NF-L, NF-M, and NF-H are available (15, 29), but the regulation of neurofilament gene expression is not well understood.

2. Posttranslational Modification

The spectrum of dynamic behaviors of neuronal cytoskeletal proteins, from local subunit assembly to the formation of stable cross-linked polymer networks, is influenced by a host of protein kinases and phosphatases (see Phosphorylation, Protein). The amino-terminal domains of NF-L and NF-M have multiple phosphorylation sites, at least 5 and 9, respectively, in the mouse (3, 4). Results from consensus sequence analysis and *in* vitro phosphorylation assays are compatible with regulation of these sites by protein kinase A, protein kinase C, and calmodulin-dependent protein kinase II (94). As neurofilaments are transported along axons, phosphate turnover continually changes the locations of phosphate groups on each subunit (4) (30). It is believed that phosphorylation/ dephosphorylation along the amino-terminal domain of NF-L, and possibly NF-M, early after subunit synthesis, modulates polymer assembly and disassembly (30, 31). The amino-terminal head domains of rat NF-L and NF-H are also posttranslationally modified by adding of O-linked *N*-acetyl glucosamine moieties (5) (see O-Glycosylation).

The NF-H carboxy-terminal domain contains more than 50 mols of phosphate. The same regions of NF-M and NF-L contain at least 10 mols and 3 mols, respectively. A number of known protein kinases, mitogen-activated kinases (ERK1) (32), (ERK2) (33), glycogen synthase kinase-3 (GSK3a, GSK3b), cyclin-dependent kinase cdk5 (21, 32, 34, 35), SAP kinase (36, 37), a neurofilament associated (115 kDa) kinase (38), a casein kinase I-like kinase (39), and several less well characterized kinases are considered candidates for regulating the function of this domain, although no kinase has yet been proven to phosphorylate neurofilaments *in vivo*. Phosphorylation begins soon after the subunits are synthesized but becomes extensive only after the neurofilaments have moved into the axon, implying that this process has a specialized role in axons (40, 41). Phosphorylation of the NF-H and NF-M tail domains induces neurofilaments to straighten, align, bundle, and develop cross-bridges in *vitro* and in cultured cells (22, 24). NF-L head phosphorylation is modulated during neuronal signal transduction (94).

3. Neurofilament Dynamics and Turnover

Neurons, especially those with long axons, export most neurofilament proteins into axons within 6 to 12 hours after their synthesis (40). It is believed that newly synthesized subunits are transported mainly as polymers (42, 43). It is possible, however, that some transported subunits can also incorporate into existing neurofilaments to maintain neurofilament structure or to extend filament length (44, 45, 95, 96).

Transported neurofilaments (or neurofilament proteins) advance along axons by slow axonal transport at a rate between 0.25–3 mm per day depending on subunit composition (97), the type of neuron, stage of neuronal development, and location along the nerve (46). Rates reflect the average of many intermittent rapid movements and pauses (43). Transport is more rapid in immature or regenerating axons than in mature axons and slows during aging. During transport, the addition of specific phosphate groups on the carboxy-terminal domains of NF-M and NF-H primarily at the KSP motifs (41, 47, 48) is associated with changes in neurofilament behavior and morphology. As negative charge from the introduced phosphate groups accumulates along neurofilament sidearms, the minimal spacing between neighboring neurofilaments changes from 25 to 30 nm to 50 to 55 nm (41, 48). A family of cross-linking proteins, such as BPAG and plectin (101-104), may contribute to this process. The addition of specific phosphate groups to the NF-M and NF-H tails is also associated with slowing or cessation of the movement of some filaments (47, 49, 98), facilitating their incorporation into a stationary cytoskeletal network within which individual components of the cytoskeleton associate for varying periods before advancing further along axons or being degraded locally (44, 45, 48-50). This stationary network is non-uniform along some axons, particularly at specialized sites, such as nodes of Ranvier (41, 48, 49). In addition to neurofilament protein expression levels, the equilibrium between moving and stationary neurofilaments in large part determines the size of the neurofilament network, which, in turn, influences axon caliber (51, 52). Signals from oligodendroglial cells during the earliest stages of myelination have a remarkable influence on these events (53-55). Association of oligodendroglia with regions of the axon destined to be myelinated induces phosphorylation at a specific carboxyl-terminal site on NF-H and NF-M which is closely associated with the process of neurofilament accumulation and expansion of axonal caliber (52, 55). Phosphorylation at this site may reflect important phosphorylation events at other sites on neurofilaments or other interacting proteins because mice lacking NF-H have nearly normal axon morphology (105-107).

Neurofilaments that do not incorporate along the axon reach the nerve terminals where they are presumably degraded (42, 56), although retrograde transport of neurofilaments or neurofilament fragments has not been entirely excluded (57, 58). In long peripheral axons, the radioactivity of a pulse-chase labeled pool of neurofilaments declines considerably during axonal transport (59, 60), and neurofilament breakdown products are detected along the axons (61), indicating that some neurofilaments, especially those that are stationary for long periods (49), may be turned over locally within axons. The possibility cannot be excluded, however, that neurofilaments, parts of neurofilaments, or subunits are slowly released from the cytoskeleton and then are moved into the

terminals for degradation. Phosphorylation seems to protect neurofilaments against proteolysis (62), suggesting that kinase and phosphatase activities might partly determine the turnover rate of neurofilament proteins.

4. Neurofilament Function and Dysfunction

Intermediate filaments in many cell types provide a structural scaffold that supports cell shape and helps to organize cytoplasmic constituents (see Intermediate Filaments). Because of their unique sidearm extensions and ability to arrange in parallel arrays, neurofilaments are particularly well suited to fill space and support the extreme polar shape of neurons. Once axons reach their targets and form synapses, their further maturation involves up to a 10-fold increase in axonal diameter and commensurate increases in neurofilament content (63, 64). This growth is essential for achieving appropriate conduction velocity for electrical impulses. The strong correlation between neurofilament number and axon diameter during radial growth, regeneration, and neuropathological axonal atrophy or hypertrophy has suggested that neurofilaments function as a major determinant of axonal caliber (63-66). Several observations now firmly establish their importance to axonal growth. In the Japanese quail, a recessive mutation (quiverer) that interferes with NF-L synthesis (67) severely reduces radial growth, slows axonal conduction velocity, and causes the bird to quiver. Targeted disruption of mouse NF-L selectively eliminates neurofilaments and severely inhibits radial growth (68). Furthermore, expression of a mouse NF-H b-galactosidase fusion protein in transgenic mice selectively blocks neurofilament transport into axons and substantially reduces axonal growth (69). Studies of transgenic mice overexpressing single subunits or combinations indicate that proper subunit ratios and states of phosphorylation are important for normal radial axonal growth (66, 70, 71) but not for axonal outgrowth during development (99). NF gene deletion analysis (68, 72-75, 100) confirms the importance of NF-L and NF-M for filament assembly and caliber expansion and that the role of NF-H in this function can be partially fulfilled by compensatory phosphorylation on NF-M (52).

Given the complexity of neurofilament dynamics and regulation by multiple protein kinases, it is not surprising that neurofilaments are frequent cellular targets in neuropathological disorders, and that neurons with large caliber axons and abundant neurofilaments are particularly vulnerable. In the central nervous system, neurofilaments are a major constituent of inclusions known as Lewy bodies that develop in susceptible neuronal populations in two relatively common forms of *senile* dementia, diffuse Lewy body disease and Lewy body variant of Alzheimer's disease (76). Although a-synuclein is now considered to be the principal component of Lewy bodies (76), these structures also contain all three neurofilament subunits. Neurofilaments are also major constituents of NFTs in Alzheimer brain, although the presence of neurofilaments in these tangles is overshadowed by the formation of paired helical filaments (PHF) containing tau protein (76). Neurofilament hyperphosphorylation, however, may be the earliest cytoskeletal change in neurites and neuritic plaques in preclinical stages of AD (77).

The most striking disorders involving neurofilaments are those which affect spinal motor neurons, where neurofilaments are most abundant. Abnormal accumulations of neurofilaments in the cell bodies and proximal axons of motor neurons have been established to be hallmarks of both sporadic (79) and familial (80) forms of amyotrophic lateral sclerosis (ALS) and certain less common neuroaxonal dystrophies. ALS is primarily characterized by selective degeneration of upper and lower motor neurons, beginning in mid adult life and invariably progressing to paralysis and death over a 1–5 year time period. Transgenic mouse models lend credence to the idea that these aberrant accumulations of neurofilaments contribute to the motor neuron dysfunction, rather than being simply by-products of the pathogenesis process. When wild-type mouse NF-L (81) or human NF-H are over expressed (71), mice develop selective motor neuron dysfunction associated with marked neurofilament accumulation along proximal parts of axons and atrophy more distally, as well as neurogenic atrophy of skeletal muscle. Despite these changes, large caliber neurofilament-rich axons are not lost during the disease. However, a variety of transgenic mouse constructs that alter subunit phosphorylation, polymer assembly, or neurofilament network formation can cause neurofilament

aggregations leading to neuronal dysfunction (71, 78, 81-84). Overexpression of a mouse NF-L subunit, which has a point mutation (85) within the rod domain produced pathological symptoms in mice resembling human motor neuron disease, including preferential loss of large caliber neurofilament rich axons. A possible etiological role of neurofilament protein mutations in ALS cases is suggested by analyses of the KSP repeat domains of the NF-H gene, which reveal mutations in about 1% of ALS patients. Mutations found in sporadic ALS, and very rarely in familial ALS (FALS), have included small in-frame deletions involving one or more KSP repeats and an 84-bp insertion comprising four extra KSP repeats (86-88). Recently, mutations of NF-L, which involve a single base substitution within an exon encoding a region on the rod domain, have been identified in two families afflicted with Charcot-Marie-Tooth Disease type 2, an inherited motor and sensory neuropathy (89). The relationship of these mutations to disease susceptibility is not known.

Although neurofilament gene mutations are extremely rare in FALS, about 2% of ALS patients have autosomal dominant mutations in the gene encoding the ubiquitous cytoplasmic enzyme Cu/Zn superoxide dismutase (SOD1)(90). More than 50 mutations in SOD1 have been identified in patients with FALS, the majority of which are point mutations. Neurofilament accumulations are also characteristic of the pathology in these cases, and seem to be important to the neurodegenerative mechanism. In mouse models of SOD1 – related FALS, neurologic disease develops even when neurofilaments are eliminated genetically; however, neurofilaments seem to influence the onset and pace of degeneration (91, 92, 108).

In conclusion, neurofilaments continue to figure prominently in mechanisms of human neurodegenerative disease although whether they are more important as agents of disease or as disease targets requires further investigation. Genetic evidence links mutations of neurofilament genes to human neuroaxonal disease and investigations of these mutations in mouse models should be informative. A firm understanding of neurofilament protein regulation should help to clarify the role played by neurofilaments in neurodegenerative disease.

5. Neurofilament Dynamics and Turnover

Neurons, especially those with long axons, export most neurofilament proteins into axons within 6 to 12 hours after their synthesis (58). It is believed that newly synthesized subunits are transported mainly as polymers or at least oligomers, based on observations that they enter axons in the same subunit stoichiometry as isolated neurofilaments (48). It is also believed that they behave identically during transport (61), even when either slow transport or the subunit itself is altered in pathological or experimental conditions (62, 63). When NFM is overexpressed by using viral **vectors** in transgenic mice that lack axonal neurofilaments, some subunits move by slow axonal transport (64). Furthermore, tagged NFL subunits **microinjected** into neurons incorporate along the length of existing neurofilaments (65, 66). These observations suggest that transported subunits can also incorporate into existing neurofilaments to maintain neurofilament structure or to extend filament length. Indeed, a large pool of NFH subunits is present during development and decreases during brain maturation (67).

Transported neurofilaments (or neurofilament proteins) advance along axons by the active process of slow axonal transport at a rate between 0.25 and 3 mm per day depending on the type of neuron, stage of development, and location along the nerve (references in 68). Transport is more rapid in immature or regenerating axons than in mature axons and slows during aging. As newly synthesized neurofilament proteins move along the axon, the carboxy-terminal domains of NFM and NFH become extensively phosphorylated, primarily at the KSP motifs (59, 60, 69). The addition of specific phosphate groups is associated with changes in neurofilament behavior and morphology. As negative charge from the introduced phosphate groups accumulates along neurofilament sidearms, they extend peripherally from the filament core and change the minimal spacing between neighboring neurofilaments from 25 to 30 nm to 50 to 55 nm (59, 69). The addition of specific phosphate groups to the NFM and NFH tails also slows or stops movement of some filaments (60, 70), facilitating their incorporation into a stationary but dynamic cytoskeletal network (64-66, 69,

70). This stationary network is nonuniform along some axons, particularly at specialized sites, such as nodes of Ranvier (59, 69, 70). In addition to neurofilament protein expression levels, the equilibrium between moving and stationary neurofilaments in large part determines the size of the neurofilament network, which in turn influences axon caliber. Signals from oligodendroglial cells during the earliest stages of myelination have a remarkable influence on these events (71-73). Association of oligodendroglia with regions of the axon destined to be myelinated induces phosphorylation at specific carboxyl-terminal sites, triggering incorporation of transported neurofilaments into a stationary network and leading to neurofilament accumulation and expansion of axonal caliber.

Neurofilaments that do not incorporate along the axon reach the nerve terminals where they are presumably degraded (74, 75), although retrograde transport of neurofilaments or of neurofilament fragments has not been entirely excluded (76). In long peripheral axons, the radioactivity of a **pulse-chase** labeled pool of neurofilaments declines considerably during axonal transport (77, 78), and neurofilament breakdown products are detected along the axons (79), indicating that some neurofilaments may be turned over locally within axons. Axons contain ample proteinase activity for this suspected purpose (79, 80). Neurofilaments that remain stationary along axons for long periods turn over at the same rate at proximal and distal levels of the axon (70). This pattern is consistent with a mechanism of local turnover, although the possibility cannot be excluded that neurofilaments, parts of neurofilaments, or subunits are slowly released from the cytoskeleton and then are moved into the terminals for degradation. Phosphorylation seems to protect neurofilaments against **proteolysis** by divalent cation-independent proteinases associated with cytoskeleton preparations and by calpains (see **Thiol proteinase inhibitors**) (81, 82). These results raise the possibility that kinase or phosphatase activity might partly determine the turnover rate of neurofilament proteins.

6. Neurofilament Function and Dysfunction

Intermediate filaments in many cell types provide a structural scaffold that supports cell shape and helps to organize cytoplasmic constituents (see Intermediate Filaments). Because of their unique sidearm extensions and ability to arrange in parallel arrays, neurofilaments are particularly well suited to fill space and support the extreme polar shape of neurons. Once axons reach their targets and form synapses, their further maturation involves up to a 10-fold increase in axonal diameter and commensurate increases in neurofilament content (83, 84). This growth is essential for achieving appropriate conductional velocity for electrical impulses. A strong correlation between neurofilament number and axon diameter during radial growth, as well as during regeneration and neuropathological axonal atrophy or hypertrophy (83-86), had suggested earlier that neurofilaments function as a major determinant of axonal caliber. Several observations now firmly establish their importance to axonal growth. In the Japanese quail, a recessive mutation (quiverer) that interferes with NFL synthesis (87) severely reduces radial growth, slows axonal conduction velocity, and causes the bird to quiver. Furthermore, expression of an NFH- **b-galactosidase** fusion protein in mice selectively blocks neurofilament transport into axons and substantially reduces axonal growth (88). Although neurofilaments are essential for achieving normal caliber, the factors that specify caliber size and neurofilament number are less clear.

Given the complexity of neurofilament dynamics and regulation by multiple protein kinases, it is not surprising that neurofilaments are commonly implicated in neuropathological states, particularly those involving neurons with large caliber axons and abundant neurofilaments. In the central nervous system, neurofilaments are a major constituent of inclusions known as Lewy bodies that develop in susceptible neuronal populations in two relatively common forms of *senile dementia*, diffuse Lewy body disease and Lewy body variant of Alzheimer's disease (89). The most striking disorders involving neurofilaments affect spinal motor neurons, where neurofilaments are most abundant. Neurofilaments accumulate markedly in the cell bodies and proximal axons of these neurons in various human motor neuron diseases, including amyotrophic lateral sclerosis (ALS) (90, 91). Transgenic mouse models lend credence to the idea that these aberrant accumulations of neurofilaments contribute to the motor neuron dysfunction, rather than being simply by-products of

the pathogenic process. When wild-type mouse NFL (92) or human NFH are overexpressed (93), mice develop selective motor neuron dysfunction associated with a marked neurofilament accumulation proximally and axonal atrophy distally, as well as neurogenic atrophy of skeletal muscle. Moreover, a growing number of transgenic mouse constructs that disrupt subunit phosphorylation, polymer assembly, or neurofilament network formation can cause neurofilament aggregations leading to neuronal dysfunction (92-97). Also suggesting a possible etiological role of neurofilaments in some individuals who have ALS are analyses of the KSP repeat domains of the NFH gene in DNAs from 356 sporadic ALS cases, which revealed a one-codon deletion in four patients and a 34-codon deletion in one patient, conditions that were not observed in over 300 normal individuals (98). The relationship of these mutations to disease susceptibility is unknown. Although neurofilament gene mutations have not been observed in cases of *familial* ALS (FALS), there are more than 45 mutations in the enzyme *superoxide dismutase* each of which can lead to FALS. Neurofilament accumulations are also characteristic of the pathology in these cases, and oxidative damage to the long-lived neurofilament subunits has been proposed as a mechanism that leads to aberrant filament assembly or organization, which then blocks axonal transport (99). A firm understanding of neurofilament protein dynamics should help to clarify the significance of the role played by neurofilaments in these and other neurodegenerative diseases.

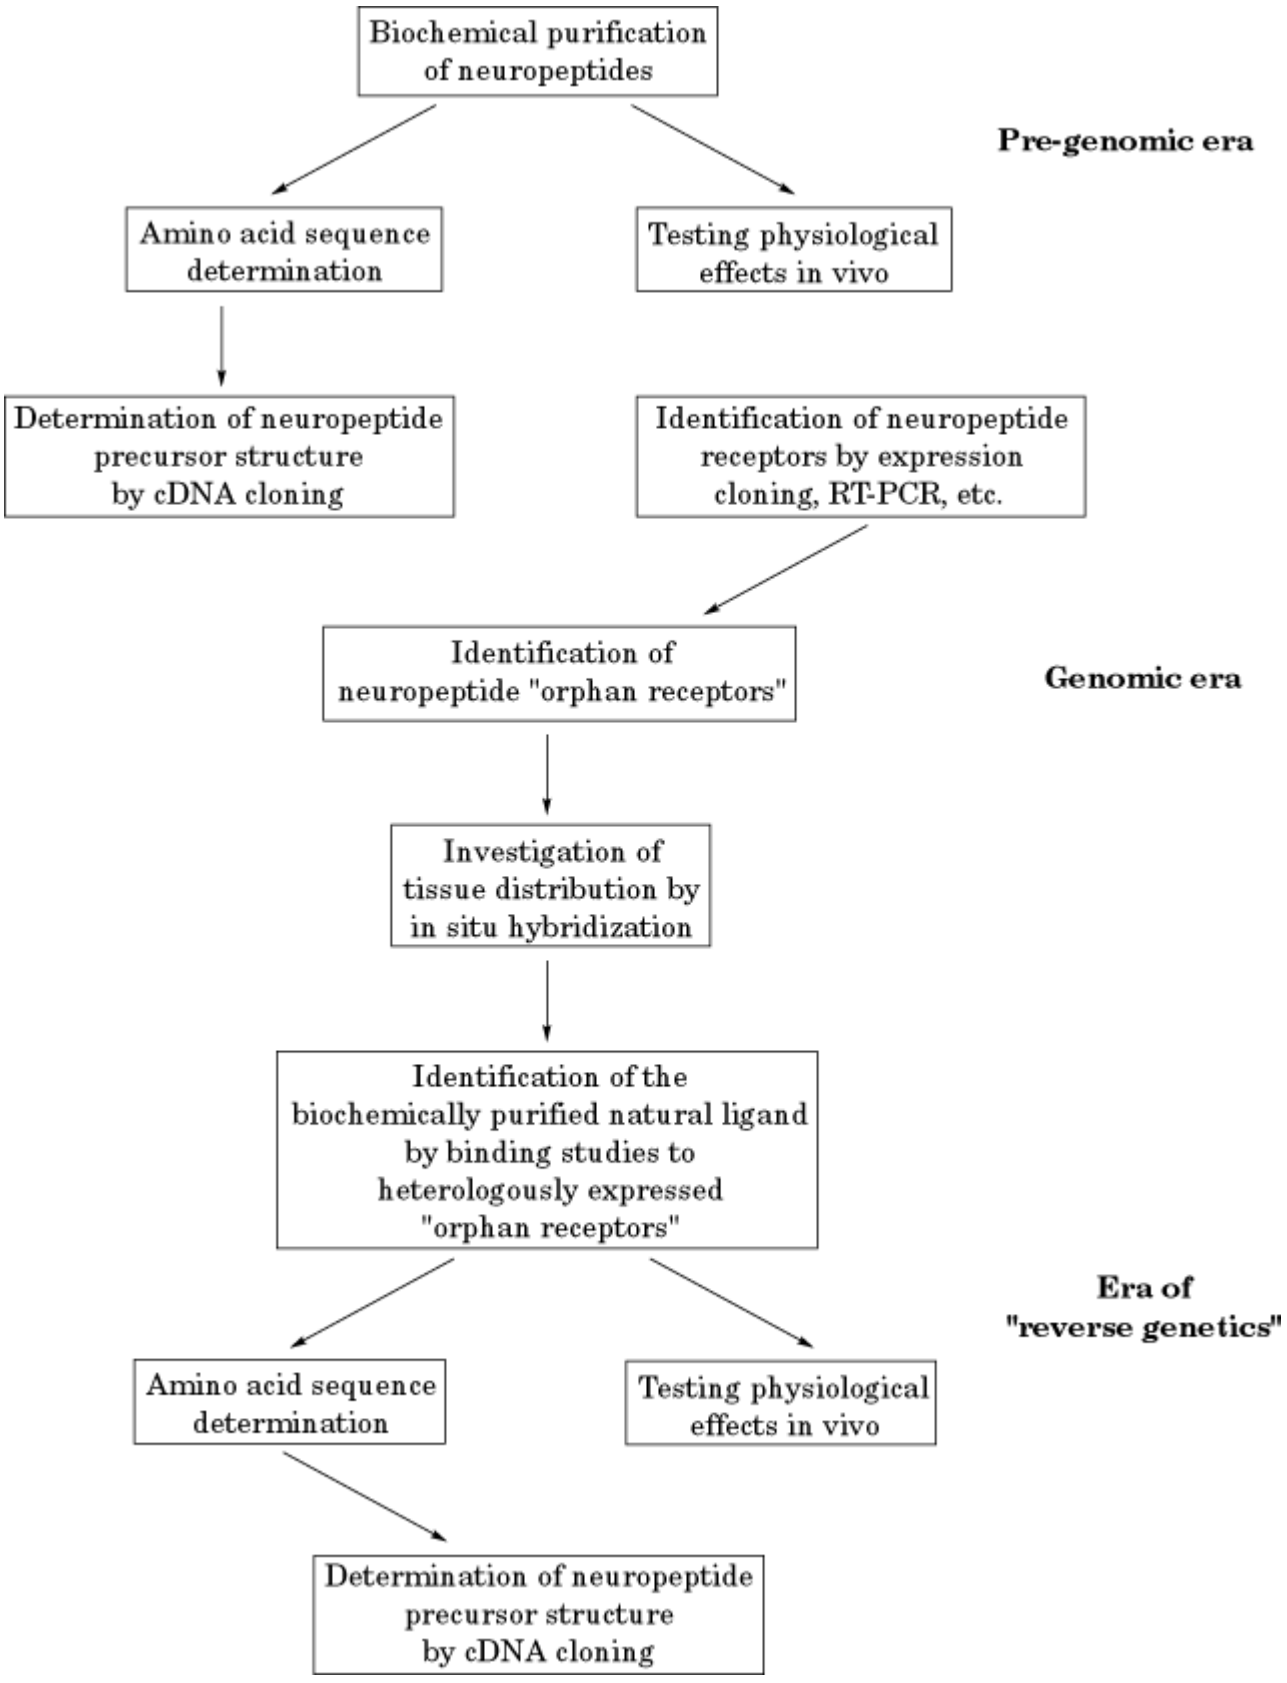
Neuropeptides

1. History

By definition, neuropeptides are synthesized in nerve cells of the central and peripheral nervous systems and act as either neurohormones, neurotransmitters, or neuromodulators. They regulate and influence the behavior and homeostasis of a given organism in many and complex ways.

The concept of the peptidergic neuron in vertebrates and invertebrates was developed by Ernst and Berta Scharrer in 1928, and their work still forms the basis of contemporary neuropeptide research. Numerous neuropeptides were discovered in the late 1960s and early 1970s by work that began as a tour de force, and resulted in their biochemical isolation from huge amounts of various tissues. The advent of molecular biological techniques in the 1980s greatly facilitated the identification and characterization of novel neuropeptides in vertebrates and invertebrates. This "era of neuropeptides" was followed by extensive work aimed at identifying their cognate receptor proteins. Today, at least one type of seven-membrane-spanning-domain G-protein-coupled receptor (GPCR) has been identified for each neuropeptide. A growing number of receptors also share structural similarities with known neuropeptide receptors or neuropeptide receptor families. These putative neuropeptide receptors, referred to as "orphan receptors," await the identification of their ligands. As a consequence, neuropeptide research has experienced a revival in the late 1990s, and now strategies called "reverse genetics" (an example is given later) are being developed to unravel the identity of the natural ligands for these orphan GPCRs and their functions within the central and peripheral nervous systems. Figure 1 schematically summarizes the history of neuropeptide and neuropeptide receptor research from the 1960s to the late 1990s.

Figure 1. Outlook on the history of neuropeptide and neuropeptide receptor research. During the "pregenomic" era, biochemical work prevailed. Neuropeptides were purified to homogeneity by liquid chromatography procedures. The amino acid sequence was determined by Edman Degradation. Physiological effects were analyzed by *in vivo* administration of the purified neuropeptide. Identification and characterization continued during the "genomic" era. Neuropeptide precursor structures were determined by sequencing the corresponding cDNAs. A little later, the structures of the first neuropeptide receptors became known. This revealed that they belong to the large group of seven membrane-spanning-domain, G-protein-coupled receptors. Different procedures have been applied to receptor characterization, including expression in *Xenopus* oocytes (expression cloning) and polymerase chain reaction (**PCR**) amplification after **reverse transcription** of the mRNA (RT-PCR). In some instances, receptors ("orphan receptors") were identified that failed to be activated by any of the known neuropeptides. In the era of "reverse genetics," work is aimed at identifying natural ligands. This can be done by expressing "orphan receptors" in cell culture and analyzing receptor activation after applying of peptide extracts isolated from appropriate tissues. These "activities" are finally purified and analyzed, as described previously.



2. Neuropeptides and Neuropeptide Families

It is not feasible to list of all the neuropeptides discovered thus far in nerve cells throughout the animal kingdom. As a matter of fact, nearly every peptide hormone of a given organism is located in

nerve cells and consequently can be regarded as a neuropeptide. Table 1shows a selection of mammalian neuropeptides, some of which can be grouped into families according to structural or functional similarities. It should be stressed, however, that this classification is somewhat arbitrary. For example, the hormones vasopressin (VP) and oxytocin (OT) (the vasopressin/oxytocin family) are synthesized in magnocellular neurons of the hypothalamo-neurohypophyseal tract and are secreted from the nerve terminals in the posterior pituitary into the systemic circulation to exert their biological functions in various peripheral organs (VP: kidney, liver, blood vessels; OT: smooth muscles of the uterus and mammary gland). They are also synthesized in parvocellular neurons of the hypothalamic paraventricular nucleus and have axonal projections to the portal blood vessel system that delivers neuropeptides to the anterior pituitary, where they act as release factors for adenohypophyseal hormones. In addition, VP and OT are produced in various extrahypothalamic neurons that have central projections and thus presumably play a role as neurotransmitters and/or neuromodulators. The same is principally true for the "hypothalamic-release and release-inhibiting hormones" thyrotropin-releasing hormone (TRH), somatostatin (SST), luteinizing-hormone releasing hormone (LHRH), etc., all of which are produced in nerve cells that have central projections. Other neuropeptides, such as cholecystokinin (CCK) and vasoactive intestinal polypeptide (VIP), were initially attributed with functions outside the brain before their synthesis and actions in the central nervous system were acknowledged.

Table 1. Selected Mammalian Neuropeptides

Neuropeptide Family	Number of Amino Acid Residues
Oxytocin (OT)	9
Vasopressin (VP)	9
Hypothalamic-releasingand release-inhibiting hormones	
Corticotropin-releasing hormone (CRH)	41
Growth-hormone releasing hormone (GHRH)	44
Luteinizing-hormone releasing hormone (LHRH)	10
Somatostatin (SST)	14 and 28
Thyrotropin-releasing hormone (TRH)	3
Opioid peptide family	
b-Endorphin	30
Dynorphin (DYN)	17, other forms
Leu-Enkephalin (Leu-Enk)	5
Met-Enkephalin (Met-Enk)	5
Nociceptin/orphanin FQ	17, other forms?
Tachykinin family	
Neurokinin A, Substance K	10
Neurokinin B	10
Neuropeptide K	36
Substance P (SP)	11
VIP/Glucagon family	
Glucagon-like peptide-1 (GLP-1)	29

Peptide histidine-isoleucine (PHI)	27
Pituitary adenylate cyclase activatingpeptide (PACAP)	27 or 38
Vasoactive intestinal polypeptide (VIP)	28
NP Y family	
Neuropeptide tyrosine (NP Y)	36
Pancreatic polypeptide (PPP)	36
Peptide tyrosine-tyrosine (P YY)	36
Other peptides	
Brain natriuretic peptide (BNP)	32
Calcitonin gene-related peptide (CGRP)	37
Cholecystokinin (CCK)	8
Cortistatin (CST)	14 or 29, other forms?
Galanin (GAL)	29 or 30
Hypocretin/orexin	14 or 29
Neurotensin	13
Parathyroid hormone-related protein	34 or 37

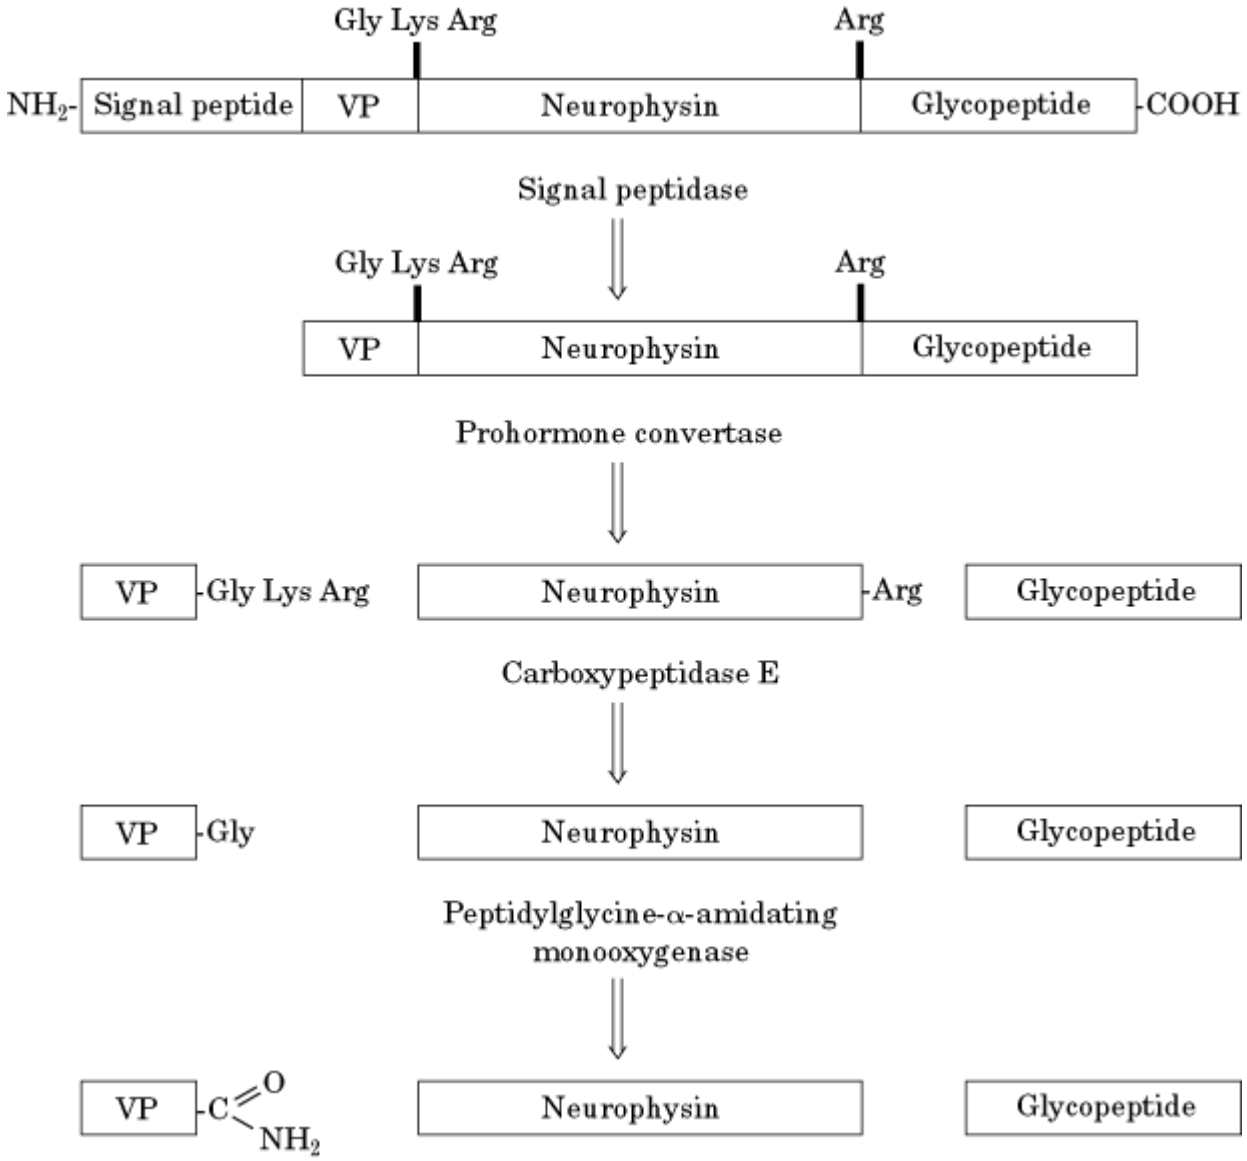
3. Neuropeptide Biosynthesis, Maturation, and Release

Neuropeptides are synthesized as parts of larger precursor molecules, the pre-prohormones, on the rough endoplasmic reticulum (ER). These precursors consist of a signal peptide that is cotranslationally cleaved off in the lumen of the rough ER by signal peptidases to yield the prohormones. After passage through the **Golgi complex**, where they are eventually equipped with complex carbohydrate moieties, the precursors are sorted to the regulatory secretory pathway in neurosecretory granules (also termed dense-core vesicles) by mechanisms that remain to be fully elucidated. The biologically active entities are generated in the trans-Golgi network or, more frequently, within immature **vesicles** by the enzymatic activities of endopeptidases, the prohormone convertases (PCs). PCs belong to the family of subtilisin/kexin-like serine proteinases (1). The enzymes cleave precursor molecules at the carboxyl side of either specific single or pairs of basic amino acid residues (most commonly Lys-Arg or Arg-Arg). A number of PCs have been identified. Of these, PC1 and PC2 are expressed primarily in endocrine and nerve cells. The supernumerary basic amino acids are subsequently removed by carboxypeptidase E.

The molecular composition of neuropeptide precursors is rather diverse. The VP and OT precursors, for example, harbor one copy of the respective peptide, whereas others, such as the TRH precursor, contain multiple copies of the same peptide. In a few cases, for example, in the opioid peptide precursor family, different sets of peptides arise from processing. Thus, the human enkephalin precursor contains six copies of Met-enkephalin and one copy of Leu-enkephalin (2). Before the mature neuropeptides are secreted, modification at the carboxy- and/or amino-terminal ends is frequently required for biological activity. The most common modification is the conversion of a carboxy-terminal glycine into the a-amide, a two-step reaction that is catalyzed by peptidylglycine a-amidating monooxygenase and requires copper, molecular oxygen and ascorbate (3, 4). Glutaminyl cyclase converts the amino-terminal glutamine residue in TRH, LHRH and a few other peptides into a pyroglutamyl residue (5). Figure 2 schematically depicts maturation steps of preprohormones exemplified by the VP precursor. It should be mentioned, however, that processing of proneuropeptides in some invertebrates, particularly in cnidarians, might be even more complex and

involve enzymes that have no counterparts in mammalian species (6). Cloning of the genes for various cnidarian neuropeptide precursors has shown that sequences other than monobasic and dibasic residues must also function as processing signals. These include Thr, Ser, and Tyr residues, and X-Pro or X-Ala sequences (where X is any amino acid). These novel processing signals are located exclusively at the amino-terminal side of neuropeptides. The **proteolytic** enzymes remain to be fully characterized.

Figure 2. Structural organization, processing, and modification of pre-provasopressin. Neuropeptide precursor processing and further maturation of the neuropeptide is schematically shown for pre-provasopressin. The preprohormone consists of a signal peptide, the nonapeptide vasopressin (VP), a carrier protein called neurophysin, and a glycopeptide moiety of unknown function. The signal peptide is removed by signal peptidase, an enzyme that resides in the lumen of the rough endoplasmic reticulum. Subsequent maturation steps take place in immature dense-core vesicles, that are directed to the regulated secretory pathway. The VP precursor contains two processing signals for endoproteolytic cleavage by prohormone convertases: a dibasic sequence Lys-Arg on the amino-terminal side and a monobasic Arg residue on the carboxy-terminal side. The basic amino acids are finally removed by carboxypeptidase E. The Gly residue preceding the dibasic signal is important for subsequently modifying the neuropeptide. Peptidylglycine-a-amidating monooxygenase catalyzes the conversion of the carboxy-terminal Gly residue into an amide in a two-step reaction. Amidation of VP is required for its biological activity. Secretion of the mature neuropeptide takes place by exocytosis from dense-core vesicles after appropriate physiological stimulation.



Unlike classical transmitter-containing synaptic vesicles, which are organized in an active zone at the synapse, in principle, dense-core vesicles can be released from any part of the nerve cell. Initially, it was thought that release took place only from the axonal compartment. There is now compelling evidence, however, for dendritic release of at least some neuropeptides. This has been documented unequivocally for VP and OT, which can be secreted from the dendrites of hypothalamic magnocellular neurons into the central nervous system (7). In some instances, neurons synthesize both classical transmitters (for example noradrenaline, serotonin, acetylcholine, and GABA) and neuropeptides, and the parameters necessary for their release are quite distinct. Neuropeptide secretion often requires high-frequency or prolonged firing activity. Classical transmitter release, in contrast, follows the action potential in a one-to-one fashion (2, 8). At normal firing rates, neuropeptides might not be secreted and should consequently not exert any postsynaptic effects at all. High-frequency stimulation, on the other hand, allows concomitant release of classical transmitters and neuropeptides. A number of examples demonstrate either synergistic or antagonistic effects of classical transmitter/neuropeptide interactions. A synergistic interaction of acetylcholine and VIP has been demonstrated, for example, in the cat salivary gland. Acetylcholine induces saliva secretion. VIP facilitates secretion by triggering vasodilation, and it enhances acetylcholine binding to the acetylcholine receptor. In some noradrenergic neurons of the mouse *vas deferens*, the coexisting neuropeptide Y (NP Y) plays a role as a functional antagonist by inhibiting noradrenaline release (8).

4. Neuropeptide Inactivation in the Central Nervous System

Enzymatic degradation of neuropeptides is the major pathway for terminating the action of the signaling molecules and for adjusting neuropeptide concentrations in the extracellular fluid. To date, a small number of peptidases in the central nervous system that act as neuropeptide-degrading ectoenzymes have been characterized, and most of these also exist in the periphery, for example, in the kidney and in other tissues (9). Endopeptidase-24.11 (E-24.11) was first detected by its ability to inactivate enkephalins. The enzyme is distributed widespread within the central nervous system and is present predominantly on nerve cells at both pre- and postsynaptic sites. Besides enkephalins, other neuropeptides are effectively hydrolyzed by E-24.11 *in vitro*. Presumably, the enzyme acts at numerous peptidergic synapses. Aminopeptidase-N (AP-N) was identified as the major membrane-associated aminopeptidase engaged in the hydrolysis of enkephalins. This enzyme is also heterogeneously distributed on pre- and postsynaptic elements and, in addition, on nonneuronal cells, such as astrocytes. *In vitro*, AP-N shows broad substrate specificity and hydrolyzes the amino-terminal amino acid residues from nearly all unsubstituted peptides. Even though AP-N could play a role in inactivating all neuropeptides that have unprotected amino-termini, its action *in vivo* has only been confirmed for the enkephalins. Another aminopeptidase that has surprisingly stringent substrate specificity was identified recently. Pyroglutamyl aminopeptidase II (PGA II), a membrane-associated metallopeptidase, hydrolyzes the pyroglutamate-histidine bond of TRH. The enzyme is highly specific for TRH inactivation. It cannot degrade other neuropeptides that have pyroglutamyl-protected amino-termini, including LHRH, neurotensin, and gastrin (10). A number of neuropeptides are hydrolyzed *in vitro* by angiotensin-converting enzyme (ACE), whose main role is to convert angiotensin I to angiotensin II and inactivate bradykinin. Despite the broad distribution of ACE within the central nervous system of a variety of mammalian species, however, no clear cut evidence for its involvement in neuropeptide metabolism other than the previously mentioned peptides has been obtained.

Additional peptidases, it is claimed are involved in neuropeptide degradation/inactivation, but their precise roles have remained obscure. This is largely due to the fact that the majority of these enzymes have a predominantly cytosolic (or endosomal) localization, which contradicts a role in neuropeptide inactivation. In some instances, membrane-associated forms might exist, generated, for example, by alternative splicing of the corresponding pre-**messenger RNA**. More work must be done to clarify the precise roles of these enzymes. It is to be anticipated that novel ectoenzymes with neuropeptide-degrading activity will be discovered in the next few years (9).

5. Neuropeptide Signal Transduction via G-protein-Coupled Receptors

Defining the target molecules of neuropeptides, in particular those of opioid peptides, has been of great interest because this might pave the way for drug design (either agonists or antagonists) for treating analgesia, provided these compounds pass the blood–brain barrier. Despite extensive scientific work all over the world, it was not until the late 1980s that the structures of the first neuropeptide receptors (two tachykinin receptors and one neurotensin receptor) were elucidated by molecular biological techniques. To date, at least one receptor for each neuropeptide is known, and very often multiple forms exist, as in the case of SST receptors in rat, mouse, and humans. With rare exceptions, all neuropeptide receptors belong to the large family of GPCRs. Their subcellular pre- and/or postsynaptic localization within the target cells of neuropeptides and their regulation and desensitization are under intensive study now to clarify more precisely neuropeptide actions within the brain and in the peripheral nervous system (11-14).

6. Physiological Roles of Neuropeptides

The function of neuropeptides as neurohormones in the periphery is quite well defined. Their role in the central nervous system, in contrast, has largely remained elusive, despite vast literature in this field. Neuropeptide actions in the brain are extremely diverse and presumably depend on various parameters, for example, on the projection areas of peptidergic neurons and on the receptor subtype and its location at pre- and/or postsynaptic sites. It is believed that neuropeptides, either alone or in concert with classical transmitters, are engaged in aspects of learning and memory, pain perception, feeding and obesity, anxiety, aggression, reproductive behavior, sleep-wakefulness, etc. It is beyond the scope of this article to review fully the presumed central actions of all neuropeptides. Therefore, the reader is referred to the original literature in this field. Selected publications and review articles with particular reference to the roles ascribed to individual neuropeptides or neuropeptide families in the central and peripheral nervous system are listed in “Suggestions for Further Reading.”

To demonstrate the complex interplay of a variety of neuropeptides (and other signaling molecules), possible mechanisms involved in the control of feeding and energy homeostasis are briefly described. Brain lesion experiments have suggested that the hypothalamus plays an important role in energy homeostasis. Disruption of the ventromedial hypothalamus (“satiety center”) leads to obesity, whereas animals that have lesions of the lateral hypothalamus (“feeding center”) lose weight and may even starve to death in some instances. The neurochemical system in the brain that underlies the complex regulation of body weight includes a variety of classical transmitters and neuropeptides (15, 16). Recent genetic mouse models, molecular cloning techniques, and behavioral studies have succeeded in identifying at least some of the important positive and negative regulators of energy balance. Several neuropeptides, injected into the brain, stimulate feeding behavior. These include, for example, NP Y, galanin, melanin-concentrating hormone, and the recently identified orexins/hypocretins. A negative effect on food consumption is observed with corticotropin-releasing hormone, the closely related and even more potent urocortin, and a melanocortin-stimulating hormone (a MSH), one of the peptides derived from the complex and tissue-specific proopiomelanocortin (POMC) precursor processing. Interestingly, the action of a MSH at the melanocortin 4 receptor is antagonized by the Agouti protein, which is ectopically expressed in the central nervous system of the *lethal yellow* (A^y/a) mouse, an autosomal dominant obesity model, and by the Agouti-related peptide (AGRP), a newly discovered hypothalamic neuropeptide. It is believed that the resulting feeding behavior depends on the ratio of agonist to antagonist. There are almost certainly more factors that have to be identified. This is exemplified by a genetic mouse model that is deficient for an “orphan receptor,” termed bombesin receptor type-3, which also results in an obese phenotype. To date, the interplay between positive and negative regulators of food intake is far from clear. For example, targeted deletion of the NP Y precursor gene surprisingly failed to show a body weight or feeding behavior phenotype. Furthermore, the metabolic state of the periphery must be signaled to the brain by substances that cross the blood–brain barrier. Leptin, a hormone synthesized

in adipocytes, is a potentially interesting molecule that negatively and positively regulates NP Y and POMC expression, respectively. Although the physiological consequences of leptin deficiency are clear, namely, obesity, leptin levels are elevated in most human obese patients, and in rodent models, indicating that most obesity is leptin-resistant. Much work remains to be done before neuropeptide actions in the brain are precisely understood.

7. How Neuropeptides Are Studied

Earlier work on neuropeptide expression and distribution was based mainly on immunological procedures. **Antibodies** raised against particular peptides can be used to evaluate the tissue distribution and subcellular localization of neuropeptides. **Radioimmunoassays** continue to be used for measuring peptide secretion in different physiological (or diseased) states of a given organism. When molecular biological procedures became available, neuropeptide gene expression could be monitored qualitatively, and even quantitatively, by a variety of techniques including ***in situ* hybridization**, **Northern blot** analysis, and **solution hybridization** . In some instances, it might be interesting to measure the release of neuropeptides into the central nervous system *in vivo*, and this can be done by microdialysis and the application of push-pull systems. The biological role of neuropeptides in various aspects of behavior (learning, anxiety, feeding, reproduction, etc.) can be studied by injecting the peptide under investigation into the brain and subsequently using several behavioral paradigms. Intracerebroventricular injection of urocortin, for example, has suggested anxiogenic-like properties of this neuropeptide (17). Neuropeptide genes may also be "knocked out" by targeted deletion to investigate the physiological and/or behavioral effects of the absence of a neuropeptide. As with the NP Y "knock out" mouse mentioned before, however, the animals often do not show a phenotype deviating from that of normal individuals which carry the corresponding gene. This may be due to mechanisms operative during embryogenesis and subsequent development that ultimately compensate for the loss of function of an individual neuropeptide. To alleviate this drawback, a novel technique, called "conditional knockout," is employed. This technique permits shutting off the expression of defined genes postnatally in a reversible manner.

Two different approaches have been chosen recently to identify novel neuropeptides, the orexins/hypocretins. In a search for the natural ligand of a cloned "orphan" receptor, the biologically active entity, termed orexin, that binds to and activates the heterologously expressed receptor was purified biochemically. After determining of the amino acid sequence of the peptide, degenerate oligonucleotide primers were designed and used to screen a cDNA library. Employing this procedure, called "reverse genetics," the structure of the orexin precursor was elucidated (18). Interestingly, the same precursor, called pre-prohypocretin, was identified by a second research group using a completely different approach. In this case, subtractive hybridization cDNA cloning techniques were employed to identify proteins specifically expressed in the rat hypothalamus (19). Other neuropeptides have been similarly identified recently. These include cortistatin, a neuropeptide structurally related to SST and possibly involved in sleep behavior (20). Another example is nociceptin/orphanin FQ, which is structurally related to the opioid peptide dynorphin A and has been characterized independently by two research groups (21, 22). It is likely that additional novel neuropeptides will be discovered as a result of the human genome project.

Neurotoxins

Given the fundamental importance for survival of animals having a fully functional neuromuscular apparatus, particularly in the wilderness, it is no surprise that most toxins are specific for components of nerve and muscle cells. Some of these are ion channel-specific toxins (1-4) (see

Alpha-Bungarotoxin and Curare-Mimetic Toxins, Conotoxins, and Dendrotoxins). Here, only toxins affecting neuroexocytosis will be considered.

Many snakes and some insects produce neurotoxins with secondary and tertiary structures closely similar to those of the pancreatic phospholipase A2 (PLA_2). It appears that during the course of evolution, the PLA_2 structural module has been remodeled by some animals to produce highly toxic neurotoxins (5). Some neurotoxic PLA_2, such as the *Bungarus multicinctus* ß-bungarotoxin and the rattlesnake crotoxins, are coupled to other proteins that are responsible for specific binding to the presynaptic membrane; in other toxins, such as notexin , neurospecificity is determined by the PLA_2 molecule itself. PLA_2 neurotoxins induce a transient release of neurotransmitter, followed by a persistent blockade of neuroexocytosis. Their molecular mechanism of action has so far escaped intense investigation, but it appears that the PLA_2 activity is required only in the inhibitory phase.

An opposite synaptic effect is caused by intoxication with the a-latratoxin, or the insect-specific latroinsectotoxin , which is produced by black widow spiders of the genus *Latrodectus*. These excitatory neurotoxins are very large proteins of more than 1,400 residues that induce a massive neurotransmitter release from synaptic terminals of all types of neurons. Fusion of the small synaptic vesicles with the presynaptic membrane is not followed by endocytosis, and the poisoned synaptic boutons are enlarged. Functional latratoxin receptors have not been identified, but the very large **glycoproteins** known as neurexins appear to play a role in toxin binding (7).

Anaerobic bacteria of the genus *Clostridium* produce large neurotoxins that are the cause of the neuroparalytic syndromes of tetanus and botulism. These diseases are caused, respectively, by *tetanus* neurotoxin (TeNT) and by one of eight *botulinum* neurotoxins (BoNT, from A to G) (8). The BoNT block the release of acetylcholine at the neuromuscular junction and cause a flaccid paralysis, whereas TeNT acts on the inhibitory interneurons of the spinal cord, whose impairment results in a spastic paralysis. These toxins act in the neuronal cytosol via a zinc-endopeptidase activity that is specific for three protein components of the neuroexocytosis apparatus (8).

The clostridial neurotoxins are produced as a single inactive polypeptide chain of 150 kDa and released upon bacterial lysis. BoNT are complexed with nontoxic accessory proteins, which protect them during their transit through the stomach, and the complexes dissociate at the neutral pH of the intestine (8). Active two-chain neurotoxins, composed of disulfide-linked heavy (H, 100 kDa) and light (L, 50 kDa) chains, are generated by proteolytic cleavage at an exposed loop. TeNT and BoNT each consist of three functionally distinct domains, which play different roles in cell intoxication (8). Domain L is the catalytic part, whereas the 50-kDa amino-terminal half of the H chain governs cell penetration, and the 50-kDa carboxyl-terminal half of the H chain is responsible for the absolute neurospecificity of these toxins. Together with their intracellular enzymatic activity, this accounts for the fact that they are the most potent toxins known (mouse LD_{50} ranging between 0.1 and 1 ng/kg). No receptors for TeNT and BoNT are known, but there is evidence that polysialogangliosides play a role in their fixation at nerve terminals and the amino-terminus of synaptotagmin is implicated in BoNT/B binding (8).

After binding to peripheral motoneurons, TeNT and BoNT are internalized inside vesicles of unknown nature, in a temperature- and energy-dependent process (9, 10). TeNT penetrates central nervous system neurons by binding to the luminal side of synaptic vesicles during neurotransmitter release, which is followed by vesicle endocytosis (11). Refilling of the vesicle with neurotransmitter is coupled to acidification of the lumen by the vacuolar **ATPase proton pump** . Similar to diphtheria toxin (DT), this causes a conformational transition of TeNT to an acidic conformation that mediates the translocation of its L chain into the cytosol (6, 11, 12).

The L chains of TeNT and BoNT/B, /D, /F, and /G specifically recognize and cleave

VAMP/synaptobrevin, whereas BoNT/A and /E hydrolyze SNAP-25, and BoNT/C cleaves both syntaxin and SNAP-25 (8). This indicates that VAMP, SNAP-25, and syntaxin play key role(s) in exocytosis. With the exception of TeNT and BoNT/B, each of the different clostridial neurotoxins catalyzes the hydrolysis of different peptide bonds (8). As in the case of DT, it is likely that one molecule of toxin is capable of cleaving all target molecules present in the intoxicated cell. At variance from DT, but similar to **cholera toxin** and pertussis toxin, the clostridial neurotoxins do not cause neuronal death: They only paralyze the intoxicated synapse, and the poisoned animal may die because of the impairment of neuronal and muscular functions. If the animal survives, the synapse recovers its normal function within a few months. Such reversibility is at the basis of the clinical use of BoNT, which are the best available therapeutic agents for several diseases that benefit from a functional paralysis of selected neuromuscular junctions (13).

Neutral Mutation

can be classified into three groups, depending on their effect on the individual affected: advantageous, neutral, and deleterious. Deleterious mutations are usually eliminated quickly from the population by , namely, negative selection. It is quite possible that an advantageous mutation increases its frequency in a population by natural selection that is positive selection. In the case of a neutral mutation, its fate is determined by mere chance due to random mating (see). Strictly speaking, both advantageous and deleterious mutations are also affected by genetic drift, unless the effective population size (N) is infinitely large. The theory of population genetics shows that any **alleles** behave as if they are neutral when $|Ns|$ is less than 1, where s is a selection coefficient (1). The selection coefficient, s, is defined by formulating the fitness (f) by $f = 1+s$ (for an explanation of fitness, see). Therefore, even if an advantageous mutation arises, the mutation can be treated as a neutral mutation when the effective population size is very small.

The neutral theory of molecular evolution contends that a large proportion of molecular mutations

that have become fixed in populations are neutral rather than advantageous. On the other hand, selectionists maintain that most such mutations should be advantageous, and they consider them to be the driving force of evolution. Both, however, agree that the majority of mutations are deleterious. Nevertheless, these mutations do not contribute to because they disappear quickly from the population. Therefore, the core issue of the controversy between selectionists and neutralists is what proportion of mutational changes in amino acid and nucleotide sequences is neutral when all deleterious mutations are excluded.

The controversy over the neutral theory has made great contributions to molecular evolution and population genetics in the following two aspects. Firstly, it provided general recognition that the effect of genetic drift cannot be neglected in the study of the evolutionary dynamics of molecular changes. The other was to accelerate the fusion of molecular evolution and population genetics by the recognition that molecular evolution and genetic **polymorphism** are two facets of the same phenomenon (2).

Neutron Diffraction And Scattering

Neutron diffraction and scattering yield structural information on biological molecules and their complexes at multiple levels of resolution. Neutron diffraction and scattering methods generally complement X-ray methods and other structural techniques, frequently offering unique pieces of information that enable one to put together the final jigsaw puzzle picture of how a biological molecule or complex works. Neutron diffraction analysis of crystalline samples is analogous to X-ray crystallography, but at modestly high resolution (<3 Å) one can locate precisely individual hydrogen atoms that can be key to enzymatic mechanisms (1) or ligand binding (2). One can also study solvent and its role in protein stability (3-5). Medium-resolution neutron diffraction (3 to 8 Å) has been used to orient alpha-**helices** (6) and to locate specific groups, such as the retinal chromophore in two-dimensional crystals of the membrane protein bacteriorhodopsin (7), and to locate water molecules in DNA **structures** (8). Low-resolution neutron diffraction (>8 Å) with contrast variation gives information on disordered regions in membrane protein crystals, or in large biomolecular complexes such as viruses, and specific examples of this applications are described in Contrast variation. Small-angle scattering of neutrons can yield information on the overall shapes of biological macromolecules in solution and, when combined with contrast variation, can give information on the shapes and dispositions of individual components in biomolecular complexes.

1. Interactions of Neutrons with Matter and Basic Scattering Theory

Neutrons offer a number of advantages as a structural probe in biology. They are less damaging to biomolecules than X-rays. They can be produced in a range of wavelengths from tenths to tens of angstroms and hence are useful for probing many orders of magnitude of dimensions relevant in biological structures: from ~1 to 10^3 Å. Neutrons are neutral particles and interact principally with the atomic nuclei in a sample. Their scattering properties depend upon the complex neutron–nucleus

interaction; as a consequence, isotopes of the same element can have very different neutron scattering properties. In addition to the coherent component that can interfere and hence yield structural information the scattering of neutrons by atoms can have a significant incoherent component. The incoherent component is only significant for nonzero spin nuclei (9), and in elastic scattering experiments it gives rise to isotropic scattering that contributes to the background. The incoherent scattering is very large for the hydrogen atom, and consequently for many structural biology applications of elastic neutron scattering it is optimal to minimize the amount of hydrogen in a sample by isotopic substitution with deuterium. Alternatively, investigators have used the incoherent, inelastic scattering from neutrons to probe the dynamics of biomolecules (10). Table 1lists the coherent scattering amplitudes and incoherent scattering cross sections for the nuclei commonly found in biomolecules.

Table 1. Coherent Neutron Scattering Lengths, b_{coh}, and Incoherent Cross Sections, s_{inc}, for Biologically Relevant Nuclei

Atom	Nucleus	$s_{inc}(10^{-24}$ cm$^2)$	b_{coh} $(10^{-12}$ cm)
Hydrogen	^{1}H	80	–0.3742
Deuterium	^{2}H	2	0.6671
Carbon	^{12}C	0	0.6651
Nitrogen	^{14}N	~0	0.940
Oxygen	^{16}O	0	0.5804
Phosphorus	^{31}P	~0.3	0.517
Sulfur	Mostly ^{32}S	~0	0.2847

Neutrons can be considered as plane waves with wavelengths (l); when they are scattered by atoms in a molecule, whose positions are designated by the vector **r** from an arbitrary origin, the resultant interference of the elastic, coherent scattering is related to the spatial distribution of those atoms and can be expressed as

$$\sum_i \sum_j b_i b_j e^{-i\mathbf{Q}\cdot\mathbf{r}_{ij}} \qquad (1)$$

where $\mathbf{r}_{ij} = \mathbf{r}_i - \mathbf{r}_j$ and the summations are over all atoms. **Q** is the difference between the incident and scattered wave vectors, and its amplitude is 4p(sinq)/l, where 2q is the scattering angle. *b* is the neutron scattering amplitude for the atom in units of length. Unlike those for X-rays, neutron scattering amplitudes show little or no dependence on scattering angle, because the dimensions of the scattering nuclei are much smaller than the wavelengths of the incident neutrons. In low-resolution solution scattering experiments, one can describe molecules as continuous density distributions, rather than sums of discrete point atom scatterers. Neutron scattering densities are calculated as the sum of the scattering lengths of atoms within a finite volume element, divided by that volume, Sb_i/V, and a molecule can be described by a scattering density distribution r(**r**). The total coherent scattering intensity distribution, $I(Q)$, for a randomly oriented molecule in a solvent with a mean scattering density r_s is

$$I(Q) = \left\langle \left| \int \Delta\rho(\mathbf{r}) e^{-i\mathbf{Q}\cdot\mathbf{r}} d\mathbf{r} \right|^2 \right\rangle \tag{2}$$

$$= \int \int \Delta\rho(\mathbf{r}_1)\Delta\rho(\mathbf{r}_2) \frac{\sin Q|\mathbf{r}_1 - \mathbf{r}_2|}{Q|\mathbf{r}_1 - \mathbf{r}_2|} d\mathbf{r}_1 d\mathbf{r}_2 \tag{3}$$

The brackets ⟨¼⟩ indicate averaging over all orientations of the particle, and the integration is over the volume of the molecule. The term Dr(**r**) = r(**r**)–r_s is the contrast between the scattering density of the molecule and the solvent, and contrast variation experiments involve the deliberate manipulation of this factor to alter the resultant scattering. The total scattering intensity distribution for a solution of monodisperse molecules will be directly proportional to both the number density and the square of the molecular weight of the particles. Analysis of the small-angle scattering from biological macromolecules in solution yields structural parameters, such as the radius of gyration, R_g, molecular weight, M, and the vector length distribution function, $P(r)$, for the macromolecule. $P(r)$ is sensitive to the symmetry of the scattering particle, and it goes to zero at its maximum linear dimension (see Small-Angle Scattering). $P(r)$ is related to the scattering intensity distribution, $I(Q)$, by a Fourier transformation:

$$I(Q) = 4\pi \int P(r) \frac{\sin Qr}{Qr} dr \tag{4}$$

$$P(r) = \frac{1}{2\pi^2} \int I(Q) Q \cdot r \sin(Q \cdot r) dQ \tag{5}$$

In the case of samples that are ordered in one, two, or three dimensions, the scattered intensity is *not* spherically averaged, but rather convoluted with the repeating lattice to yield a diffraction pattern that has discrete intensity maxima that can be interpreted in terms of the repeat distances in the sample and sometimes give more detailed structural information about the ordered molecules themselves. For example, one can learn about the superhelical structures formed by protein–DNA complexes (11-13), or about the structures of membranes and the proteins they contain (6, 7). Neutron crystallography is the use of neutron diffraction data from three-dimensional crystals of macromolecules to solve the structure of the crystallized molecule at high resolution. The crystal diffraction data form a complex pattern whose maxima are indexed according to the crystal lattice indices h, k, l. The unit cell diffraction is generally described mathematically in terms of the square of the structure factor F_{hkl}, which is simply the ratio of the radiation scattering by any real sample to a point scatterer at the origin, and

$$I(Q_{hkl}) = F_{hkl}^2 = \left| \int_j b_j e^{-2\pi i(hx_j + ky_j + lz_j)} \right|^2 \tag{6}$$

where x, y, and z are the atomic coordinates of each atom in the crystallized molecule, and the summation is over all atoms. One "solves" a crystal structure by using the measured I_{hkl} values to calculate the amplitudes of the structure factors, to which a phase must be assigned in order to extract, by Fourier transformation, the coordinates (x, y, z) for each atom or chemical group in the crystallized structure. The correct assignment of phases (which cannot be measured directly) is known as the "phase problem." Methods for solving the phase problem that are successful for X-ray crystallography, such as molecular isomorphous replacement, are not useful for neutron

crystallography. The reason is that they depend upon crystallizing isomorphous molecules with heavy atom labels that scatter X-rays much more strongly than other atoms in the structure and hence can be located and used to generate an initial set of model phases. Neutron crystallography does not have the equivalent of a "heavy atom," because the neutron scattering lengths of most atoms lie in a narrow range of values. As a result, neutron crystallography generally is most useful when the X-ray crystal structure is already available and there are outstanding issues regarding for example, the locations of light atoms. Because neutron scattering amplitudes show no systematic dependence on atomic number, light atoms such as hydrogen are readily located in a neutron crystallography experiment.

One of the largest differences in coherent neutron scattering amplitudes for atoms in biological systems is between the isotopes of hydrogen (^{1}H and ^{2}H). Note from Table 1that the scattering amplitude for ^{1}H is negative, resulting from a 180° phase shift between neutrons scattered by ^{1}H compared to the other nuclei. Thus, selective deuteration of one component of a complex in solution provides a way of altering the mean neutron scattering density of that component. Furthermore, by changing the deuterium level in the solvent, the neutron scattering contrast of each component is varied. It is these properties that facilitate contrast variation methods that, when combined with small-angle scattering, provide a means for extracting structural information on the individual components of a complex and their relative dispositions in solution. In combination with low-resolution crystallography, contrast variation can be used to locate components or features that are of too low contrast in the corresponding X-ray crystallography experiment to be distinguished.

2. Production of Neutrons

Neutron beams with sufficient intensity for studying the structures of biological molecules require sophisticated technology for their production. There are two classes of sources for high-intensity neutron beams for condensed matter studies operating in the world today: nuclear reactors and accelerators. Nuclear fission reactors produce energetic neutrons in quantities beyond those needed to sustain the chain reaction. The excess neutrons escape and are moderated by various substances surrounding the core of the reactor. The neutrons equilibrated with the moderator substance will have Maxwell–Boltzmann distributions of energies appropriate for the moderator temperature. High-resolution neutron crystallography instruments typically use neutrons moderated at room temperature, yielding a peak in the energy distribution around 1 Å. Small-angle neutron scattering benefits from having longer wavelengths available, and thus "cold sources" (eg, liquid hydrogen) are used to slow the neutrons further to have energy peaks in the region 4 to 10 Å. Recently, accelerator-based spallation neutron sources (14) have evolved to the point where they can be useful for biological studies. These sources use high-energy proton pulses directed onto a target of heavy nuclei. Neutrons are captured by the heavy nuclei, producing an unstable nucleus that decays, giving off pulses of neutrons in a process referred to as spallation. Pulsed neutron sources are very bright, but on average over time deliver fewer neutrons than a steady-state reactor source. Advantages in pulsed source instrumentation can be gained, however, by using time-of-flight methods to determine the wavelengths of neutrons reaching a detector (15), thus enabling the experimenter to use the entire "white" neutron beam. As spallation sources become more powerful, they are becoming more competitive with reactor sources for scattering applications. In spite of technological advances in neutron sources and instrumentation over the past few decades, however, neutron sources have intensities many orders of magnitude lower than even that of a conventional laboratory X-ray source. Some of this disadvantage can be overcome by long exposures of samples in experiments, because neutrons are less-damaging radiation. However, neutrons are generally used only when their unique properties confer an important advantage that gives specific information that cannot otherwise be obtained.

3. Examples of Neutron Diffraction and Scattering Applications

3.1. High-Resolution Neutron Diffraction Reveals Locations of Hydrogens in Protein Crystals

High-resolution neutron diffraction studies of three-dimensional crystals of proteins have yielded detailed information on the protonation state of individual chemical groups as well as the solvent structure that plays a role in protein folding and stability. In 1980, Kossiakoff and Spencer (1) reported the neutron crystal structure of bovine **trypsin** covalently inhibited by a **transition-state analogue**, thus revealing the protonation states of the active-site residues Asp102 and His57 of the catalytic triad. This result resolved the much debated mechanistic issue by showing conclusively that the catalytic base in the transition state of the reaction is His57 and not Asp102. High-resolution neutron diffraction data to 2.1 Å from crystals of trypsin (4) localized two-thirds of the waters of hydration expected from thermodynamic data. In comparison, X-ray studies at higher resolution (1.35 Å) located about half the waters of hydration, and a number of these were found in the neutron study to be spurious. In another high-resolution neutron diffraction study of carbobon monoxy-myoglobin (5), 87 water and 5 ion molecules were localized, and a number of X-ray-determined waters of hydration were identified as spurious. Neutron crystallography presents a number of difficulties as a result of the relatively low fluxes of neutron sources (compared with X-rays), and the signal-to-noise ratio is low because of the high incoherent backgrounds from hydrogenated proteins. In 1994, Kossiakoff and colleagues (16) reported obtaining 1.5-mm^3 crystals of perdeuterated **Staphylococcal nuclease**. They showed that there are no structural differences between the protiated and deuterated proteins at 1.9-Å resolution. Perdeuteration of proteins is thus a promising tool for gaining signal-to-noise in neutron crystallography experiments.

3.2. Subunit Structure of Biomolecular Assemblies: The Ribosome

Ribosomes are complex assemblies of proteins and RNA that act as protein factories in all living cells. They are composed of a small and large subunit. The 70S ribosome from *E. coli* is the most extensively studied ribosome, and different subunits have been the target of neutron scattering investigations. Early studies used contrast variation to locate the protein and RNA in both subunits (17-19), and more recent studies have used deuteration, triangulation (20, 22), or triple isotopic substitution (23) methods to give more structural details. In 1987, Moore and co-workers published a complete map of all 21 proteins of the small ribosomal subunit from *E. coli* using triangulation by measuring distances between pairs of proteins within the small subunit (20). In their experiment, the 30S ribosomal subunit was reconstituted from 16S ribosomal RNA and a mixture of purified 30S proteins, one or more of which was deuterated. Using the small-angle neutron scattering data from these samples, they determined the distance between the centers of mass for each pair of deuterated proteins, plus the radius of gyration for each protein. Over a 10-year period, this group obtained 105 distance data sets relating 93 different protein pairs in the 30S subunit. Using triangulation, they constructed a three-dimensional map of the 21 proteins of the 30S subunit (Fig. 1).

Figure 1. Representation of the neutron map of the 30S subunit of the *E. coli* ribosome (20). Each protein is represented by a sphere whose volume equals that of the protein. The numbering of the proteins adheres to the standard nomenclature for ribosomal proteins.Courtesy of Malcom Capel.

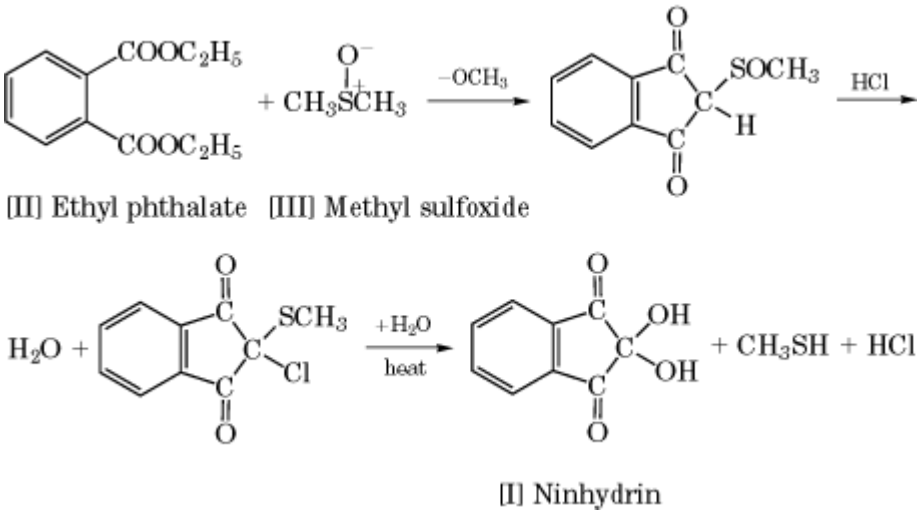
Ninhydrin

Ninhydrin [I] generates a blue-purple color on reacting with free amino groups in amino acids, **peptides**, or proteins. It has a molecular weight of 178.14 and occurs as colorless or faint yellow crystals. Ninhydrin, also called 2,2-dihydroxy-1,3-indanedione, is synthesized from ethyl phthalate [II] and methyl sulfoxide [III] (Scheme 1):



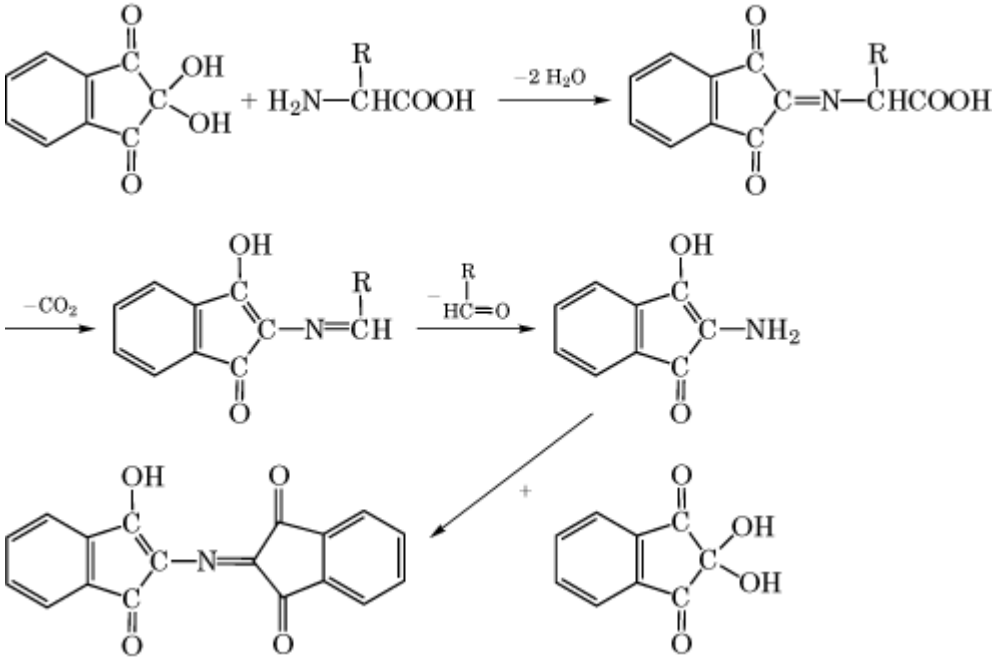
[II] Ethyl phthalate [III] Methyl sulfoxide

[I] Ninhydrin

1. Ninhydrin Reaction

When a solution containing amino acids, peptides, or proteins is boiled with ninhydrin under mildly acidic conditions, an intense blue-purple color with an absorption maximum at 570 nm develops

(Scheme 2):



Amino acids, such as proline and hydroxyproline, develop color with an absorption maximum at 440 nm.

In the original instruments for automatic amino acid analysis, a protein sample that has been hydrolyzed with 6 N HCl at 110°C for 24 h to amino acids is separated with an ion-exchange **chromatographic** column, and the eluate is monitored at 570 nm after being developed with the ninhydrin reaction. To detect peptides or amino acids on filter paper or other solid supports, the paper is dipped in or sprayed with ninhydrin solution in acetone.

2. Protein Detection by Ninhydrin Method

A solution containing 20 to 500 µg protein is dried on a filter paper. Nonprotein compounds that might react with ninhydrin are eluted by washing with a **trichloroacetic acid** solution. Then the proteins are hydrolyzed with $Ba(OH)_2$ solution at 120°C for 10 min, and the amino acids released are measured by the ninhydrin reaction (1). Because the amount of protein present is determined by the amino acids produced, this is an accurate method suitable for all proteins.

Nitration

Tyrosine residues are nitrated with tetranitromethane (TNM) [I] to form 3-nitrotyrosine residues [II] under mild conditions (Scheme **1**) (1):3-Nitrotyrosine is colored, with an **absorbance** maximum at 428 nm at alkaline pH, and can be utilized as a reporter group. TNM also oxidizes thiol groups at low pH. The nitration reaction often causes protein polymerization, especially at high protein concentration. The modified nitrotyrosine residue is reduced with sodium hydrosulfite to an aminotyrosine residue, which then can be subjected to further modifications.

Nitric Oxide

Nitric oxide (NO, nitrogen monoxide) is one of the smallest molecules to be synthesized in biological systems. Carrying an unpaired electron, NO is a short-lived free radical and is highly reactive in biological environments. Nitric oxide was previously well known for its roles as an air pollutant that contributes to the formation of photochemical smog, as a participant in bacterial nitrogen fixation, and as a probe to study the metal-binding sites of metalloproteins. Not until 1987 did scientists discover that NO is actually produced in many organs and tissues of mammals. Even more astonishing, this molecule has remarkably diverse functions, ranging from neurotransmitter and vasodilator to microbicidal mediator. It has earned a reputation as a double-edged sword, responsible for both beneficial and deleterious effects (1). Depending on the site, duration and amount of NO produced, NO can have either cytoprotective or cytotoxic effects. How can such a small and simple inorganic molecule exhibit such diverse functions? How is NO production regulated in different cell types? How can we apply our knowledge to control diseases where NO plays significant roles? Seeking answers to such questions has been the focus of intensive research for the past ten years. Our current understanding of regulation of NO biosynthesis and the roles of NO in mediating biological processes under physiological and pathophysiological conditions are the themes of this article.

1. Nitric oxide

The biological roles of NO were initially discovered through several lines of investigation in the fields of toxicology, immunology, cardiovascular pharmacology, and neurobiology. As early as 1916, Mitchell et al. observed that the amount of nitrate (NO_3^-) in the urine of rats, pigs, and humans exceeded the amount present in their diets and suggested that mammals produce nitrogen oxides (2). This study was largely ignored until the late 1970s and early 1980s, when Tannenbaum and coworkers (3) demonstrated that nitrogen oxides are important products of mammalian metabolism and that infection caused a greater than tenfold increase in plasma nitrate and nitrite (NO_2^-) levels (4, 5). By 1985, Stuehr and Marletta (6) identified **macrophages** as a source for nitrate and nitrite production. This was based on the observation that macrophages isolated from mice that were previously injected with infectious agent produced high amounts of nitrate and nitrite and that *Escherichia coli*–derived endotoxin induced nitrate and nitrite synthesis by cultured macrophages (6). This *in vitro* finding led to the observation that nitrogen oxides (NO_x^-) are synthesized enzymatically from the amino acid L-arginine, with L-citrulline as coproduct (7). Independently, Hibbs et al. discovered that conversion of L-arginine to nitrogen oxides was required for macrophage-mediated cytotoxicity toward tumor cells (8) and that the synthesis of reactive nitrogen oxide intermediates from L-arginine, as well as the cytotoxicity of macrophages, could be blocked by a series of N_w-substituted L-arginine analogs (9). Addition of nitrite and nitrate to cultured tumor cells did not duplicate the macrophage's ability to kill, whereas NO could. These studies suggested an important role (or roles) for NO in the immune defense system (10-12). It is now known that NO is indeed a macrophage-derived cytostatic agent.

In 1980, Furchgott and Zawadski reported that the endothelium (the innermost cell layer of blood vessel walls) releases a liable substance that diffuses into the underlying smooth muscle layer, activates soluble guanylate cyclase, and thus causes vascular smooth muscle relaxation (13). This liable agent was termed *endothelium-derived relaxation factor* (EDRF). In 1987, Moncada and coworkers (14) as well as Ignarro and coworkers (15), independently demonstrated that NO was produced by the endothelium and was indeed the EDRF (16, 17). These initial important discoveries in the immune and cardiovascular systems were further extended by Garthwaite and coworkers, who identified an EDRF-like activity in the brain after stimulation with N-methyl-D-aspartic acid (18). Taken together, these discoveries hinted at the wide distribution of the L-arginine:NO synthesis pathway in mammals. Studies to date have revealed that nearly every organ and tissue can produce NO.

Although NO is a simple diatomic molecule, the complexity of its **redox** chemistry in biological systems may account for its diverse functions (19, 20). Nitric oxide is a gaseous molecule with an unpaired electron (·N = O). It tends to react rapidly with other atoms or molecules that also contain unpaired electrons, for example, with oxygen (O_2), superoxide (O_2^-) and transition metals. Unlike most known signal transduction transmitters, NO is unique in being nonpolar and able to diffuse freely across cell membranes. The reaction between NO and superoxide is a diffusion-controlled reaction, and it generates peroxynitrite ($ONOO^-$). Peroxynitrite is a powerful oxidant that can oxidize a variety of biological molecules (eg, nitration of tyrosine residues) and may therefore be responsible for certain types of NO-mediated toxicity. On the other hand, NO can effectively scavenge oxygen radicals and thus may protect against cellular damage and cytotoxicity caused by reactive oxygen radicals (21). The ultimate products of NO reacting with oxygen are nitrite and nitrate, which are largely unreactive anions and represent the biological fate of NO.

In biological environments, NO reacts primarily with transition metals, thiol groups, and with nitrogen and oxygen radicals generated under certain conditions. Metal- and thiol-containing proteins are well-described targets for NO. The interaction between NO and prosthetic iron groups or thiol groups leads to the formation of adducts that either activate or inactivate the target protein. These represent the major mechanisms by which NO exerts many of its biological functions. For example, binding of NO to the heme iron of soluble guanylate cyclase results in activation of the

enzyme and, thus, elevation in intracellular levels of the second messenger, cyclic GMP. It is through the activation of soluble guanylate cyclase that NO mediates vasorelaxation, inhibition of platelet aggregation, and neurotransmission in the central nervous system (22). Another heme-containing enzyme that is activated by NO is cyclooxygenase involved in eicosanoid synthesis (23). However, this NO-dependent activation is thought to result from S-nitrosylation of a thiol group, not from interaction with the heme moiety [reviewed by Salvemini and Masferrer (24)]. Another critical target of NO in cell signaling is $p21^{ras}$, a monomeric G protein family member that plays essential roles in converting extracellular signals into intracellular biochemical events (25); see *ras* proteins). S-nitrosylation of a single cysteine residue by NO results in activation of $p21^{ras}$ and thus downstream signaling (26). Nitric oxide–mediated nitrosylation of non-heme iron, heme iron, or critical thiol groups of enzymes can also result in inhibition of enzyme activity. Examples of enzymes belonging to this category include aconitase, NADH:ubiquinone oxidoreductase, succinate:ubiquinone oxidoreductase, cytochrome P450, glyceraldehyde-3-phosphate dehydrogenase, ribonucleotide reductase, NADPH oxidase (22, 27, 28) and caspases involved in **cytokine** maturation and apoptosis (29-31); see Table 1).

Table 1. Biological Targets of Nitric Oxide

Target Site	Examples
Heme-containing proteins	Soluble **guanylyl cyclase**
	Cyclooxygenase
	Hemoglobin/myoglobin
	NO synthase
	Cytochrome P450
Fe-S cluster containing enzymes	*cis*-Aconitase/IRE-BP
	NADH: ubiquinone oxidoreductase
	Succinate: ubiquinone oxidoreductase
	Ribonucleotide reductase
Thiol groups	Caspases
	Glutathione
	Glyceraldehyde-3-phosphate dehydrogenase
	Plasminogen activating factor
	Adenylate cyclase

	NADPH oxidase
	$p21^{ras}$
	Albumin
	N-methyl-D-aspartate receptor
	Protein kinase C
Free radicals	Superoxide Lipid radicals
DNA[a]	

[a] Via deamination.

Although typically short-lived because of its reactivity with cellular targets and oxyhemoglobin of red blood cells, NO probably can also exert actions remote from the site of synthesis. Nitric Oxide has been shown to form stable adducts. Relatively long-lived nitrosothiol adducts can occur on albumin, glutathione, and hemoglobin, which all still possess the biological functions of NO, probably by its release (32-35).

2. Nitric oxide synthase

Our understanding of the regulation and function of NO have greatly advanced through studies on nitric oxide synthase (NOS, EC1.14.13.39), the enzyme responsible for NO synthesis. Nitric oxide is synthesized via the oxidation of one of the two chemically equivalent guanidino nitrogen atoms of L-arginine, with L-citrulline formed as the coproduct (Fig. 1). Oxidation of arginine by NOS occurs via two successive monooxygenation reactions, producing an intermediate N^{w}-hydroxyl-L-arginine. This is a five-electron oxidation reaction, with NADPH as the electron donor. Five bound **cofactors** and **prosthetic groups** are required for NOS activity: flavin adenine dinucleotide (FAD), flavin mononucleotide (FMN), iron-protoporphyrin IX (heme), tetrahydrobiopterin (BH_4), and calmodulin (CaM). There are at least three NOS **isoforms**; each represents a distinct gene product and exhibits unique expression patterns and mechanisms of regulation (Table 2). The constitutive isoforms, neuronal NOS (nNOS, ncNOS, or NOS1) and endothelial NOS (eNOS, ecNOS, or NOS3), are expressed constitutively and require binding of Ca^{2+}-CaM for catalytic function. Binding of the Ca^{2+}-CaM complex to cNOSs is triggered by transient increases in intracellular Ca^{2+} levels. In contrast, CaM binds tightly to the inducible NOS isoform (iNOS or NOS2) even at basal Ca^{2+} level and thus renders iNOS activity independent of fluctuation of Ca^{2+} levels (36). In response to Ca^{2+} transients, cNOS intermittently produces small amounts of NO (NO "puffs") that participate in physiological signaling processes such as vasorelaxation and neurotransmission; and on induction by endotoxin or cytokines (immunologic or inflammatory stimuli), iNOS produces large and sustained amounts of NO that exhibit not only signaling functions but also antimicrobial activity and cytotoxic effects. The roles of NO under physiological and pathophysiological conditions are typically studied via pharmacological and genetic approaches (Table 3).

Figure 1. The reaction catalyzed by nitric oxide synthase.

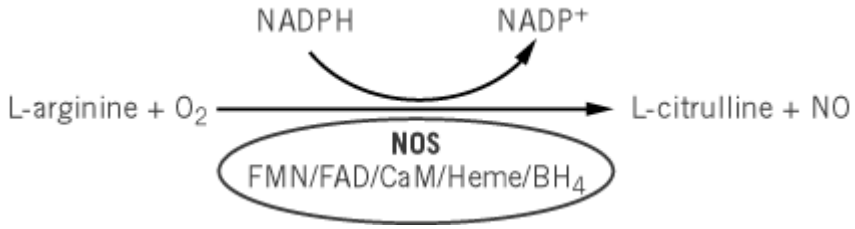

Table 2. Characteristics of Human Nitric Oxide Synthase Isoforms

Isoform	ncNOS	iNOS	ecNOS
Predicted polypeptide size	61 kD/1434aa	131 kD/1153aa	133 kD/1203aa
Cofactor/prothetic groups	FAD, FMN, BH_4,P450-like heme, CaM	FAD, FMN, BH_4,P450-like heme, CaM	FAD, FMN, BH_4,P450-like heme, CaM
Primary cellular location	Cytosol	Cytosol	Golgi, caveolae
Active enzyme	Dimer	Dimer	Dimer
Ca^{2+} dependency	Yes	No	Yes
Gene size	>200 kb	≈37 kb	≈21 kb
Gene loci	12q24.2	17q11.2–q12	7q3.5–q3.6
Number of exon/intron	29 / 28	26 / 25	26 / 25
mRNA size	10.0 kb	4.5 kb	4.7 kb
Translation initiation/termination site	Exon 2 / 28	Exon 2 / 26	Exon 1 / 26
Predominant regulation mechanism	Ca^{2+} transients	Transcription	Ca^{2+} transients[a]

[a] Ca^{2+}–independent activation also occurs.

Table 3. Tools to Study Nitric Oxide

Approach	Pharmacological	Example	Genetic
Remove NO	Inhibitors:		Knockout mice (106)

	nonselective	N^{w}-substituted L-Arg analogs	ncNOS
	selective	NIL[a]	iNOS
			ecNOS
	Scavengers	Oxyhemoglobin	Antisense oligonuclotides
Supply NO	NO donors	SNAP, nitroprusside	Gene transfer (107)
		nitroglycerin	

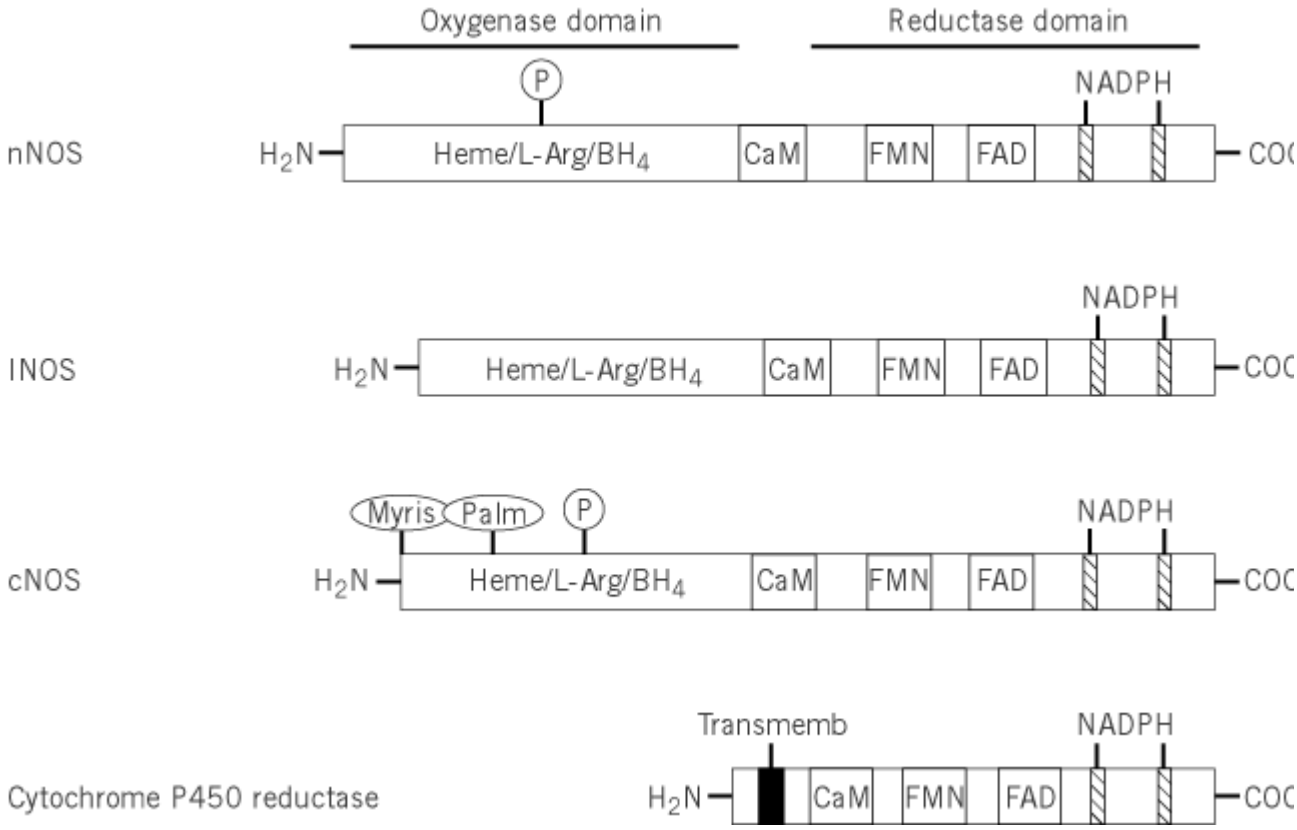
[a] NIL: *N*-iminoethyl lysine; SNAP: S-nitroso-*N*-acetylpenicillamine.

The three NOS isoforms share 50% to 60% amino acid sequence identity with each other, whereas the same NOS isoform from different species has homology ranging from 80% to 96% identity [eg, 80% sequence identity between murine macrophage iNOS and human hepatocyte iNOS at both nucleotide and amino acid levels (37, 38).

2.1. Shared Characteristics

Molecular cloning of **cDNA** of each NOS isoform has greatly advanced our understanding of the structure, functional **domains**, and potential regulatory sites of NOS. Analysis of amino acid sequences derived from NOS cDNA revealed consensus sequences for binding of NADPH, FAD, FMN, and calmodulin (Fig. 2). The C-terminal half of each NOS shows significant homology to NADPH-dependent cytochrome P450 reductase (39, 40). The active form of all NOS isoforms appears to be a homodimer. Each subunit is composed of an N-terminal oxygenase domain and a C-terminal reductase domain, connected by a CaM-binding region (reviewed in 41). Experiments utilizing limited **proteolysis** or **gene expression** of individual domains have confirmed the location of the heme, BH_4, and L-arginine binding sites within the oxygenase domain and of those for FAD, FMN, and NADPH within the reductase domain. The flavins appear to transfer electrons from NADPH to the catalytic heme group, which is P450-like (42). The CaM-binding region may facilitate **electron transfer** between the reductase and oxygenase domains. Dimerization of two subunits is through the oxygenase domain and dependent on BH_4, L-arginine, and heme (43-47). The three-dimensional structure of the iNOS oxygenase domain complexed with inhibitor imidazole or aminoguanidine has been most recently unraveled, allowing the first glimpse at the NOS active site (48). The structure provides a basis for designing highly selective drugs against iNOS, which may overproduce NO in a number of diseases, such as septic shock, inflammatory bowel disease, rheumatoid arthritis, multiple sclerosis, and stroke.

Figure 2. Schematic comparison of various nitric oxide synthase isoforms and cytochrome P450 reductase. P, phosphorylation site; Myris, myristylation site of ecNOS; Palm, palmitoylation site of ecNOS.



2.2. ecNOS

The distribution of endothelial cNOS is relatively limited to vascular endothelial cells, neurons and some epithelial cell types. Nitric oxide derived from vascular ecNOS exhibits many functions, including maintenance of basal vascular tone, mediation of blood vessel relaxation, regulation of blood flow and prevention of platelet adhesion and aggregation.

The ecNOS gene has been cloned from bovine (49, 50) and human (51-53) endothelial cells. The human ecNOS gene is present as a single copy in the haploid human genome, encoded by 26 **exons** spanning ~21 kb and located on chromosome 7. Analysis of the human ecNOS **promoter** reveals the presence of elements that are found in several constitutively expressed genes, namely, the SP1 and GATA motifs (51, 54). Identification of a shear stress response element in the **TATA**-less 5′-flanking region of the human ecNOS gene is consistent with the finding that shear stress produced by the flow of blood increases endothelial-dependent NO release and ecNOS gene expression. Hypoxia also up-regulates transcription of ecNOS (55), and chronic exercise in dogs has been shown to increase coronary artery NO production and specifically ecNOS gene expression (56). Conversely, tumor necrosis factor a (TNFa) down-regulates ecNOS by decreasing the stability of ecNOS mRNA (57).

ecNOS undergoes several post-translational modifications. N-**myristylation** (58) and reversible palmitoylation (59) are unique to ecNOS among the NOS family and account for the membrane targeting of ecNOS to the **Golgi complex** and plasmalemmal caveolae (small invaginations in plasma membrane that may serve as sites for signal processing) (60-63). Association of ecNOS with the Golgi region has been shown to be necessary for ecNOS to respond to intracellular signals and to produce NO in intact cells efficiently (64). Other reported post-translational modifications of ecNOS include **phosphorylation** (65).

ecNOS activity is regulated by the intracellular Ca^{2+} levels (see Calcium Signaling). Agonists that

elevate the intracellular Ca^{2+} level, by either influx of extracellular Ca^{2+} following receptor activation or release of Ca^{2+} from intracellular stores, can increase NO synthesis and, hence, the NO-dependent vasculature relaxation. These agonists include acetylcholine, bradykinin, serotonin, and norepinephrine. Apart from the well-established intracellular Ca^{2+} transient dependency, accumulating evidence demonstrates that ecNOS can also produce NO via a Ca^{2+}-independent pathway in response to fluid shear stress and isometric stretching (reviewed in 66).

2.3. ncNOS

Neuronal cNOS is expressed in neurons of the central nervous system, particularly of the cerebellum and in the peripheral nervous system. In addition to the nervous system, the enzyme and/or its Messenger RNA are also detected in human skeletal muscle; spinal cord; epithelial cells of lungs, uterus, and stomach; pancreatic islet cells; male sex organ; pituitary gland; and kidney macula densa cells. In the brain, on activation of *N*-methyl- D-aspartate (NMDA) receptor by a stimulatory amino acid, such as glutamate, released from adjacent neuron (presynaptic terminus), a channel in the receptor opens, resulting in an influx of Ca^{2+} to the postsynaptic neuron, where Ca^{2+} binds to calmodulin. The Ca^{2+}-CaM complex then activates ncNOS, and NO is produced from L-arginine. Nitric oxide may then exert effects through activating soluble guanylate cyclase and, subsequently, by the elevation of the cyclic GMP content. Also, NO may diffuse back to the presynaptic terminus. A role for NO in the formation of long-term memory has been proposed. High levels of NO production following NMDA receptor stimulation may contribute to the neurotoxicity seen in strokes. In periphery nerves (referred to as nonadrenergic noncholenergic nerves), NO produced from ncNOS has been shown to be a regulator of intestinal motility and penile erection.

The ncNOS cDNA has been cloned and characterized from rat (39) mouse(67), and human (68). The human ncNOS gene consists of 29 exons and 28 introns that span over 200 kb of genomic DNA and is present as a single copy in the haploid human genome (69). One characteristic of ncNOS is the remarkable diversity of the 5′-flanking regions of its mRNA isolated from different human tissues (reviewed in 70). This diversity results from using different first exons, followed by alternate splicing to a common exon 2. The encoded polypeptide chain remains the same because the translation initiation site is located in exon 2. Although ncNOS is constitutively expressed, the various mRNA species are subject to different transcriptional regulation that is development- and tissue-specific, implying that other roles of NO produced by ncNOS will continue to unfold.

As with the ecNOS, generation of NO by ncNOS is triggered by Ca^{2+} transients. Binding of Ca^{2+}-CaM to ncNOS acts as a switch that facilitates electron flow from the donor NADPH via flavins to the catalytic heme. The primary sequence of ncNOS also contains a consensus region (Lys-Arg-Phe-Gly-Ser) for phosphorylation by cyclic AMP-dependent kinase (protein kinase A, PKA). Although ncNOS can be phosphorylated *in vitro* by PKA, as well as by protein kinase C and CaM-dependent kinase, the lack of convincing evidence for an effect of phosphorylation on ncNOS activity raises questions about the physiological significance of this post-translational modification.

2.4. iNOS

Essentially every tissue and nucleated cell type has the capacity to express functional iNOS when stimulated with endotoxin lipopolysaccharide (LPS) or proinflammatory cytokines, such as TNFa, **interleukin**-1 (IL-1), interferon g (IFN-g), or combinations thereof. These stimuli often act synergistically to induce iNOS expression. Hypoxia can also up-regulate iNOS expression (71). Cell types that have been shown to express iNOS on stimulation include, but are not limited to, macrophages, monocytes, hepatocytes, lymphocytes, chondrocytes, vascular smooth muscle cells, vascular endothelial cells, pancreatic islets, neutrophils, and glial cells. Under normal physiological conditions, iNOS is usually absent in cells. There is some evidence, however, that basal levels of iNOS are expressed in normal cells. For example, continuous NO is generated from iNOS in normal human lung epithelial cells *in vivo* (72), as well as from the intestinal ileal epithelium in rodents (73).

Murine macrophage was the first cell type identified to produce NO by iNOS upon microbe infection or inflammation. The large amount of NO produced by activated macrophages accounts for these cells' ability to eliminate some invading pathogens (reviewed in 74). The mechanism underlying the NO-mediated antimicrobial effects is not fully understood, but it may be due to a combination of NO actions on various intracellular targets, such as inhibiting the **mitochondrial** respiratory chain (complex I and II), suppressing total **protein biosynthesis**, and inhibiting aconitase of the tricarboxylic acid cycle. As mentioned above, NO may also react with superoxide (O_2^-) generated from activated macrophages or neutrophils to form peroxynitrite, which can generate even more deadly hydroxyl radicals. Widespread inducible NO synthesis is also seen during experimental acute sepsis and both acute and chronic inflammation. In sepsis, increased NO production helps to maximize tissue perfusion through its action on vasculature and prevent microvascular thrombosis by inhibiting platelet aggregation and neutrophil adhesion. However, overexpressed iNOS may unavoidably cause hypotension and shock or even tissue damage (75). Hence, specific iNOS inhibitors may have significant clinical implications (reviewed in 76).

Unlike murine macrophages, which respond vigorously toward LPS and IFNg, induction of iNOS in human cells, including macrophage and monocytes, was initially difficult to demonstrate, even upon stimulation with various combinations of cytokines and LPS (77). Based on the finding that rat Kuffer cells (liver macrophages) express iNOS in response to inflammatory stimuli in much the same way as macrophages (78), subsequent coculture of rat hepatocytes with Kuffer cells or with the conditioned culture medium from LPS and INFg-treated Kuffer cells led to the discovery that, besides immune systems, hepatocytes are able to produce NO in response to multiple inflammatory products (79, 80). More importantly, the same combination of cytokines synergistically induced high-level expression of iNOS and NO generation in human hepatocytes (81), providing conclusive evidence that put to rest any doubt about the capacity of human cells to express significant level of iNOS. The human iNOS cDNA and gene were then subsequently cloned and characterized from cytokine-stimulated human hepatocytes (37, 82).

To date, iNOS cDNA has been cloned from mouse (83, 40, 84), rat (85-87) and human(37, 88-91). There is 80% sequence identity between the cDNAs of human iNOS and murine macrophage iNOS at both the amino acid and nucleotide levels. This is distinct from the two cNOS isoforms, where the homology between human and other species is consistently around 93% to 95% identity. Human iNOS cDNA has been isolated from five different cell types, namely, stimulated hepatocytes, chondrocytes, a human adenocarcinoma cell line, a human glioblastoma cell line, and cardiac monocytes. They share more than 99% identity or are nearly identical, suggesting existence of a single human iNOS gene.

The human iNOS gene is located at chromosome 17, consists of 26 exons and 25 introns spanning @ 37 kb of the genomic DNA, and encodes a polypeptide of 1153 amino acids (82). The transcription start site was identified 30 bp downstream of a TATA box, and the translational **initiation** and **termination codons** reside in exons 2 and 26, respectively. Active iNOS is a homodimer, with each subunit sharing the same **consensus sequences** for binding NADPH, flavins and calmodulin as the two cNOS isoforms (Fig. 2).

Regulation of inducible NO production by iNOS occurs at multiple levels, with transcriptional regulation as the predominant mechanism. Analysis of the 5′-flanking region of human iNOS gene reveals several consensus elements for nuclear factor-kB (NF-kB), TNF response element (TNF-RE), and g-IRE, which are reported to be involved in LPS and INF-g-induced gene expression (82). A @ 16-kb fragment of the 5′-flanking region of human iNOS gene was found to function as a promoter that is responsive to cytokines and capable of inducing iNOS in a human liver cell line (92). A general method used to identify the promoter region responsive to various stimuli (in this case cytokines) is to delete the complete promoter from the 5′-end systematically and to connect the shortened ones to a reporter gene. After transfecting target cells with various gene constructs, the cytokine inducibility of each construct can be evaluated easily by detecting the expressed reporter.

Using this technology, the human iNOS cytokine-responsive regulatory element (or elements) was mapped upstream of –3.8 kb, namely between –16 to –3.8 kb. Further studies identified three regions containing cytokine-responsive elements in the human iNOS gene: –3.8 to –5.8, –5.8 to –7.0, and –7.0 to –16 kb (92). This contrasts markedly with the murine macrophage iNOS promoter, where the LPS and cytokine-responsive regions locate within only -1 kb of the proximal 5′-flanking region (93-96), suggesting differences in transcriptional regulation between human and murine iNOS gene. Indeed, there is only about 50% sequence identity in the 5′-flanking region of human and murine iNOS genes, in contrast to the 80% identity between their cDNAs.

The cytokine-mediated up-regulation of iNOS gene transcription appears to require the transcription factor NF-kB in both human and rat hepatocytes (97). Compared to the murine iNOS promoter, where two functional elements reside: an NF-kB element at –76 to –85 bp and an IRF-E/ISRE site at –913 to –923, the human iNOS gene is regulated by a much more complex promoter-regulatory region that requires cytokine-responsive elements upstream of –3.8 kb to confer cytokine-regulated transcription. Studies of the complex mechanisms of iNOS gene regulation will undoubtedly be paramount, given the diverse roles that iNOS plays in various human disease processes.

Besides cytokines and endotoxin, a host of other agents have been shown to affect the induction of iNOS. Glucocorticoids such as dexamethasone decrease iNOS mRNA levels by down-regulating NF-kB activation. Steroids and induction of the **heat shock** response also inhibit iNOS gene induction (98). Hepatocellular **mitogens** and cell growth regulators, such as hepatocyte growth factor (HGF), epidermal growth factor (EGF), and transforming growth factor (TGF-a), as well as p53 (99), all down-regulate iNOS gene expression. Intriguingly, NO itself suppresses it own gene expression, probably by inhibiting the binding of NF-kB to the iNOS promoter. This kind of negative feedback regulation may prevent cells from overgenerating NO (reviewed in 100).

Another level of regulation of inducible NO production by iNOS is the availability of substrate and cofactors. Since L-arginine is the sole nitrogen source and NADPH the only known electron donor for NO synthesis by NOS isoforms, availability of these two substrates could potentially regulate the rate of NO production. In fact, glucose-6-phosphate dehydrogenase, a regulatory enzyme acting as a valve in the pentose phosphate pathway that generates NADPH, has been shown to be coinduced with iNOS in murine bone marrow–derived macrophages (101). The rate-limiting enzyme for L-arginine biosynthesis, argininosuccinate synthetase, as well as the arginine transport system are up-regulated by the same inflammatory mediators that stimulate inducible NO production (see 102). *De novo* synthesis of BH_4, another essential cofactor that is required for maximum catalytic activity and for iNOS dimerization, is also necessary for cytokine-induced NO generation in vascular smooth muscle (103). In this regard, the mRNA level of GTP cyclohydrolase-1, the rate-limiting enzyme for BH_4 biosynthesis, is increased along with iNOS in vascular smooth muscle and hepatocytes (104, 105).

In summary, production of NO by a variety of NOS enzymes is under stringent and complex regulation at multiple cellular levels, including cellular NOS distribution and transcriptional, post-transcriptional, translational, and post-translational regulatory mechanisms. Considering the numerous targets of NO, the role of this dual-faced molecule is likely to depend on NO chemistry in a given biological milieu. For example, NO has been recently shown to be able to activate or suppress apoptosis (programmed cell death). Detailed study into NO production and function under both normal and disease conditions will be the focus of many future investigations.

Nitrocellulose

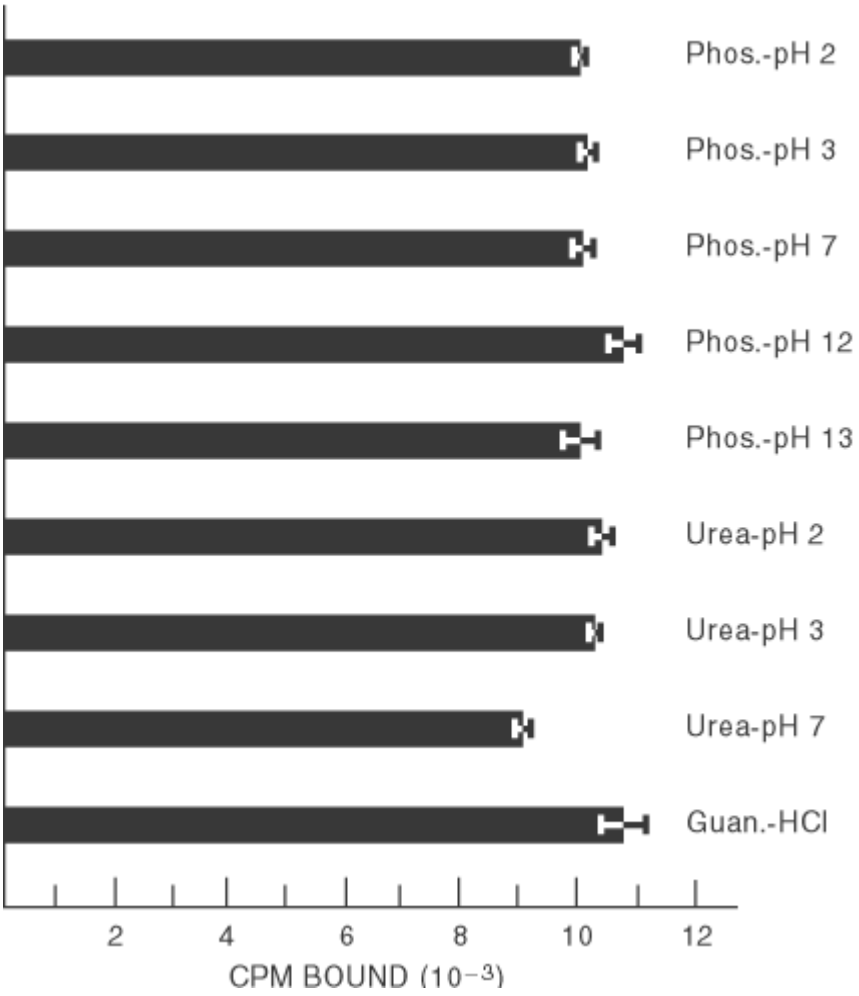
Cellulose nitrate (nitrocellulose) is produced by treating cellulose with nitric acid. Each glucose unit in the cellulose polymer is esterified with three nitrate groups, and these nitrate groups are responsible for both the negative charge of nitrocellulose at neutral pH and the unusual flammability of dry nitrocellulose. Nitrocellulose membranes are made by dissolving the nitrocellulose in organic solvents and spreading the solution as a thin film on a smooth surface. The evaporation rate of the solvent determines the porosity of the membranes, and pore sizes of 0.05 to 0.45 µm are commercially available. Membranes with smaller pore sizes have higher binding capacities for **macromolecules** and are frequently used to bind smaller macromolecules, like **peptides**. Depending on the pore size, pure nitrocellulose membranes have a binding capacity of 80 to 150 µg/cm^2. Because nitrocellulose membranes can become brittle with harsh treatment, they can be cast on an inert synthetic support, which are also commercially available. The tensile strength of these supported membranes is 500 times greater than ordinary nitrocellulose, but the binding capacity and background levels are the same as ordinary nitrocellulose (1). Some nitrocellulose membranes are not made from "pure" cellulose nitrate but may also contain cellulose acetate. Generally, membranes made with "pure" cellulose nitrate are preferred for most techniques in molecular biology, because "pure" cellulose nitrate has a higher binding capacity.

Nitrocellulose membranes are widely used in molecular biology because they are easy to handle, have a high binding capacity, and are compatible with a variety of assay conditions and detection systems. Although nitrocellulose membranes were originally used to filter out particles, such as **bacteria**, they are now used primarily to adsorb macromolecules throughout the filter matrix, as in filter binding assays and in blotting. Procedures that frequently specify nitrocellulose membranes include: Southern blots and **Northern blots**; nucleic acid and protein dot-blots and slot-blots; immunoblots; and colony/plaque lifts. Nitrocellulose membranes are used in **Western blots** of proteins, but they cannot be used for Edman Degradation sequencing, because the membranes will dissolve in the sequencing solvents.

How macromolecules bind to nitrocellulose is not well understood, but both **electrostatic** and **hydrophobic** interactions have been suggested as possible binding mechanisms (2, 3). The following observations imply that hydrophobic interactions play a dominant role in the binding of macromolecules to nitrocellulose: (a) **SDS**–protein complexes, which are negatively charged, bind to negatively charged nitrocellulose membranes; (b) native double-stranded DNA, which is negatively charged, does not bind to nitrocellulose until the DNA is **denatured** by heat or alkali treatment; (c) nonionic detergents, such as **Triton**® X-100 (4), NP-40 (5), and Tween® 20 (6), remove proteins from nitrocellulose membranes; and (d) increasing the salt concentration, which increases hydrophobic binding, strengthens the binding of proteins to nitrocellulose. Additional support for the hypothesis that hydrophobic interactions play a dominant role in the binding of proteins to nitrocellulose membranes comes from a study that compared the binding of **antibodies** and other proteins to nitrocellulose membranes in acidic, neutral, basic, and chaotropic buffers (7). In this study, **radiolabeled** proteins of various molecular weights and isoelectric points bound equally well to nitrocellulose in a variety of buffers (at pH 2, 3, 7, 12, and 13) and in the presence of 8 M urea (at

pH 2, 3, and 7) and 6 M **guanidinium chloride** (Fig. 1). This study demonstrated that the binding of most proteins to nitrocellulose was not influenced by the ionization of the proteins or by denaturing solvents.

Figure 1. Binding of ^{125}I-labeled human anti-tetanus antibodies to a nitrocellulose membrane in different solvents. The indicated buffers and denaturing solvents were used for both membrane equilibration and protein dilution. After dilution, 0.3 μg of ^{125}I-labeled human anti-tetanus toxoid antibodies (12,000 cpm) were added to the appropriate wells of a dot-blot unit. After binding the antibodies to the membrane, each was washed four times with 200 µL of 0.1 M phosphate buffer (pH 7). The nitrocellulose membrane was removed from the dot-blot unit, and the areas that contained the radioactive proteins were counted in a gamma counter. Each point is the mean of four different wells, ±2 standard deviations.(Adapted from Ref. 7.)



Although nitrocellulose membranes are preferred for many nucleic acid and protein immobilization methods, there are a number of precautions that should be followed to protect the membranes, to prepare them for use and to maximize the binding of macromolecules:

1. Store dry nitrocellulose membranes away from organic solvents, oil, and dust. Vapors of some organic solvents may cause the nitrocellulose to curl, and both oil and dust may prevent binding of macromolecules.
2. Wear gloves and use forceps to handle the membranes. Fingerprints will limit binding of macromolecules to nitrocellulose.
3. Wet a nitrocellulose membrane by floating, not immersing, the membrane on the top of water to remove air that may be trapped within the matrix. Air bubbles trapped under the membrane can

be removed by using tweezers to lift a corner. After wetting, immerse the membrane in the appropriate buffer for at least five minutes. Wet nitrocellulose membrane will have a uniform darkening, and any white spots or irregularities are signs of incomplete wetting. Discard any membrane that does not wet uniformly.

4. Macromolecules bind with varying affinities to nitrocellulose. Verify that the macromolecule of interest binds to the nitrocellulose membrane and is not eluted by the detergents or other solutions used in the assay.
5. Solutions containing methanol or ethanol may cause the nitrocellulose to shrink, and acetone will dissolve it. However, xylene and toluene can be used to make the nitrocellulose transparent for scanning with a transmission densitometer (8).
6. Do not exceed 80°C in the vacuum baking oven when drying nucleic acid blots, because nitrocellulose is quite flammable.
7. Unsupported nitrocellulose membranes are brittle when dried or baked at 80°C, so handle them very carefully!

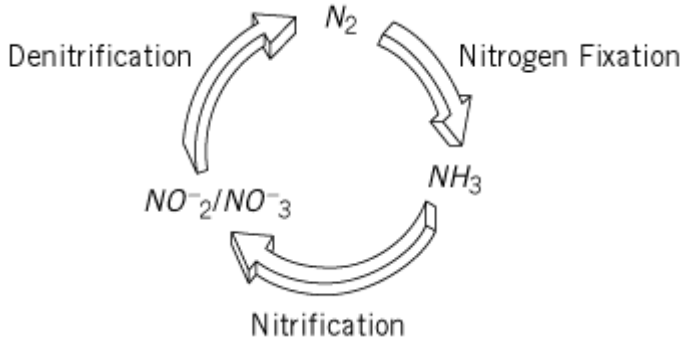
Nitrogen Fixation

The conversion of dinitrogen gas (N_2) to ammonia (NH_3) is called nitrogen fixation. Because ammonia is necessary for the formation of biologically essential, nitrogen-containing compounds, such as amino acids and **nucleic acids**, a fixed nitrogen source is necessary to sustain life on earth. Furthermore, the ammonia necessary to support essential biosynthetic reactions is continually sequestered into sediments or reconverted to N_2 through the combined biological processes of nitrification and denitrification (Fig. 1). So the pool of fixed nitrogen within the biosphere must constantly be replenished. Nitrogen fixation is necessary to maintain the diversity of life on earth

because most organisms cannot metabolize the abundant but relatively inert N_2 molecule and must assimilate nitrogen in a “fixed” form, such as ammonia or nitrate. The three ways that nitrogen fixation occurs in the biosphere include (1) lightning and other natural combustion processes, (2) the industrial Haber–Bosch process, and (3) biological nitrogen fixation. Of these three, biological nitrogen fixation, the most significant contributor, accounts for about 65% of the total (1, 2). In addition to its pivotal role in the global nitrogen cycle, nitrogen fixation has agronomic importance because the availability of fixed nitrogen—commonly referred to as fertilizer nitrogen—usually limits to crop production. Consequently, the need to grow sufficient crops to feed the world's population requires the application of nitrogen fertilizers as a common agricultural practice. Such application of nitrogen fertilizers is expensive for several reasons: First, the Haber-Bosch process used to produce fertilizer nitrogen requires high consumption of nonrenewable resources in the form of fossil fuels. Secondly, significant transportation costs are incurred in shipping industrially produced fertilizer nitrogen to the field. Third, the application of nitrogen fertilizers often results in run-off contamination of local water systems. An alternative approach to the Haber-Bosch process for nitrogen fertilizers is to exploit the biological process, and toward this end a considerable effort has been directed at understanding the molecular mechanism of biological nitrogen fixation.

Figure 1. Simplified diagram of the biological nitrogen cycle.



1. Diazotrophs and nodulation

Although most organisms cannot fix nitrogen, a select group of **microorganisms** can. These organisms are called diazotrophs, which means “nitrogen eaters,” and they are widely distributed among and restricted to the **Archae** and **Bacterial** kingdoms. Examples of bacterial species that fix nitrogen and have been extensively studied include *Azotobacter vinelandii* (an obligate **aerobe**), *Clostridium pasteurianum* (an obligate **anaerobe**), *Klebsiella pneumoniae* (a facultative anaerobe), *Rhodospirillum rubrum* (a **photosynthetic** bacteria), ***Anabaena*** *sp.* 7120 (a heterocyst-forming **cyanobacterium**), and *Bradyrhizobium japonicum* (a symbiotic bacterium). From the agronomic perspective, symbiotic nitrogen fixers are the most important. These organisms invade leguminous plants, such as pea and alfalfa, and induce the formation of specialized structures, called nodules, on their roots. In this symbiotic association, the root nodule contains differentiated bacteria that specialize in nitrogen fixation (3). In this symbiosis, the plant provides the microbe a carbon energy source through the process of photosynthesis whereas the microbe supplies the plant host a fixed nitrogen source through the process of nitrogen fixation. Because the enzyme that **catalyzes** biological nitrogen fixation, nitrogenase , is extremely oxygen sensitive, another important functional feature of the root nodule is to provide an anoxic environment for nitrogen fixation. Protection of nitrogenase within the root nodule occurs by separating the oxygen-evolving process of photosynthesis and the oxygen-sensitive process of nitrogen fixation. This separation is accomplished in two primary ways: First, the plant-derived, outer cortical layer of the nodule provides a relatively strong barrier against free oxygen diffusion into the central core of the nodule,

where the nitrogen-fixing bacteria are located and where photosynthesis does not occur. Secondly, the oxygen needed for bacteroidal respiration, which in turn is necessary to provide the energy and reducing equivalents to drive nitrogen fixation within the bacteroid, is delivered by an oxygen-binding plant protein called leghemoglobin.

Establishing of a symbiotic relationship between a leguminous plant host and an associated rhizobium is a complicated process that is specific between a particular host and a particular symbiont (4). During initiation of the infection process, bacteria induce the formation of curls at the tip of plant root hairs (5, 6), which then envelop the invading bacteria. Then infection threads are formed within the root hair. Infection threads are tubular structures of plant origin that penetrate the root hairs and the root cortex through which the invading bacterium traverse (7). At or about the time infection thread formation occurs, **cell division** is also induced within the root cortex, resulting in the formation of a nodule primordium (8). When the infection thread contacts a newly divided primordial cell within the root cortex, the bacteria are released from the infection thread tip. Subsequent penetration of the released bacterial cell into the cytoplasm of the primordial cell occurs through a process of endocytosis resulting in the formation of a plant cell membrane (bacteroidal membrane) that surrounds the bacterium (9). Bacterial cell division and bacteroid membrane proliferation then occur, resulting in the host plant cell cytoplasm becoming filled with bacteria. These bacteria then differentiate into cells specialized for nitrogen fixation that are called bacteroids.

To establish an effective symbiosis, developmental and metabolic cooperation between the plant and microbe are necessary. This cooperation is accomplished through the reciprocal communication and control of gene expression between the two partners. During nodule development, signaling occurs through the action of nodulation (*nod*) **gene expression** by the bacterium and expression of nodulins (ENOD sequences) by the plant. The first of these signals is provided by flavanoid molecules, three-ring aromatic compounds derived from phenylpropanoid metabolism, which are produced by the plant and found in the root exudate (10). Flavanoids act as specific **inducers** of bacterial *nodD* gene expression (11). The *nodD* gene encodes a regulatory protein that controls the expression of other *nod* genes. The concerted action of other *nod* gene products, whose synthesis is induced by *nodD* gene expression, results in forming and releasing bacterial signal molecules called Nod factors (12) . Nod factors are responsible for signaling the initial root hair curling event. Their core structures are composed of b1-4 linked *N*-acetylglucosamine residues of various length (usually one to four molecules). The specificity of a particular Nod factor is determined by its level of oligomerization and by certain chemical modifications of the oligosaccharide core, such as O-acylation or N-acylation at the nonreducing end of the oligosaccharide and sulfation at the reducing end. The *nodABC* gene products are common among all the rhizobia, and they are required for catalyzing formation of the oligosaccharide core, whereas other "host-specific" *nod* gene products are responsible for oligomerizing and modifying the oligosaccharide core.

1.1. Nitrogenase

Nitrogenase is the enzyme that catalyzes biological nitrogen fixation. The reaction is usually depicted as follows:

$$N_2 + 8\,H^+ + 8e^- + 16\,MgATP \rightarrow 2\,NH_3 + H_2 + 16\,MgADP + 16\,P_i$$

All diazotrophs studied so far contain a nitrogenase that is a complex, two-component metalloprotein (13-15). The individual nitrogenase component proteins have been designated as the Fe protein and the MoFe protein , which were derived from the respective compositions of their associated metal centers. The Fe protein is a homodimer (M_r 64,000) that contains two MgATP binding sites and a single [4Fe-4S] cluster (see Iron–Sulfur Proteins). The MoFe protein is an a_2b_2 heterotetramer (M_r 250,000) that contains two pairs of metalloclusters, called P-clusters, and iron molybdenum cofactors (FeMo cofactors). Ribbon diagrams for the three dimensional structures of the Fe protein and MoFe protein are shown in Fig. 2, and structures of the associated nitrogenase metal clusters are

shown in Fig. 3. Because the Fe protein is a specific reductant of the MoFe protein, which in turn provides the site of substrate reduction, some investigators refer to the Fe protein as dinitrogenase reductase and the MoFe protein as dinitrogenase (16).

Figure 2. Ribbon diagrams of the three-dimensional structures of the nitrogenase Fe protein and MoFe protein. The view interaction with a single ab-unit of the MoFe protein (bottom).

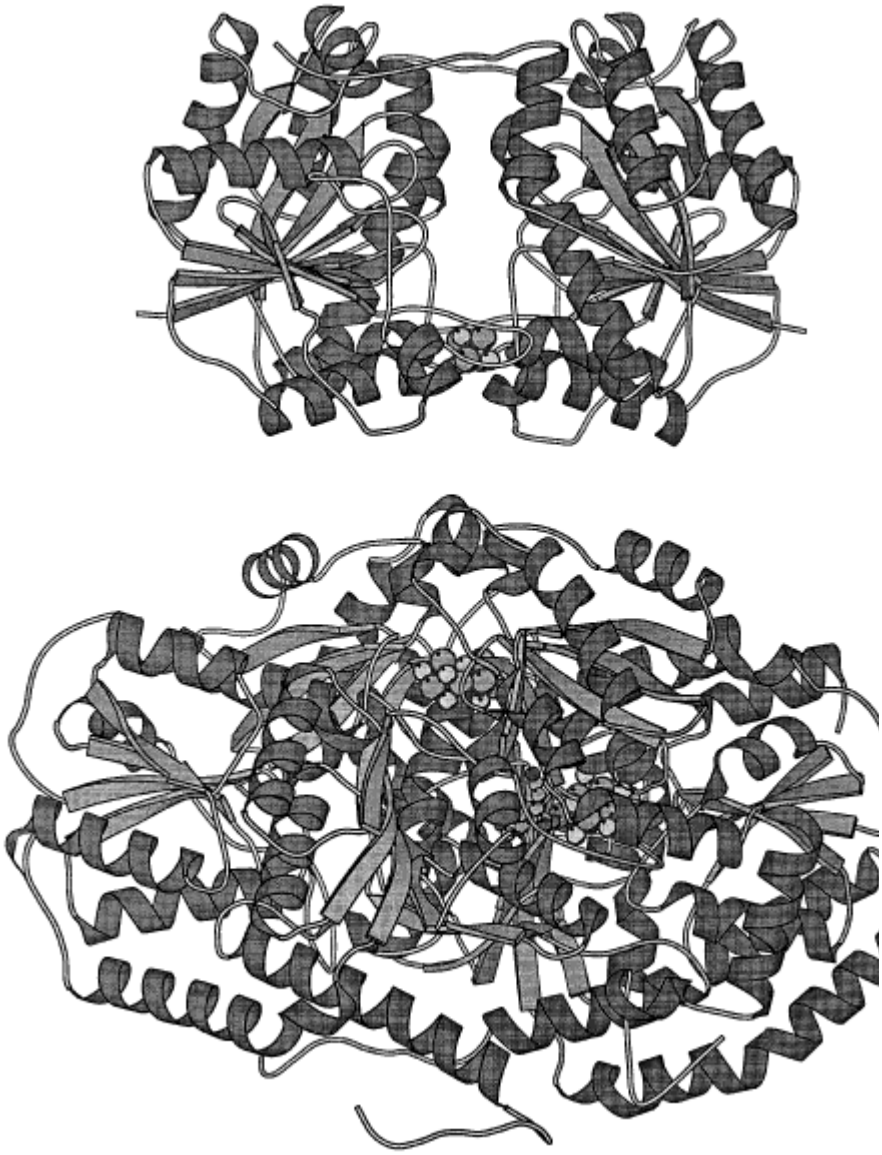


Figure 3. Organization and structures of the nitrogenase metalloclusters. The path of electrons is from the [4Fe-4S] clust cluster and then to the FeMo cofactor. Transfer of an electron from the Fe protein to the MoFe protein is coupled to MgA provides the N_2 binding and reduction site.

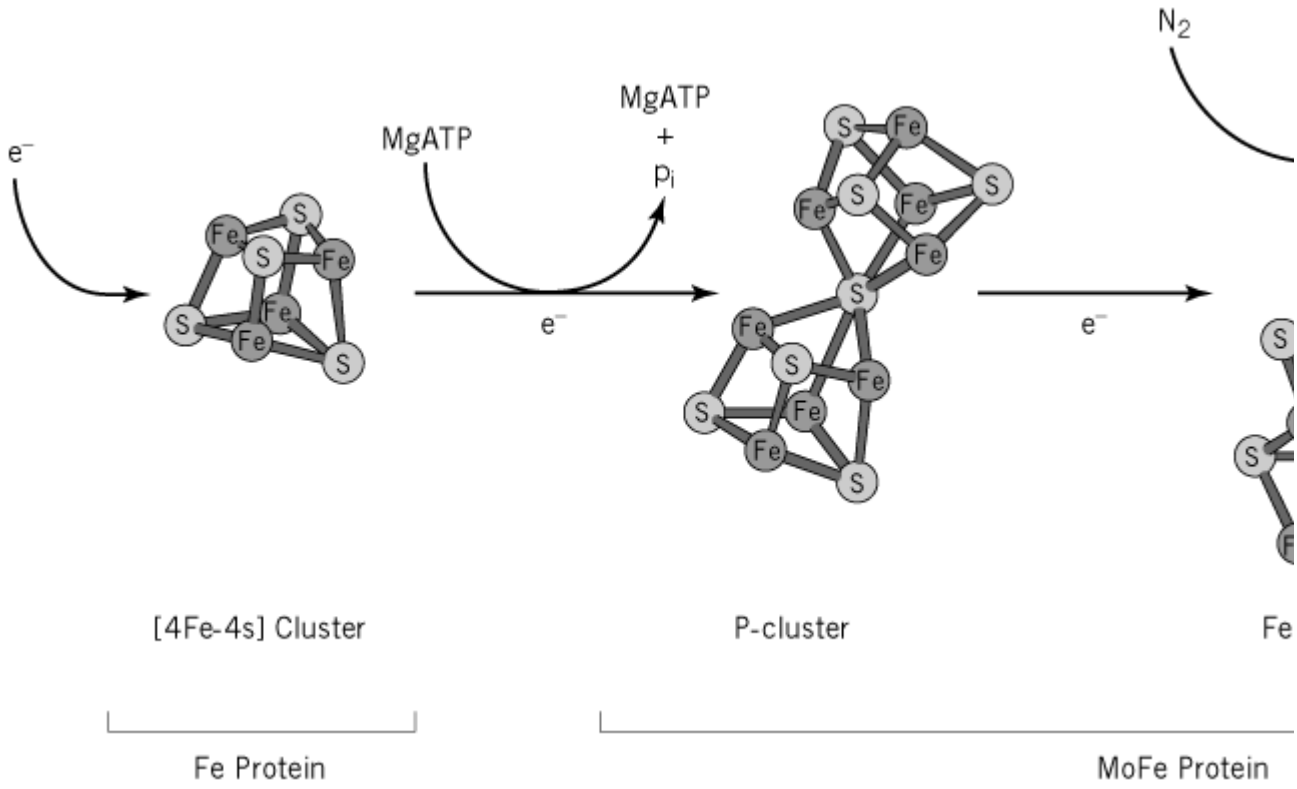


1.1.1. Nitrogenase Mechanism and Role of the Metal Centers

During catalysis, the Fe protein delivers electrons, one at a time, to the MoFe protein in a process that couples MgATP binding and hydrolysis to the association and dissociation of the two component proteins and concomitant **electron transfer**. Both component proteins are required for MgATP hydrolysis, and neither component protein reduces any substrate in the absence of its catalytic partner. The process by which electrons are sequentially delivered to the MoFe protein and subsequently to substrate has been described by a kinetic model that involves two interlocking cycles called the Fe protein cycle and the MoFe protein cycle (17). The Fe protein cycle involves oxidizing and reducing the Fe protein's [4Fe-4S] cluster between the 1^+ and 2^+ **redox** states as it sequentially delivers electrons to the MoFe protein and is re-reduced by other electron transfer proteins (usually a ferredoxin or flavodoxin). The MoFe protein cycle involves the progressive reduction of the MoFe protein, which ultimately leads to N_2 binding and reduction. Because eight electrons and eight protons are required for N_2 reduction and H_2 evolution, each MoFe protein cycle requires eight Fe protein cycles and storage of the electrons. Kinetic studies have also shown that N_2 does not become bound to the active site until at least two, and probably more, electrons have been accumulated within the MoFe protein (18). It is not yet known where and how the electrons delivered to the MoFe protein are stored before to the binding and reduction of the substrate. However, current structural and biochemical data indicates that cluster-to-cluster electron transfer occurs as shown in Fig. 3 (13, 14, 19).

In addition to the individual structural models for the Fe protein and MoFe protein (Fig. 2), an **X-ray crystallograpic** model for the docked complex has also been determined (19). In this model, docking occurs so that the two-fold symmetry axis surrounding the Fe protein's [4Fe-4S] cluster becomes paired with the surface of the MoFe protein's pseudosymmetrical ab-interface. This places the [4Fe-4S] cluster close to the P-cluster of the MoFe protein and places the P-cluster between the Fe protein [4Fe-4S] cluster and the FeMo cofactor. This arrangement is consistent with the electron transfer scheme shown in Fig. 3 and indicates that the P-cluster's role is to broker electron transfer between the Fe protein and the substrate reduction site provided by the FeMo cofactor. The P-cluster

is located at the ab interface of the MoFe protein subunits and, in its fully reduced form, is constructed from two [4Fe-4S] subclusters that share a central sulfide (Fig. 3). Upon oxidation of the P-cluster, a structural rearrangement occurs involving movement of two Fe atoms and a change in the ligand arrangement around the cluster (20). Such redox-dependent structural changes within the P-cluster might be mechanistically related to its role in accepting electrons from the Fe protein and delivering them to the FeMo cofactor.

The FeMo cofactor consists of a metal sulfur framework ($MoFe_7S_9$) and one molecule of (R)-homocitrate (Fig. 3). The framework is constructed from S-bridged $MoFe_3S_3$ and Fe_4S_3 cluster subfragments. Homocitrate is coordinated to the Mo atom through its b-hydroxy and b-carboxy groups. Several lines of evidence indicate that the FeMo-cofactor provides the substrate binding and reduction site: First, mutant strains that cannot biosynthesize the FeMo cofactor also cannot catalyze nitrogen fixation (21). When the isolated FeMo cofactor is added to crude extracts prepared from such mutant strains, the *in vitro* ability to fix nitrogen is restored. Secondly, a MoFe protein that contains an altered form of the FeMo cofactor, where citrate replaces homocitrate as its organic constituent, exhibits altered catalytic properties (22, 23). Thirdly, altered MoFe proteins that have amino acid substitutions located within the FeMo cofactor's polypeptide environment also exhibit altered catalytic properties (24). Although it is not yet known how substrates interact with the FeMo cofactor during turnover, the presence of six coordinately unsaturated Fe atoms and the attachment of homocitrate to the Mo atom has invited speculation about the nature of substrate binding (25). For example, in one model it has been proposed that the carboxylate group coordinated to the Mo atom might serve as a leaving group in a mechanism that activates Mo to provide a substrate coordination site (26).

1.1.2. The Role of MgATP in Nitrogenase Catalysis

The reduction of N_2 to yield 2 NH_3 is thermodynamically favorable. Thus, the need for MgATP binding and hydrolysis during nitrogenase catalysis is kinetic so that electron transfer toward substrate reduction is favored and the flow of electrons back toward the Fe protein is prevented. One way of envisioning this process is to consider that the energy released through MgATP binding and hydrolysis could be used to open and close electron gates to ensure that multiple electrons are accumulated within the MoFe protein before they are donated to substrates. In support of this model, primary sequence and structural comparisons have revealed that the Fe protein is a member of a large class of signal transduction proteins that undergo conformational changes upon MgATP binding and hydrolysis. A consensus view (27) of the events that occur during a single turn of the Fe protein cycle and which accounts for the role of MgATP in nitrogenase catalysis is as follows. Intercomponent interaction is initiated when the reduced Fe protein binds two MgATP molecules. This elicits a conformational change in the Fe protein that makes it competent to interact with the MoFe protein. Upon complex formation, changes occur in the midpoint potentials of the respective clusters such that electron flow toward the FeMo cofactor is energetically favorable. For example, in the complexed form, the Fe protein's [4Fe-4S] cluster has a **redox potential** of about –620mV, the P-cluster a potential of about –390mV, and the FeMo cofactor a potential of about –40mV (28). In addition to eliciting redox changes that lead to electron transfer, the component docking event also triggers MgATP hydrolysis at about the same time as, or shortly after, electron transfer. Conversion of the Fe protein from the MgATP-bound state to the MgADP-bound state subsequently causes complex dissociation, which is believed to be the **rate-limiting step** in nitrogenase catalysis (29). Thus, the accumulation of electrons within the MoFe protein is a dynamic process that involves transmitting signals back and forth between the Fe protein and MoFe protein. Then the role of MgATP is to synchronize these events through sequential conformational changes induced by MgATP binding, component protein interaction, and nucleotide hydrolysis.

1.1.3. Alternative Nitrogenases

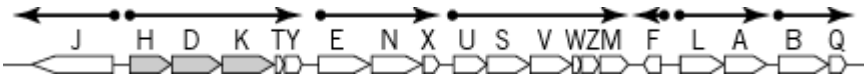
All organisms capable of nitrogen fixation that have been examined at the biochemical level have a Mo-containing nitrogenase as described previously. All such nitrogenases exhibit a high level of **primary structural** identity compared to each other. Particularly high sequential conservation is

found in the respective MgATP- and metallocluster-binding sites (30). There is, however, another class of nitrogenases that do not contain Mo, and these have been designated alternative nitrogenases (31). Two types of alternative nitrogenases have been identified so far (32, 33). One of these contains a cofactor whose Mo atom is substituted by vanadium, V (FeV cofactor), and the other contains a cofactor whose Mo atom is substituted by Fe (FeFe cofactor). The conservation in primary sequences recognized among the Mo-dependent nitrogenases also extends to the alternative nitrogenases. Thus, all nitrogenases have common structural and mechanistic features. All three nitrogenase types are found in *A. vinelandii*, and expression of each of them is under a hierarchical control that depends on the availability of Mo or V in the growth medium (34, 35). When Mo is present in the growth medium, expression of the Mo-dependent nitrogenase is stimulated, and the expression of the alternative nitrogenases is repressed. Similarly, when Mo is absent, but V is available, only expression of the V-dependent enzyme occurs. When neither Mo nor V is available, only the alternative nitrogenase that contains FeFe cofactor is expressed. Such hierarchical control by the availability of metals makes physiological sense because the Mo-dependent nitrogenase has an intrinsically higher capacity to reduce nitrogen than either of the alternative nitrogenases, and the V-dependent nitrogenase is more efficient than the Fe-only nitrogenase (36).

1.2. Nif-Genes and Maturation of Nitrogenase

In addition to the structural genes for nitrogenase, other genes are required for (1) coupling the reduction of the Fe protein to intermediary metabolism, (2) maturation of the nitrogenase components, and (3) regulating the expression of the nitrogenase genes. The organism that has the simplest organization of nitrogen fixation specific (*nif*) genes and is best studied at the molecular genetic level is the facultative anaerobe *Klebsiella pneumoniae*. There are 20 *nif* genes in this organism, organized into seven transcriptional units (Fig. 4). The specific designations for individual *Klebsiella pneumoniae nif* genes are also used to denote genes whose products have homologous functions in other organisms. For example, the *nif* structural genes from all diazotrophs are designated *nifH*, *nifD*, and *nifK*, and they respectively encode the Fe protein and the a- and b-subunits of the MoFe protein. A complication in the genetic nomenclature of genes, whose products are involved in nitrogen fixation, is that some organisms do not have homologues to all of the *Klebsiella pneumoniae nif*-specific genes, but have other genes related to nitrogen fixation that are not present in *K. pneumoniae*. The general convention used is that the "*nif*" designation is reserved only for those genes that have functional counterparts in *K. pneumoniae*. Genes in other organisms, whose products are involved in the process of nitrogen fixation but do not have functional counterparts in *K. pneumoniae*, have been given various other designations. One example is the designation "*fix*" which designates such genes from the rhizobia.

Figure 4. Organization of the nitrogen fixation specific (*nif*) genes of *Klebsiella pneumoniae*. Black arrows indicate transcription units and the direction of their transcription. Structural genes encoding the nitrogenase Fe protein (*nifH*) and MoFe protein subunits (*nifDK*) are shaded. Functions of the *nif* gene products are described in the text.



1.2.1. Electron Transport to Nitrogenase

A source of reducing equivalents of sufficiently low potential is required to regenerate reduced Fe protein after it has donated an electron to the MoFe protein. Both flavodoxins and ferredoxins serve this function *in vitro*. In *K. pneumoniae*, two genes, *nifF* and *nifJ*, are involved in coupling the reduction of Fe protein to intermediary metabolism (37, 38). The *nifF* gene product is a flavodoxin that, in its reduced hydroquinone form, donates an electron to the oxidized Fe protein, thereby generating the semiquinone form of the flavin moiety. The re-reduction of flavodoxin is accomplished through the catalytic activity of the *nifJ* gene product (pyruvate-flavodoxin oxidoreductase), which couples the oxidation of pyruvate, yielding acetyl-CoA and CO_2, to the reduction of the semiquinone form of flavodoxin to the hydroquinone form.

1.2.2. Maturation of the Fe Protein and MoFe Protein

The primary translation products of the nitrogenase structural genes are not active. Instead, a consortium of other *nif*-specific genes are required to activate the immature structural components. The function of the *nif*-specific maturation gene products is to catalyze the formation and insertion of the metalloclusters into apo-forms of the Fe protein and MoFe protein. In the Fe protein, only the *nifM* gene product is specifically required for its maturation (39). The *nifM* gene product has not yet been isolated in an active form, but it is a member of a family of peptidyl prolyl cis/trans isomerases (40). Such enzymes are thought to assist in **protein folding** by catalyzing the ***cis*/*trans* isomerization** of certain prolyl peptide bonds in some proteins. The requirement for such an activity in maturation of the Fe protein is not obvious but could be related to the appropriate organization of the cysteine ligands needed for properly inserting the [4Fe-4S] cluster that is located at the Fe protein dimer interface.

Maturation of the MoFe protein, particularly the formation and insertion of the FeMo cofactor into the MoFe protein, is much more complicated. This process involves the products of the *nifH*, *nifE*, *nifN*, *nifB*, *nifV*, and *nifQ* genes (41). The nitrogenase Fe protein, a product of *nifH*, is required for both forming and inserting the FeMo cofactor (42, 43). Although the specific function of Fe protein in these processes is not known, neither its MgATP-binding or MgATP-hydrolytic properties nor its ability to transfer electrons are necessary (44, 45). Biochemical complementation experiments have shown that the FeMo-cofactor is synthesized separately and then inserted into an apo-form of the MoFe protein that contains intact P-clusters but lacks the FeMo cofactor (46). At least a portion of the biosynthetic process occurs within a complex of the *nifEN* products. The *nifEN* gene products bear primary sequential similarity to the products of the *nifDK* structural genes (47), and an a_2b_2 complex of the *nifEN* products is a molecular scaffold for FeMo cofactor assembly (48). The product of the *nifB* gene catalyzes the formation of a FeMo cofactor precursor called the B-cofactor (49). The B-cofactor probably provides the Fe-S cage necessary for FeMo cofactor construction and is inserted into the NifEN complex at an intermediate stage in FeMo cofactor formation (50). The *nifV* gene catalyzes the condensation of acetyl-CoA and a-ketoglutarate to form homocitrate, the organic constituent of the FeMo cofactor (51, 52). The *nifQ* gene product has a role in inserting the Mo atom into the FeMo cofactor, but its exact role in this process is not known (53). The products of the *nifW* and *nifZ* genes might also have some role in FeMo cofactor biosynthesis because mutations in either or both or them result in lowered MoFe protein activity (54). In *K. pneumoniae,* apo-MoFe protein produced by strains lacking *nifB* or *nifEN* activity contain a low molecular weight protein encoded by *nifY*. The *nifY* gene product has a role in stabilizing a conformation of the apo-MoFe protein that is amenable to FeMo cofactor insertion (55, 56). In *A. vinelandii*, a different low molecular weight protein (called gamma), not encoded by *nifY*, serves the same function (57).

In addition to the gene products that are specifically involved in nitrogenase metallocluster biosynthesis, there are two other *nif*-genes, *nifS* and *nifU*, whose products catalyze reactions that are generally involved in mobilizing Fe and S for metallocluster assembly (58, 59). The *nifS* gene product is a cysteine desulfurase that activates S for [Fe-S] cluster formation, whereas the *nifU* gene product probably has a complementary role as an Fe carrier. Homologues to *nifU* and *nifS*, whose expression is not under *nif*-specific control, are present in many organisms. The products of these genes probably have general functions in [Fe-S] cluster formation and repair (60).

1.3. Regulation of Nitrogenase Expression

For most free-living, nitrogen-fixing organisms, such as *K. pneumoniae*, *nif*-gene expression should be responsive to three environmental conditions. These parameters include (1) the availability of a fixed nitrogen source, (2) whether or not oxygen is present, and (3) the energy charge status of the cell (see Adenylate Charge). The reasons that these conditions are important is that nitrogenase activity is both oxygen-sensitive and requires the intense consumption of metabolic energy. Thus, if oxygen is present, if a fixed nitrogen source is already available, and if cellular growth is limited by the availability of a carbon source rather than a nitrogen source, the

expression of *nif*-genes would represent a waste of metabolic energy. In free-living nitrogen fixers that have alternative nitrogenases, the expression of *nif*-genes is additionally controlled by the availability of Mo or V.

The organism that has been most thoroughly studied in terms of *nif*-gene expression is *K. pneumoniae*. The 20 *nif*-specific genes from *K. pneumoniae* are organized into seven transcriptional units (Fig. 4). Six of these transcription units include the *nif* structural genes, electron transport genes, and nitrogenase maturation genes, whereas the seventh transcription unit contains the *nif*-specific regulatory genes, *nifL* and *nifA* (61). Expression of the *nifLA* genes is controlled by the global regulatory elements, products of the *ntrC*, *ntrB*, and *ntrA* genes. The expression of the other *nif* transcriptional units is controlled by the products of *nifL*, *nifA*, and *ntrA* . The *ntrA* gene product (NTRA) is an alternative sigma factor that controls the expression of a wide variety of gene families. The *nif* and *ntr* genes are only two examples (62). NTRA (also called a^{54}) imparts a specificity to **RNA polymerase** so that it recognizes the consensus **promoter** sequence CTGG-N_8-TTGCA. This consensus sequence spans a region located 24 to 12 base pairs preceding the transcription initiation site. In contrast, normal RNA polymerase contains the abundant sigma factor, called a^{70}, and this form of RNA polymerase recognizes the typical prokaryotic promoter sequence TTGACA-N_{17}-TATACA. The so-called housekeeping RNA polymerase binding site is located in the -35, -10 regions preceding the transcription initiation site. Expression of *ntrA* is not tightly controlled. Instead, the presence of NTRA is a way for the cell to reserve a certain portion of the RNA polymerase for specialized functions, such as nitrogen fixation.

Specific regulation of the expression of the *nifLA* genes is controlled by the products of the global nitrogen regulatory genes *ntrC* (NTRC) and *ntrB* (NTRB). NTRB is a phosphatase/kinase sensor protein that controls the **phosphorylation** of NTRC in response to the ratio of a-ketoglutarate to ammonia in the cell (63). When this ratio is high, NTRC is phosphorylated. When the ratio is low, NTRC is dephosphorylated. The former represents a condition of fixed nitrogen limitation and high energy charge, which signals the initiation of a two-tiered regulatory cascade that first leads to activation of the *nifLA* promoter and then results in activation of the other *nif* promoters. In its phosphorylated form, NTRC recognizes a DNA **consensus sequence** located upstream from the *nifA* a^{54}**-RNA polymerase** binding site. Once bound at this upstream activator site, phosphorylated NTRC catalyzes an ATP-dependent conformational isomerization at the promoter site, which ultimately results in transcriptional initiation of the *nifLA* promoter (64). Then accumulation of the products of *nifL* (NIFL) and *nifA* (NIFA) permits specific control of the other *nif*-promoters. NIFA is structurally and functionally similar to NTRC (65, 66). Like NTRC, it binds to an upstream activator sequence, although one that differs in consensus sequence to the NTRC binding site. The NIFA binding site has a consensus sequence motif (TGT-N_{10}-ACA) located approximately 100 bp preceding each of the *nif* promoters, except the *nifLA* promoter (67). NIFA probably activates expression of the *nif* promoters in an ATP-dependent manner analogous to the function of the phosphorylated form of NTRC.

Unlike NTRC, NIFA does not undergo phosphorylation and dephosphorylation in response to environmental signals. Instead, whether or not NIFA activates *nif* gene expression is controlled by NIFL, which acts as an antiactivator. When the oxygen level or the level of fixed nitrogen is sufficiently high, so that nitrogen fixation is either futile or not necessary, NIFL interacts with NIFA to prevent activation of the *nif* promoters. Although the details of how the complexation of NIFA and NIFL occurs are not known, it has been shown that NIFL is a flavoprotein which senses the redox status of the cell by conformational changes controlled by the oxidation state of its FAD moiety (68).

The mechanism by which *K. pneumoniae* controls *nif* gene expression is by no means universal.

For example, very little is known about how *nif* gene expression is controlled in the **clostridia** or the Archae, although control does not appear to be through the two-tiered NTR-dependent mechanism described previously. In certain organisms another layer of nitrogenase control activity also occurs at the posttranslational level. The best described example of this type of control is the reversible **ADP-ribosylation** of the nitrogenase Fe protein that occurs in *Rhodobacter rubrum*. In this organism, nitrogenase activity is controlled at the transcriptional level and also through the antagonistic activity of ADP-ribosylation and glycohydrolase enzymes whose activities are controlled by various environmental conditions (69, 70). Another example of the control of the expression of nitrogenase activity is found in the cyanobacterium *Anabaena* 7120 (71). This organism restricts nitrogen fixation to specialized cells called heterocysts . The formation of heterocysts, and nitrogenase expression are controlled both temporally and spatially by terminal differentiation events involving rearrangements of the genome.

Another specialized case of the control of nitrogenase gene expression occurs in the root nodule. It does not make sense to control nitrogenase gene expression and activity in response to the level of fixed nitrogen in the root nodule because the bacteroid functions to supply its host with fixed nitrogen. Thus, in the root nodule, *nif* gene expression is controlled by a two-tiered cascade that responds to the cellular oxygen tension. Similar to the NTRC/NTRB system, oxygen control of *nif* gene expression in rhizobia occurs through the concerted activity of an environmental sensor (FIXL) and a positive regulator of gene expression (FIXJ) (72). The sensor protein FIXL is a hemeprotein located within the cell membrane, and like NTRB, it has phosphatase/kinase activities. At low oxygen tension (microaerobicity), FIXL promotes the phosphorylation of FIXJ, which then activates the expression of *nifA* analogously to NTRC activation in *K. pneumoniae*. The rhizobia do not contain a protein analogous to NIFL, so control of *nif* gene expression in this case does not involve an antiactivator. Instead of the involvement of an antiactivator in the posttranslational control of certain rhizobial NIFA proteins, NIFA activity is directly sensitive to the presence of oxygen (73).

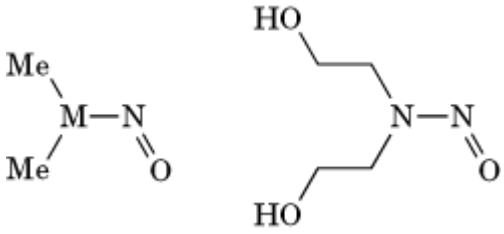
Nitrosamines

Nitrosamines (*N*-nitrosoamines), typified by *N*-nitrosodimethylamine and *N*-nitrosodiethanolamine (Fig. 1), are **mutagens** and are reactive compounds that readily alkylate DNA via an S_N1 reaction (slow formation of an alkylcarbenium ion and rapid reaction of this with nitrogen, oxygen, and

phosphorus atoms on DNA). *N*-Nitrosoamines are widespread in the environment and can be formed endogenously in humans (1-3). For example, workers in the rubber industry are exposed to high levels of *N*-nitrosodiethanolamine, which is a potent carcinogen over a considerable dose range and in more than one species. A wide range of volatile *N*-nitrosoamines are found in fried bacon and other pork products, while a different range of *N*-nitrosoamines are present in tobacco products and believed to play a significant role in human cancers associated with tobacco use. *N*-Nitrosoamines are potent carcinogens in every animal species tested; and although their role in human cancer is not definitively proved, it is considered highly likely that they are human carcinogens (2, 4).

Figure 1. Structures of the nitrosamines *N*-nitrosodimethylamine and *N*-nitrosodiethanolamine.



One of the most extensively studied compounds in this class is *N*-nitrosodimethylamine (NDMA). This chemical is nonreactive per se, but can be metabolized to an S_N1-type methylating agent, primarily by cytochrome P450 IIE1. Although the metabolite reacts primarily to form around 60% N_7-methylguanine DNA adducts, it also generates a significant amount (approximately 6%) of O_6-methylguanine, as well as other minor *N*- and *O*-alkylated bases. O_6-Methylguanine and other *O*-alkylated adducts are directly miscoding, and they introduce base pair substitutions upon DNA replication; extensive evidence exists to link these lesions with mutagenesis and carcinogenesis by NDMA and related agents. NDMA has been described as the most powerful methylating agent known (5).

NMR (Nuclear Magnetic Resonance)

Nuclear magnetic resonance (NMR) refers to a broad range of spectroscopic experiments intended to determine and analyze the absorption and emission of radiation by the nuclei of certain atoms. The radiation involved is in the radiofrequency range (RF) of the electromagnetic spectrum, typically

between 100 and 1000 MHz; in a strong magnetic field, it produces transitions among the allowed orientational states of nuclear magnetic moments. The exact frequencies are exquisitely sensitive to molecular structure and dynamics. Therefore, NMR experiments can provide information regarding three-dimensional structures, the rates of conformational change, and interactions between molecules. NMR is nondestructive, and samples can be recovered unchanged at the end of an experiment. NMR measurements may be made with samples in any physical state (solid, liquid, gas), although, given the dependence of the NMR phenomenon on molecular mobility, the kinds of experiments done and the information that can be obtained from them are different for different states.

1. Basic NMR

Atomic nuclei must possess a certain property, called angular momentum or "spin," to be observable in an NMR experiment. At least one isotope exists of every known element that has this spin property, although this isotope may not be the most prevalent form of the element. Most experiments with biological materials use so-called spin 1/2 nuclei. Table 1gives some of the characteristics of these nuclei. Notice the low natural abundance of some. Most carbon on the Earth's surface is the isotope ^{12}C, but this isotope has zero nuclear spin and is not observable in any NMR experiment. The isotope ^{13}C, however, is a spin 1/2 nucleus, and carbon NMR spectroscopy uses this isotope. There is a 1.1% chance of finding a ^{13}C nucleus at any given carbon position in a molecule, although the amount of the isotope can be increased to nearly 100% by suitable synthesis using labeled precursors. Similarly, most nitrogen in biological materials is ^{14}N, and the amount of ^{15}N at natural abundance is low but can be increased by synthesis using isotopically enriched precursor molecules.

Table 1. Properties of Spin 1/2 Nuclei

Isotope	Natural Abundance (%)	NMR Frequency (MHz) for Magnetic Field Strength 11.75 T	17.62 T	21.15 T
^{1}H	99.985	500.1	750.1	900.0
^{13}C	1.108	125.8	188.7	226.32
^{15}N	0.37	50.67	76.01	91.19
^{31}P	100.0	202.4	303.7	364.2
^{19}F	100.0	470.5	705.7	846.6

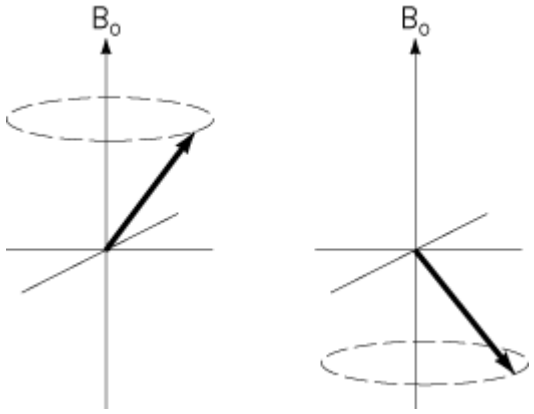
When a nucleus that has spin is placed into a magnetic field, its energy depends on its orientation in the field. A quantum mechanical description of a spin 1/2 nucleus in a magnetic field shows that the nucleus must take up one of two possible energy states, and that the difference between the energies of these states depends on the magnitude of the magnetic field. It is the transition from one of these states to the other, concomitant with the absorption or emission of a photon, that is detected in an NMR experiment.

Table 1lists the approximate frequencies for NMR transitions of selected nuclei with various magnetic fields that are used for experiments with biological molecules. The exact frequency for any

particular nucleus in a molecule will depend on the molecular structure, as reflected by the chemical shift and any scalar (J) coupling that may be present. The basic goal of an NMR experiment is to determine the frequency or frequencies that can be associated with changes of energy state for the nucleus being studied. (See Chemical Shift, Scalar Coupling.)

A useful, although not completely rigorous, model of spin behavior depicts the spin (angular momentum) of a nucleus as a vector. In the case of spin 1/2 nuclei in a magnetic field, the vector has two possible orientations ("up" and "down"; Fig. 1), corresponding to the two allowed energy states. The spin vectors rotate around the direction of the laboratory magnetic field while keeping constant their angle relative to the field. As the spin vector rotates around the field in this manner, its energy stays constant. This rotation is termed Larmor precession. The frequency of precession is the same as the frequency of the radiation involved in transition of the nuclear spin from one allowed state to the other. If the laboratory field is 17.62 T, the frequency of Larmor precession for the nuclear spin vector of the hydrogen (^{1}H) nucleus is 7.5×10^8 revolutions per second.

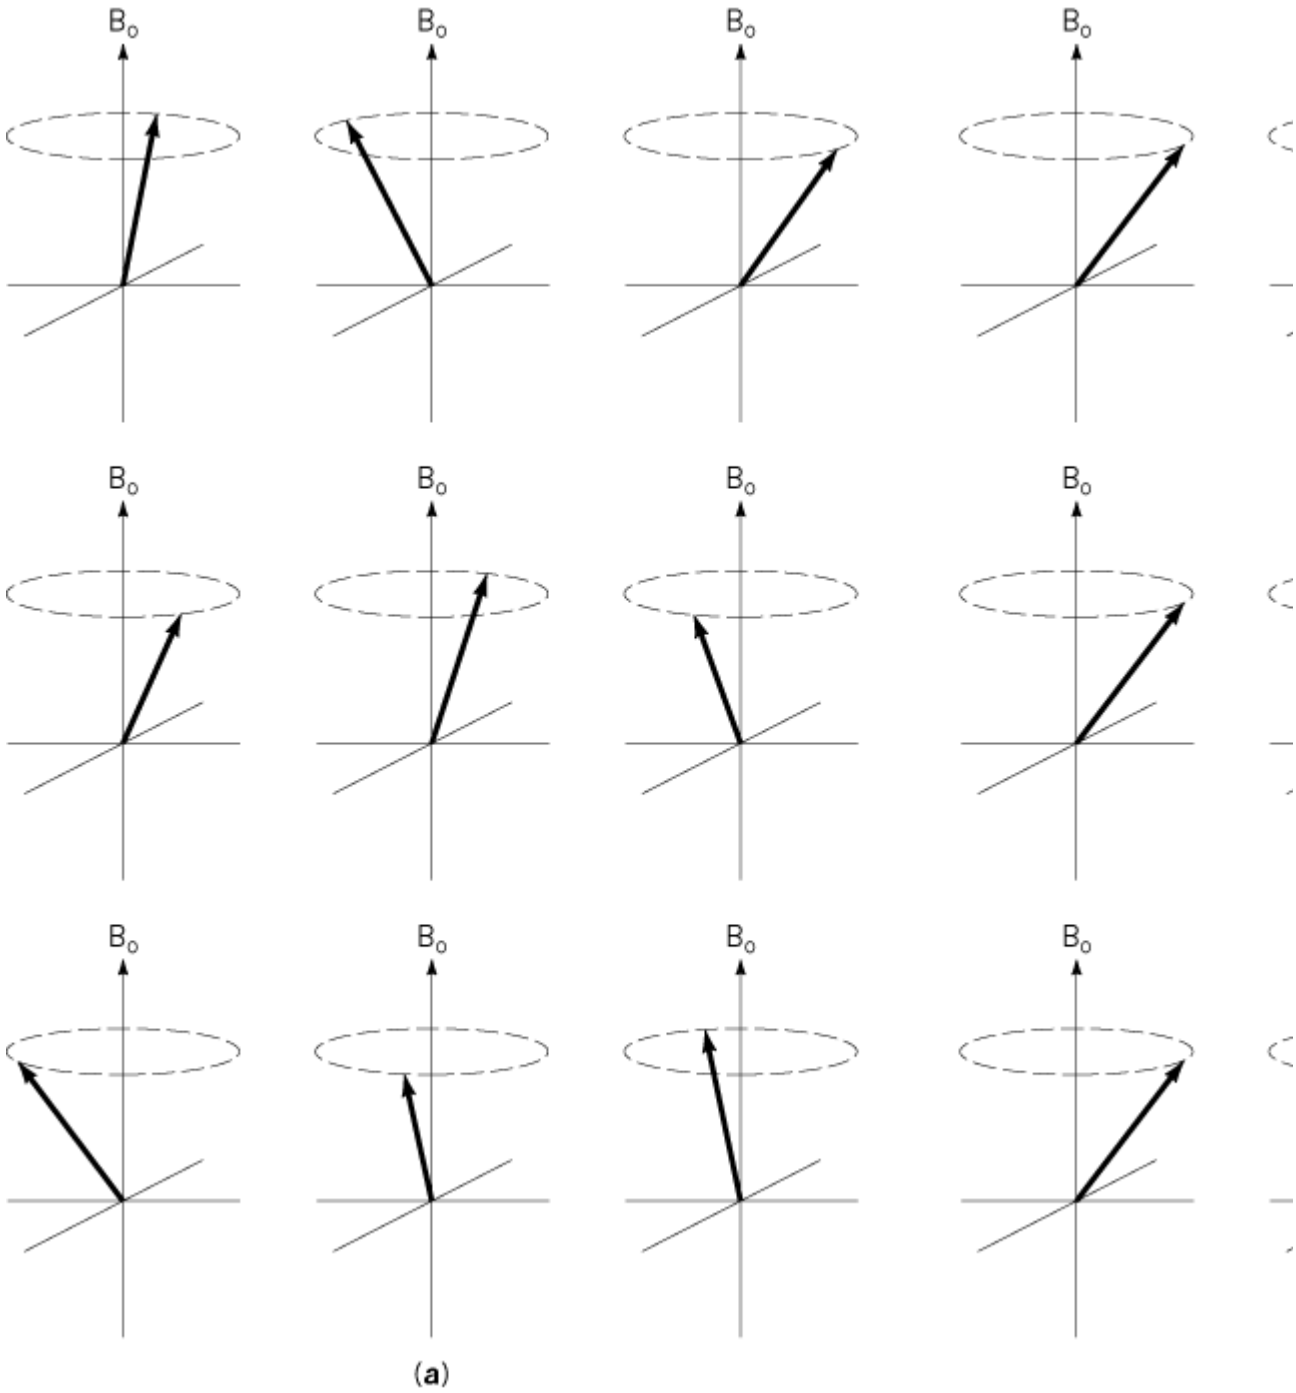
Figure 1. The behavior of a spin 1/2 nucleus in a magnetic field (B_o). Such nuclei are allowed to take one of two possible orientations relative to the field. The energies of these are different. In either state, the spin undergoes Larmor precession around the direction of the field.



NMR experiments with biological molecules typically use 20–600 mL of a solution in which the material of interest is present at a concentration of 0.5 to 5.0 m*M*. Under these conditions, a large number ($\sim10^{18}$) of nuclei of any specific type will be present. When the sample is placed into a magnetic field, each nucleus of the sample with the spin property will be sorted into one of the allowed spin energy states and will undergo Larmor precession. The number of nuclei of a given type that is present in each particular allowed spin state is governed by the Boltzmann distribution law. Every molecule in the sample is acted on by seemingly random dynamic processes that exchange energy among the molecules of the sample, driving the system toward equilibrium. These processes are collectively known as relaxation. Any experimental operation that alters the state populations will be counteracted by these relaxation processes, so that the sample eventually returns to the Boltzmann populations that are characteristic of equilibrium.

Another feature of the equilibrium state is a random distribution of spins in their precessional motion. All of the spin-up vectors shown in Fig. 2**a** have the same component along the direction of the laboratory magnetic field, but their positions around the precessional path are random. (A similar situation holds for the spin-down vectors.)

Figure 2. Precessional behavior of spin 1/2 nuclei in a magnetic field. (**a**) Noncoherent precessional behavior of a collec precessional behavior of these spins. Nuclei that have the other allowed orientation relative to B_o undergo precession at t motions, at the same time that spins in the orientation illustrated are coherent.



An NMR spectrometer is only able to report the collective behavior of the nuclei of the sample, not the behavior of any single nucleus. It can produce signals only when there is a net macroscopic magnetic field from the sample that is at right angles (transverse) to the direction of the laboratory magnetic field. Although all spins of a particular type have the same Larmor precessional frequency when the sample is placed in the magnetic field, there is no defined starting point for Larmor precession (Fig. 2**a**). In this case, the individual transverse components of each spin vector collectively cancel, while the longitudinal components of the spins of the sample combine to create a macroscopic magnetic field component that is along the direction of the laboratory field

(longitudinal to it). To generate a signal in an NMR spectrometer clearly requires that the equilibrium state of the sample in the laboratory magnetic field be altered.

To change the sample spins away from the equilibrium state requires the absorption or emission of photons, as the nuclei of the sample change spin states. The source of the needed radiation, the transmitter of the NMR instrument, typically is switched on for only a short time (1–20 μs). The energy of this RF pulse can alter the populations of nuclei in the allowed energy states. RF pulses of the appropriate strength and duration can also create coherence in the motions of individual spins (Fig. 2**b**). The resultant magnetic field produced when sample spins are precessing coherently, as suggested by Fig. 2**b**, has a macroscopic component in the plane that is transverse to the direction of the magnetic field—precisely what is needed to afford a detectable NMR signal. State populations altered by an RF pulse are eventually restored to their equilibrium values by relaxation processes. These processes also destroy any coherence of spin precession that has been created, and the NMR signal decays back to zero.

Except in special circumstances, RF pulses are nonselective—that is, if the radiofrequency energy source is pulsed on, all spins in the sample that have Larmor frequencies close to that frequency will respond to the pulse. If the RF pulse is at the proton Larmor frequency, all protons of the sample—those in methyl groups, those in aromatic rings, those in water molecules—will be affected by the pulse. If a pulse is designed to create coherence in proton spin motions, all spins in the sample will become coherent and, after the pulse, will contribute to the proton NMR signal detected by the spectrometer.

Spin coherence leads to NMR signals that oscillate at the Larmor frequency of the nuclei. If there are many coherences present (recognizable by their specific Larmor precessional frequencies), the detection system generates a signal that is the sum of the signals created by all coherences present. The signal is digitized and stored in the instrument computer as a series of 10^3–10^5 numbers. Although the signal recorded is a decaying function of time, it is the frequencies present in this signal that is of interest. A Fourier transformation of the numbers representing the signal is performed to obtain these frequencies and their relative intensities.

NMR signals appear at different frequencies because of chemical shifts and the effects of **scalar** (spin) **couplings**. The frequency axis of an NMR spectrum is thus usually calibrated in terms of the NMR shielding parameter, using ppm units. Because it is only practical to measure *differences* in shielding parameters, one shielding parameter (that of a signal chosen as reference) is arbitrarily set to 0. A number on a frequency axis of an NMR spectrum therefore represents the difference between the shielding parameter for the nucleus of interest and that for the reference nucleus.

2. Multidimensional NMR Spectra

Dimension in NMR spectroscopy refers to the number of frequency or chemical shift axes that are needed to represent the results of an experiment. The most basic proton or ^{13}C spectrum is a one-dimensional (1D) experiment: the intensities of spectral peaks are plotted as a function of one chemical shift axis. Figures 3 and 4 show 1D proton and ^{13}C NMR spectra of an amino acid derivative. A close correspondence exists between the collections of peaks present in the spectrum and the chemical structure of the molecule examined. An experienced spectroscopist can assign these peaks to specific nuclei (hydrogens and carbons) of the molecule using any of several approaches, including analysis of the fine structure of the peaks due to scalar coupling.

Figure 3. The proton NMR spectrum of *N*-acetyltryptophan obtained under conditions where the proton Larmor frequency is near 500 MHz. The sample was dissolved in d_6-dimethylsulfoxide. The signal with the smallest shielding parameter (near 10.8 ppm) is readily assigned to the N-H proton of the indole ring. The signal at 2.5 ppm arises from

residual hydrogen atoms in the solvent.

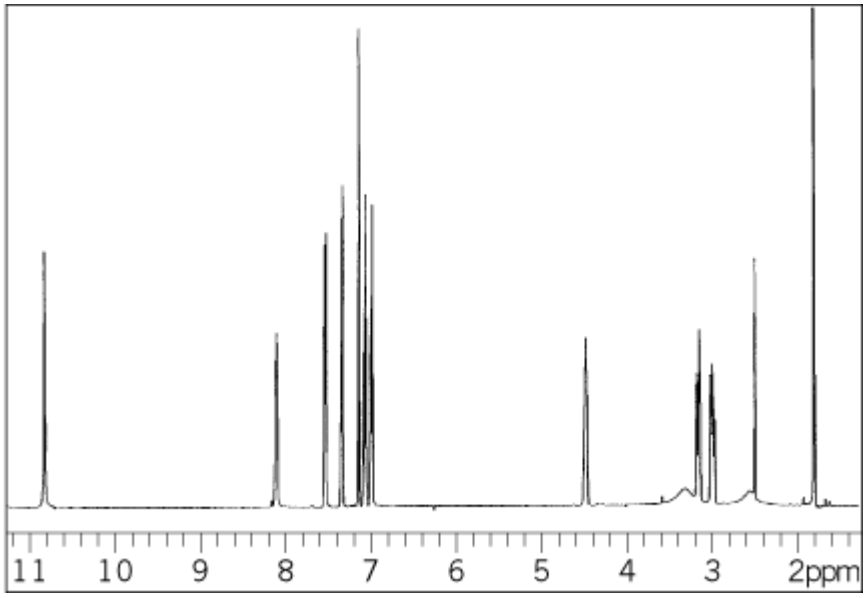


Figure 4. A ^{13}C NMR spectrum of *N*-acetyltryptophan obtained with the same sample used to acquire the proton spectrum shown in Figure 3. A signal exists for each carbon atom in the molecule. The collection of signals at 39.5 ppm is due to the ^{13}C atoms in the solvent.

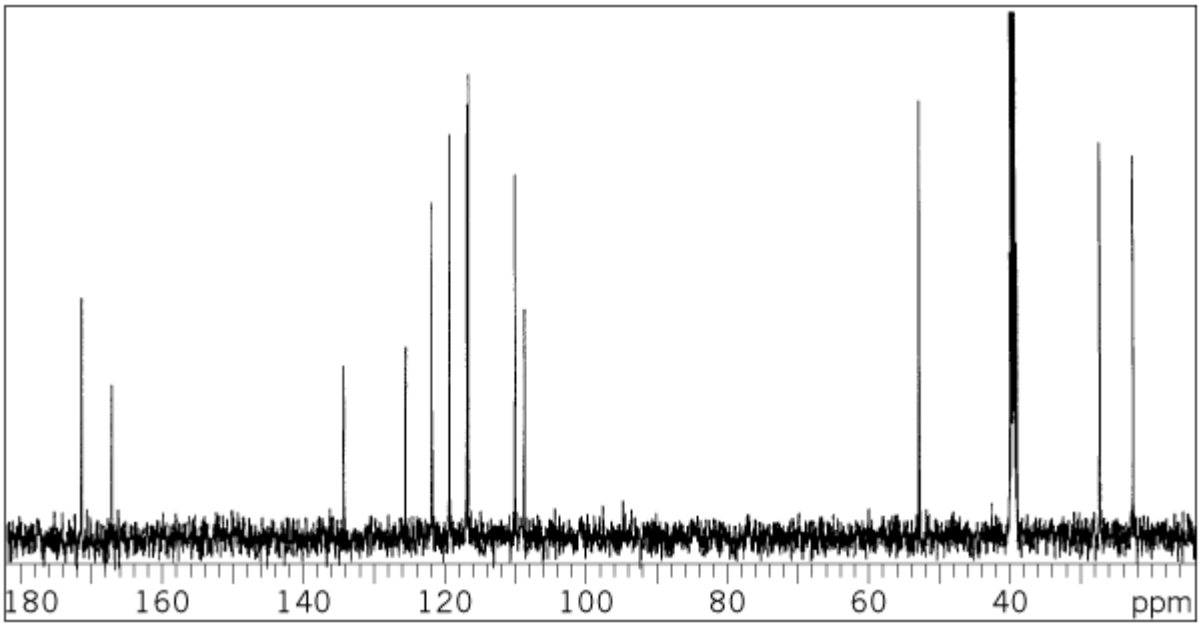


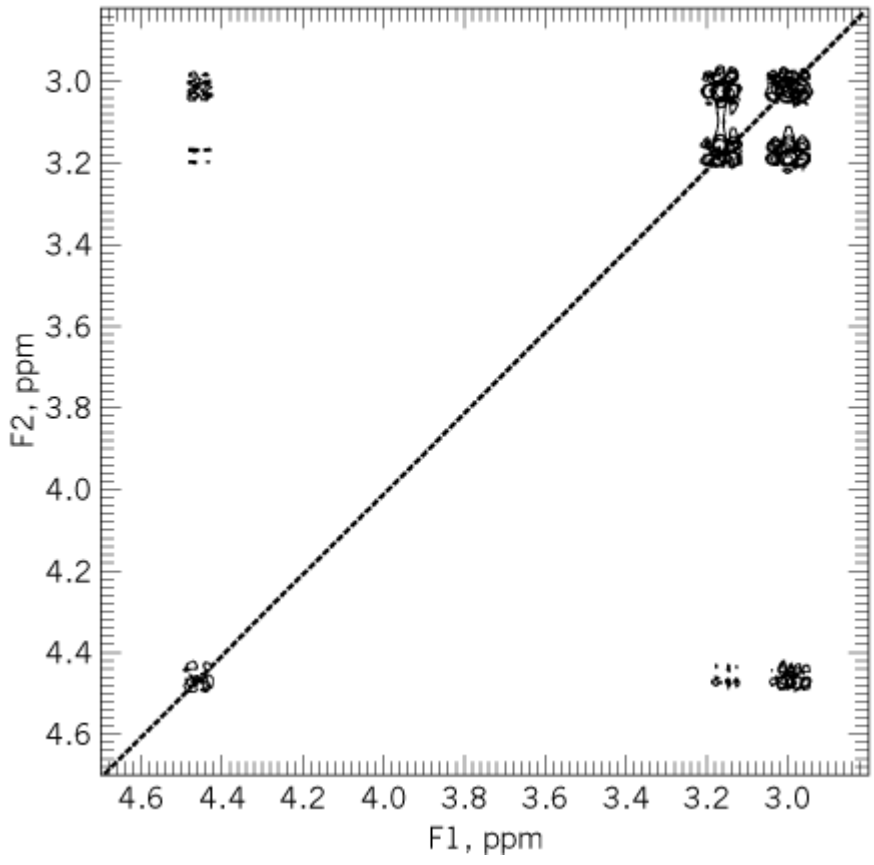
More elaborate NMR experiments can be designed in which observed intensities are dependent on two or more chemical shifts. A spectrum that involves two chemical shift axes is a two-dimensional (2D) spectrum. Reflection will show that a 2D NMR spectrum is actually a three-dimensional object with the two chemical-shift axes defining two dimensions of the object and intensity represented along the third. The most common way that 2D NMR spectra are presented is by use of a contour plot. The two chemical-shift axes appear in the plane of the page, while intensity is represented by a

series of contours that correspond to levels of intensity, in the same way that contour lines on a topographic map represent different elevations. Intensity contours in 2D experiments can be either positive or negative and therefore appear above or below the plane. One technique for indicating the sign of the intensity is to plot positive intensities with solid (continuous) lines, whereas negative intensities are plotted with dashed contours. Alternatively, contours corresponding to positive and negative intensity can be plotted in different colors.

If both chemical-shift axes of a 2D spectrum refer to the Larmor frequencies of the same nucleus, the spectrum is referred to as a homonuclear 2D experiment. Most commonly, homonuclear 2D experiments are proton-proton. In a heteronuclear 2D spectrum, the shift axes correspond to the Larmor frequencies of different types of nuclei with, perhaps, ^{13}C frequencies appearing along one axis and proton frequencies along the other.

The essential features of a homonuclear 2D spectrum are abstracted in Figure 5. In this case, the range of frequencies along the axis labeled f_1 is identical to the range of frequencies plotted along the other axis, f_2. There are always features along the 45° diagonal of a 2D map representing a homonuclear experiment. These peaks have the same coordinates (for example, S1,S1) along either axis. The coordinates of a diagonal peak correspond to the chemical shift of a peak or multiplet in the 1D spectrum of the same sample. There could be much fine structure of the diagonal peaks because of scalar coupling, but this might be obscured by the limited resolution of the manner the data are collected and displayed.

Figure 5. Part of a typical homonuclear proton-proton 2D NMR spectrum, using the same *N*-acetyltryptophan sample and experimental conditions that produced the 1D spectrum shown in Figure 3. This spectrum was produced by a DQF-COSY experiment. The cross peaks show that the aliphatic protons of the amino acid (with shielding parameters 2.98, 3.14, 4.45 ppm) are scalar coupled to each other.



Depending on the nature of the experiment and the structure of the molecule being studied, peaks that are off the diagonal at some coordinate (S1,S2) or (S2,S1) may appear in a 2D spectrum. These are called cross peaks, and their significance depends on the nature of the 2D experiment. Their presence, however, indicates that some relationship exists between the spins characterized by the S1 shift and spins that have the S2 shift. Figure 5 shows part of the homonuclear 2D spectrum that is obtained in a 2D NMR experiment with the same material used to obtain the 1D spectrum in Figure 3. For this particular spectrum (from a proton double quantum filtered Correlation Spectroscopy [DQFCOSY] experiment), cross peaks are present because there is scalar coupling between hydrogen atoms of the molecule. (see COSY Spectrum.)

For heteronuclear experiments, only cross peaks are present in the 2D spectrum. Again, the presence of a cross peak indicates that some structural relationship exists between the spins characterized by the S1 shift along one axis and spins that have the S2 shift along the other.

NMR experiments that provide results of higher dimensionality (for example, 3D, 4D, or 5D) exist and are often applied to structural studies of biological **macromolecules**. NMR spectra of higher dimensionality than 2D experiments are impossible to represent completely on a single planar surface. These spectra are viewed and analyzed by means of computer displays, which may use color-coding to convey the intensity of an NMR absorption or emission line. Although a few 3D homonuclear experiments are done, most 3D and higher-dimension NMR experiments with biological systems are heteronuclear, usually performed with materials that have carbon or nitrogen positions that are enriched in ^{13}C and ^{15}N, respectively. (See Chemical shift, Scalar coupling, COSY spectrum, NOESY spectrum, ROESY spectrum, TOCSY spectrum, Magnetization transfer, Isotope editing, Triple resonance.)

NOESY Spectrum

Proton-proton nuclear overhauser effect spectroscopy (NOESY) is a type of two-dimensional (or higher) nuclear magnetic resonance (NMR) spectrum. In it, cross peaks appear because the spins of atoms are sufficiently close to each other that their mutual interaction, through relaxation, can produce changes in the populations of the nuclear spin energy levels that are associated with those spins. The alterations of the level populations lead to changes in NMR signal intensities (NOEs). The magnitude of the effect depends on the distance between the spins; consequently, observation and calibration of NOESY cross peaks provide constraints on what can be the tertiary structure of the molecule under study.

Cross peaks in a NOESY experiment arise because magnetization that precesses at a frequency corresponding to one chemical shift during an initial phase of the experiment is transferred to a nearby spin, where it precesses at a different chemical shift during a latter phase of the experiment. The chemical-shift coordinates of a cross peak identify the shifts of the interacting sets of spins. The distance dependence of the cross-peak intensity is very great, in the simplest case varying with $1/r^6$, where r is the distance between the spins.

The distance between hydrogen atoms (protons) in a methylene group is about 0.179 nm, whereas the distance between adjacent protons attached to an aromatic ring is 0.248 nm. These distances are fixed by the covalent structure of these groups. Measurement of the NOEs between protons in these situations provides a possible means of calibrating NOESY cross-peak intensities and thereby

potentially obtaining estimates of other internuclear distances.

The usefulness of NOESY experiments is diminished by spin diffusion processes, in which the magnetization of a particular nucleus is transferred to nearby nuclei; this leads to NOE cross peaks between atoms that are not close in space but are linked to atoms that are. An experimental variable in NOESY-type experiments is the time during which the NOEs develop. Called the mixing time, it typically is set between 50 and 1000 ms. Spin diffusion is a time-dependent phenomenon, so the misleading cross peaks it produces can be minimized by reducing the mixing time. The heights of all cross peaks are altered to some extent by this procedure, however, and all cross-peak intensities may be perilously close to experimental noise if the mixing time is short.

The elements of NOESY experiments can be built into experiments that produce three-dimensional or higher NMR spectral results. (See also ROESY Spectrum, Distance Geometry, Simulated Annealing.)

Noggin

Noggin is a **gene** expressed in Spemann's organizer of the ***Xenopus*** gastrula and its **homologous** structure, the node, of mammals (1, 2). It encodes a secreted **glycoprotein** that is a **disulfide**-linked dimer in solution (3). The protein has very high affinity (**dissociation constant** of 20 pM) for the bone morphogenetic proteins (BMPs) BMP2 and BMP4 and blocks their activity by preventing them from binding to their respective receptors, the type II BMP receptor and the type I (transducing) receptor, ALK3 (4). Noggin was the first neural-inducing molecule identified from embryos (5).

Noggin was discovered in a screen for dorsalizing activities in *Xenopus* (1). *Xenopus* embryos that are UV-irradiated shortly after fertilization develop no dorsal structures. To identify the molecules that induce axial structures, messenger RNA**s** were synthesized from pools of a cDNA library and injected into UV-treated embryos; those pools that induced axial structures were split, and sib-selection was used to identify the activity. Three mRNAs—*Xwnt-8*, *noggin*, and *Xnr3* —were identified in this screen (1, 6, 7). Zygotic transcripts of all three are expressed in the prospective mesoderm. Two of them, noggin and Xnr3, an unusual member of the **transforming growth factor**-b family) are expressed in the dorsal mesoderm, Spemann's organizer. Noggin gained its name from its ability to transform the entire embryo into head structures.

The possible zygotic function of noggin was tested by applying Noggin recombinant protein to explants. When applied to prospective ventral mesoderm or epidermis, Noggin can mimic two of the known gastrula-stage activities of the organizer, namely, dorsalization of ventral mesoderm and neural induction (3, 5).

Neural induction by Noggin appears to be direct, in that no mesodermal intermediate is detected. Whereas mesoderm inducers can act only on blastula and early gastrula tissues, Noggin can induce neural tissue until late gastrulation. Although the treated explants are not homogeneous, only anterior types of tissue are present (5).

Expression of the mouse noggin gene is homologous to that of *Xenopus* in that noggin transcripts are found in the mouse organizer (node) and its axial mesodermal derivatives. *In situ* **hybridization** and a lacZ reporter gene, integrated into and replacing the endogenous noggin-coding sequences, were used to detect later sites of noggin expression; these appear to be crucial (2, 8). Although the initial steps of neural induction and somite formation occur in a Noggin-deficient mouse, neural patterning and skeletal formation are abnormal. Noggin is required for ventral fates to be induced in the neural tube. During dorsal ventral patterning of the neural tube, BMPs have been shown by pharmacologic experiments to be required to induce dorsal fates (9), and sonic hedgehog has been shown from genetic experiments to be required also (10). In the absence of Noggin, excess BMP activity blocks ventral fates in the caudal neural tube. Thus, there is an increasing severity of ventralization in the neural tube, with the loss of interneurons, motor neurons, and finally the floor plate. These defects are mirrored in the mesoderm, where a rostral to caudal gradient of defects in the somites includes loss of sclerotomal and dermomyotomal derivatives. In vitro explant experiments show that noggin can synergize with sonic hedgehog to induce sclerotome, so endogenous BMPs are likely to be potent antagonists of somite differentiation.

Noggin has become a useful pharmacologic antagonist of BMPs. It has been used to block BMP signaling from lateral plate mesoderm in the chick as well as surface ectodermal and roofplate BMP signaling (11-13). Such experiments have established the importance of BMP signaling in not only suppressing epaxial muscle fates in the somite but also in the induction of lateral plate identities.

During skeletal development, Noggin also plays an essential role in regulating BMP activity. When BMP activity is not attenuated by Noggin, excess mesenchyme is recruited into the condensing cartilage; in addition, synovial joints do not form (8).

Nonautonomous Controlling Element

"Controlling elements" was the term Barbara McClintock gave to transposable elements when she discovered them in maize in the late 1940s. This designation emphasized that these new genetic elements could control gene expression, as well as move from place to place in the genome (1). McClintock discovered two classes of controlling elements, one of which she designated *Dissociation* (Ds) and the other *activator* (Ac). She found that while Ds elements could move in the presence of Ac, they were unable to move alone, while Ac was capable of movement in the presence or absence of Ds. She hypothesized that activator made a product that could promote the movement of both Ac and Ds. We now know that this product is the Ac transposase and that Ds is a deletion derivative of Ac that contains the same special recombination sequences at its tips that the Ac transposase can act on, but is lacking a transposase. Because Ds lacks a transposase gene, it cannot promote its own movement and is dependent on this product from Ac. Ds is said to be a nonautonomous controlling element because it can't move in the absence of Ac, whereas Ac is said to be an autonomous controlling element because it encodes its own transposase that can act upon its terminal sequences to move the Ac element from place to place.

Nonautonomous elements are deleted versions of autonomous elements. Different nonautonomous versions of the same element result from different internal deletions. These deleted versions probably arise from incomplete repair events at the donor site after transposon excision (2-4); this repair involves transferring information from an intact homologue, using homologous recombination and gap repair.

In addition to Ac–Ds and several other sets of autonomous and nonautonomous elements in maize, autonomous and nonautonomous elements have been also observed in other organisms such as *Drosophila* (2), and ***Caenorhabditis*** *elegans* (3, 5). Virtually all bacterial elements that have been observed appear to be autonomous.

Noncompetitive Inhibition

1. Linear

Linear noncompetitive inhibition of an enzyme occurs whenever an inhibitory analogue of the substrate combines with a form of enzyme other than the one with which the variable substrate combines and a reversible connection exists between the points of addition of inhibitor and the variable substrate. It should be noted that reversible connections are broken either by the release of product at zero concentration or the presence of a nonvaried substrate at an essentially infinite concentration. For a two-substrate ordered kinetic mechanism (Fig. 1), the inhibition by I would be linear competitive with respect of A. It would be linear noncompetitive with respect to B, as B combines with EA, I combines with E, and a reversible connection exists between E and EA. The general form of the equation to describe noncompetitive inhibition is shown in equation (1):

$$v = \frac{VA}{K_a(1 + I/K_{is}) + A(1 + I/K_{ii})} \tag{1}$$

where K_a denotes the $\boldsymbol{K_m}$ (Michaelis constant) for substrate A,V is the maximum velocity of the reaction, and K_{is} and K_{ii} are the inhibition constants associated with the slopes and intercepts, respectively, of the double-reciprocal plot, which has the form illustrated in equation (2):

$$\frac{1}{v} = \frac{K_a}{V}\left(1 + \frac{I}{K_{is}}\right)\frac{1}{A} + \frac{1}{V}\left(1 + \frac{I}{K_{ii}}\right) \tag{2}$$

This equation shows that a plot of $1/v$ against $1/A$, at different concentrations of I, would yield a family of straight lines that intersect at a common point to the left of the vertical ordinate. The $1/v$ coordinate for the crossover point is $(1/V)[1 - K_{is}/K_{ii})]$, and thus, the intersection point can occur above, on, or below the abscissa, depending on whether K_{is} is less then, equal to, or greater than K_{ii}, respectively (Fig. 2). The term *noncompetitive* has been applied only for the case in which the lines of a double-reciprocal plot intersect on the abscissa; the term *mixed inhibition* is used to describe cases in which the lines intersect either above or below the abscissa. Such a distinction is unnecessary as the position of the crossover point is simply a function of the relative values of K_{is} and K_{ii}.

Figure 1. Kinetic mechanism for which I would give rise to linear competitive inhibition with respect to A and linear noncompetitive inhibition with respect to B.

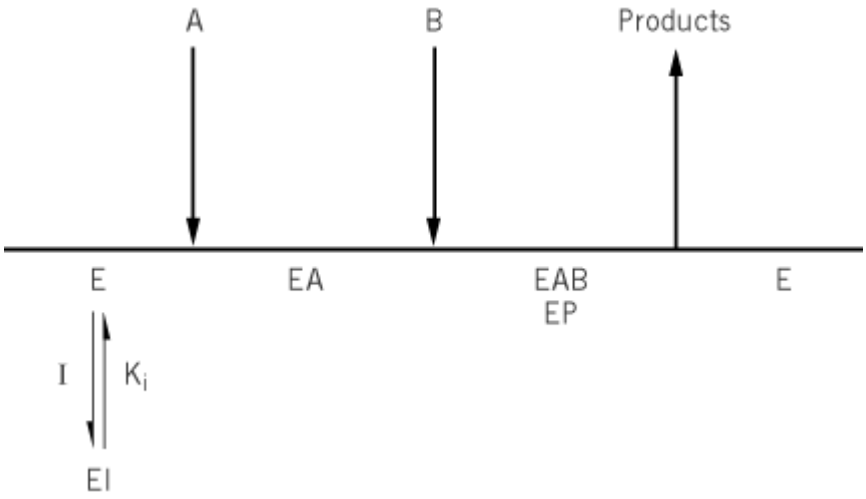

Figure 2. Double-reciprocal plots for linear noncompetitive inhibition with crossover points (**a**) above, (**b**) on, and (**c**) below the abscissa. The respective values in arbitrary units for K_{is} and K_{ii} were: (**a**) 0.5 and 2.0, (**b**) 0.5 and 0.5, and (**c**) 0.3 and 0.1.

The inhibition constants associated with the slopes (K_{is}) and intercepts (K_{ii}) of a double-reciprocal plot are calculated and interpreted as described for competitive inhibition and uncompetitive inhibition, respectively.

2. Hyperbolic

This type of inhibition would be observed for the scheme illustrated under hyperbolic competitive inhibition, when the EA and EAI complexes give rise to product at different rates. The VA term of the equation that describes this inhibition would be modified by the factor, $1+I/K_{in}$, so as to give equation (3):

$$v = \frac{VA\left(1+\frac{I}{K_{ia}}\right)}{K_a\left(1+\frac{I}{K_{ia}}\right)+A\left(1+\frac{I}{K_{id}}\right)} \tag{3}$$

which, in reciprocal form, is described by equation (4):

$$\frac{1}{v} = \frac{K_a}{V}\left[\frac{1+\frac{I}{K_{ia}}}{1+\frac{I}{K_{in}}}\right]\frac{1}{A}+\frac{1}{V}\left[\frac{1+\frac{I}{K_{id}}}{1+\frac{I}{K_{in}}}\right] \tag{4}$$

Values would be determined for K_{is} and K_{in} from the variation of the slope with varying concentrations of inhibitor I and for K_{in} and K_{id} from the variation of intercept with I in the same way as described for hyperbolic competitive inhibition.

Nonpermissive Condition

The condition under which a conditional lethal mutant cannot grow is called the nonpermissive or restrictive condition. In contrast, the permissive condition allows growth. Typical nonpermissive conditions are high or low temperature, extremes of pH, osmotic pressure, oxygen concentration, and the absence of growth factors. Particular hosts can become nonpermissive or restrictive for mutant strains of **viruses**, **bacteriophages**, or other parasites (see Conditional Lethal Mutations).

Nonpolar

A molecule or group of atoms is said to be *nonpolar* if it lacks electronegative atoms such as N, O, and S, so that it does not contain groups with substantial partial electrostatic charges. Such molecules include steroids and other lipids, and the long hydrocarbon side-chains of amino acids such as **leucine, isoleucine**, and valine. Such molecules show a tendency to move from water to oily

surroundings such as the interiors of membranes. The physical basis of this tendency, and its quantitative measurement, are discussed in Hydrophobicity and Hydrophobic Effect.

Nonrepetitive DNA

Nonrepetitive DNA is comprised of DNA sequences present in only one or in a small number of copies in a genome. It contrasts with repetitive DNA, especially Alu sequences, CpG Islands, Sines, Lines, **microsatellite** and **minisatellite** DNA. Nonrepetitive DNA has the reassociation kinetics expected from unique sequences and is characterized by a high $\mathbf{C_0t}$ value. It generally consists of protein-coding genes or a plasmid in only one copy per genome.

Nonsense Codons and Unassigned Codons

The term *nonsense codons* is usually used for the stop codons of the genetic code that do not code for any amino acid and are used to terminate translation during **protein biosynthesis** . Unassigned codons are codons corresponding to neither amino acids nor stop codons and do not exist in the open reading frames (ORF) of genes coding for proteins. Such codons should be called the real nonsense codons because they are recognized by neither tRNA nor release factors (RF), the proteins that function to terminate translation (see Stop Codons). Such unassigned codons have been recognized only with determination of the sequences of the entire genomes of mitochondria and of some organisms with small genomes. To be an unassigned codon, the tRNA or RF corresponding to this codon probably disappeared from the translation system (1). The unassigned codons determined thus far (2-6) are shown in Table 1. Recently, it has been shown that AAA is unassigned in a hemichordate (7). AAA is assigned to lysine in most metazoans and to asparagine in echinoderms. The situation in hemichordates may be an intermediate en route to the related echinoderms (7).

Table 1. Unassigned Codons*[a]

System	Probable Unassigned Codon	Cause
Mycoplasma capricolum	CGG(Arg)*[b]	AT-pressure; lack of tRNAArgCCG
Micrococcus luteus	AGA(Arg)	GC-pressure; lack of tRNAArg*UCU
AUA(Ile)	GC-pressure; lack of tRNAIleLAU	
Torulopsis glabrata mitochondriaCGN (Arg)	AT-pressure; lack of tRNAArgCCG	

Prototheca wickerhamii		
(A green alga mitochondria)	CGN(Arg)	AT-pressure; lack of tRNAArgCCG
UGA(Stop)	AT-pressure;? Lack of RF-2	
or UAG(Stop)		AT-pressure;? Lack of RF-1
Drosophila*[c]and	AGG(Ser)	?AT-pressure; lack of tRNASer*GCU (2)
Mosquito* [d] mitochondria	(2)	

[a] All except for the last item from Ref. 2, p. 66.

[b] Parenthesis means amino acid or stop codon in the universal genetic code, or for the last item in animal mitochondrial genetic code.

[c] From References 3 and 4.

[d] From References 5 and 6.

The appearance of unassigned codons may be caused by direct mutation pressure (as a result of changes in the overall AT and GC content of the genome DNA), change of release factor, or genome economization (Table 1). It is regarded as an intermediate step in codon reassignment in producing genetic code variations (1, 2). The presence of unassigned codons is important evidence for the codon capture theory (1, 2) (see "Candida code and codon reassignment theories" section in Genetic Code).

Nonsense Mutation

A nonsense mutation is a mutation that creates a translational stop codon in the coding sequence of a gene. The three chain-terminating codons, which are the normal stop signals for translation, are UGA, UAA, and UGA, called **amber**, **ochre**, and opal, respectively (although the latter is rarely

used). Nonsense mutations are created by base substitutions at sense (coding) **codons** or by frameshift mutations, which usually create a **nonsense codon** 3′ to the frameshift.

Nonsense mutations are **suppressed** by mutant transfer RNAs that recognize the nonsense codon and insert their cognate amino acid into the polypeptide chain. Thus, nonsense mutations are a class of conditional lethal mutations. Because they occur in any gene but are suppressed by the same class of suppressors, nonsense mutations are a particularly powerful genetic tool. An elegant example was determining the life cycle of **bacteriophage** T4 (1). In addition, by using mutant tRNAs with known cognate amino acids, the functional significance of amino acid replacements at various positions in a protein can be determined (2). Most suppressor tRNAs are mutant in their anticodon, although mutations and modifications elsewhere in the molecule have suppressing effects. Indeed, the first UGA suppressor discovered is mutant outside of its anticodon. Mutations in other components of the translational machinery, such as the release factors and **ribosomal** subunits, also can suppress nonsense mutations (3).

Nonsense mutations can be polar, ie, can eliminate the expression of genes in the same operon encoded downstream from the mutation. The polarity of a nonsense mutation depends on its proximity to a codon that can restart translation. In *Escherichia coli* the polarity of many nonsense mutations can be suppressed by mutations in **Rho**, the transcriptional termination factor. Thus in these cases polarity is probably caused by inhibition of **RNA polymerase** by Rho when it interacts with untranslated mRNA (4).

Nonsense Suppression

Nonsense mutations create stop codons within the coding regions of genes. Nonsense suppression occurs when mutations in the translational apparatus allow the decoding of nonsense codons as sense codons. Most nonsense suppressor mutations alter tRNA anticodons, making them cognate the stop codon; however, a handful of suppressor mutations have also altered release factors or other translational components. Suppression requires that the amino acid inserted is compatible with protein function. Furthermore, because the nonsense mutation is decoded as “stop” at least some of the time, suppression allows only a fraction of the normal level of polypeptide synthesis. Despite

these limitations nonsense suppressors have been remarkably useful research tools. Other forms of mutational suppression are described in Genetic Suppression.

There are three termination codons in the universal genetic code, UAG, UAA, and UGA. Historically, UAG nonsense mutations are called "amber," named after the mother of a pioneering worker who first isolated such mutants in phage T4 (Harris Bernstein — Bernstein means "Amber" in German. Interestingly, the molecular nature of amber mutations was not known at the time, see Ref. 1). After their discoveries, the other nonsense codons were also named according to a "color code," with UAA as "ochre" and UGA as "opal." tRNA suppressors have been isolated that can suppress each color, and because of U:G wobble decoding ochre suppressors will also suppress amber mutations.

Nonsense mutations are a type of conditional mutation, because the mutant phenotype is dependent on the absence of a suitable suppressor. This property has been used extensively in genetic studies of phage, bacteria, yeast, and the multicellular eukaryote *Caenorhabditis elegans* (2). For example, a large number of phage mutants have been isolated based on the ability to form plaques only on hosts that express nonsense suppressors. Such mutants are referred to as "suppressor-sensitive" and are commonly abbreviated as "sus" in the literature. *sus* mutations can serve as markers for genetic mapping and other routine genetic manipulations. In addition, studies of the molecular phenotypes during the nonproductive condition have helped illuminate the functions of the genes that carry nonsense mutations.

Nonsense suppression has also been extremely useful for studies of translational mechanisms (3). Suppressor tRNA genes are easy to manipulate, and suppression efficiencies are readily quantified; together, these properties make suppression the assay of choice for probing translational mechanisms. Suppressor tRNAs must compete with the peptide release factors that normally decode nonsense codons. Suppressors that are good competitors allow for efficient suppression of the nonsense mutation. Thus, the level of suppression can be used as a measure of the translational efficiency of tRNAs. Surprisingly, perhaps, tRNA suppressors can vary dramatically in their translational efficiency. Yarus observed that suppression efficiency was correlated with the tRNA nucleotides near the anticodon and proposed that decoding efficiency was a property of an "extended anticodon" in which the nucleotides near the anticodon contribute to its ability to translate codons (4). This hypothesis was confirmed by making measuring the effects mutations that saturate the anticodon arm of an amber suppressor. It was found that the native sequence was optimal for suppression, and that anticodon arm mutations reduce suppression efficiency by various degrees (5). Nonsense suppressors have also been used to show that nucleoside modifications near the anticodon increase translational efficiency. Mechanisms are not always clear, but a common theme is that bulky modification 3′ to the anticodon increases translational efficiency, as if increased base stacking stabilizes anticodon:codon complexes (6, 7).

Studies of suppressors have also shown that nucleotides outside of the anticodon region can affect translational efficiency (8-11). Mutational analyses show that the central or hinge region of the tRNA is important for translation, but probably not by directly affecting anticodon:codon pairing. Instead, this region may participate in a conformational change in the tRNA that must occur during ribosomal acceptance of the aminoacyl-tRNA. Mutations that interfere with this change affect the likelihood that the tRNA will be selected, regardless of whether the anticodon is perfectly matched to the codon (12). Certain mutations in this region allow, for example, reading with a first-position U:G pair or a third-position C:A pair. It is thought the hinge mutations facilitate conformation changes leading to ribosomal acceptance despite the mismatched base pairs.

McClain and co-workers have used nonsense suppressor tRNAs to demonstrate changes in the aminoacylation specificities of several tRNAs and thus map the determinants for tRNA amino acid "identity" (13). They engineered an amber termination site near the 5′ end of the gene for the easily isolable dihydrofolate reductase enzyme. They then mutagenized tRNA suppressors and determined

which amino acids the variants insert by sequencing the amino termini of isolated enzymes. They found that a small number of nucleotides are mostly responsible for defining tRNA identity. The use of suppressor tRNAs was critical for these studies because there is ambiguity about which tRNA actually decodes the amber site. Thus, a change in the amino acid inserted can be unambiguously attributed to the changes made in the amber suppressor tRNA.

Nonsense suppressors are also used to show that codon translation is affected by neighboring nucleotides (codon context). A large number of studies show that nonsense codons are more readily suppressed if the 3′ neighbor nucleotide is a purine. This context effect has at least two molecular sources: the anticodon:codon complex is stabilized by base stacking with the 3′ purine (14, 15), and the release factors are highly dependent on the neighbor for termination with 3′ U being optimal (16, 17).

Nonsense suppressors will also be used for protein engineering. In one approach, Abelson and collaborators have constructed an extensive set of tRNA suppressors that can be used to insert a wide range of amino acids at amber mutations (18). These tRNAs may allow systematic tests of the effects of various amino acids on protein structure and function. Proteins engineered to contain amino acids with fluorescent or especially reactive side chains would be of great use in studies of protein structure and function and for biotechnological applications. Recently, it has been demonstrated that certain nonsense suppressors can be aminoacylated with novel amino acids, and that modified tRNAs can direct the incorporation into proteins that have specific nonsense mutations within their coding sequences (19). Currently, only a few novel amino acids may be used in this way. But, hopefully, a large variety of specific labels will become available.

Nonsynonymous Substitution

Nonsynonymous substitution is an **evolutionary** term meaning the fixation in a population or subpopulation of a missense mutation, ie, a mutation that changes a **codon** into another codon that specifies a different amino acid. Nonsynonymous substitutions can be conservative, ie not greatly alter the function of the altered protein (see Conservative Substitutions). Nonsynonymous substitutions that are not conservative may indicate an adaptive change in the altered protein. This can only be confirmed, however, by demonstrating that the substitution changes the function of the protein.

Notch Signaling

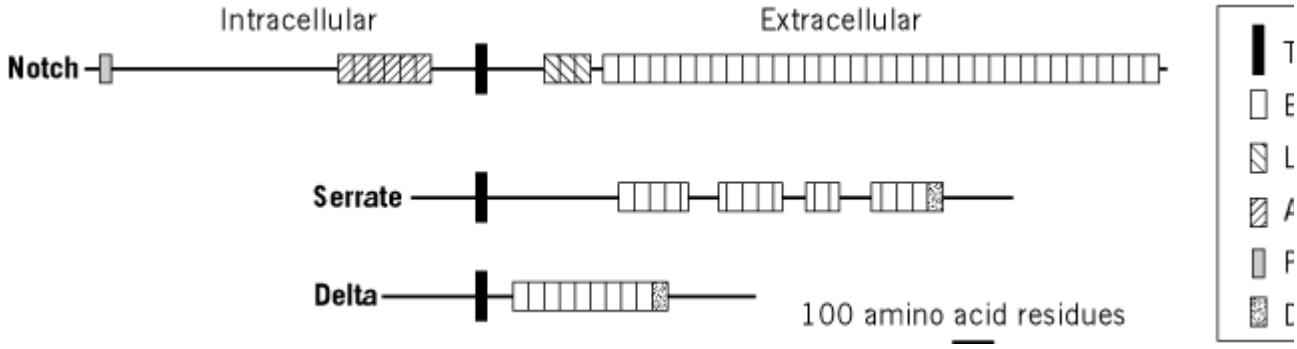
How a single cell, the fertilized egg, transforms into a complex multicellular organism is one of the most fascinating questions in biology (see Development). Two processes that are critical in this transformation are the generation of distinct cell types and the patterning of these cells into functional tissues and organs. Molecular genetic experiments in the fruit fly *Drosophila melanogaster* and the nematode worm *Caenorhabditis elegans* first revealed that similar transmembrane receptors (called the Notch receptor in *Drosophila*) play critical roles in numerous cell–cell interactions that are involved in the establishment and patterning of a wide array of cell types. Remarkably, **homologous** Notch receptors in echinoderms, amphibians, fish, birds, and mammals have subsequently been found to mediate a similar broad range of cellular interactions. This suggests that the Notch receptor is a fundamental intercellular signaling molecule used in the patterning and generation of different cell types in all metazoans. Work from a number of organisms has demonstrated that the Notch receptor is a central component of a conserved intercellular signaling pathway that has at least three additional core members. These are the transmembrane ligands Delta and Serrate and the transcription factor CSL. Consistent with the diverse interactions that the Notch pathway mediates during development, the regulation of the receptor and ligands varies a great deal in different developmental contexts. One of the most intriguing questions about the Notch signaling pathway is how this single pathway regulates the generation of such a broad range of cell types. Gaining insight into this aspect of Notch signaling has been challenging, but answers to this question promise to shed light on the fundamental question of how cells are patterned and how they assume different fates during development.

1. Components of the Notch Signaling Pathway

Notch homologous proteins are large membrane proteins that span the membrane once. In the

extracellular domain, all Notch proteins contain multiple, tandemly arranged EGF motifs and three Notch/Lin-12 repeats. In the intracellular domain, Notch proteins contain six ankyrin repeats, a motif involved in direct protein–protein interactions, as well as a **PEST sequence** that may regulate the stability of the protein (Fig. 1). Only a single Notch protein is encoded in the *Drosophila* and sea urchin **genomes** (1). In *C. elegans*, there are two Notch-like proteins, called GLP-1 and LIN-12. In vertebrates, four Notch homologous proteins have been identified.

Figure 1. Schematic diagram of the primary structures of *Drosophila* Notch receptor and its ligands, Delta and Serrate.



Delta and Serrate, the two identified ligands for Notch, are also single-spanning transmembrane proteins. Much as Notch does, all ligands for Notch contain multiple EGF-like repeats in the extracellular domain, as well as a unique **cysteine**-rich motif called the DSL domain (Fig. 1). In *Drosophila*, there appears to be only one Delta and one Serrate protein although multiple homologues of each have been identified in vertebrates (eg, 2). In *C. elegans*, there are two identified ligands, LAG-2 and APX-1, which are smaller than, but similar in structure to, Delta and Serrate. Remarkably, of the 36 EGF-like repeats in *Drosophila* Notch, only two (repeats 11 and 12) are necessary for binding to either Serrate or Delta. This has raised the possibility that additional ligands may exist that bind to the other EGF-like repeats in the extracellular domain; to date, however, no other ligands have been identified.

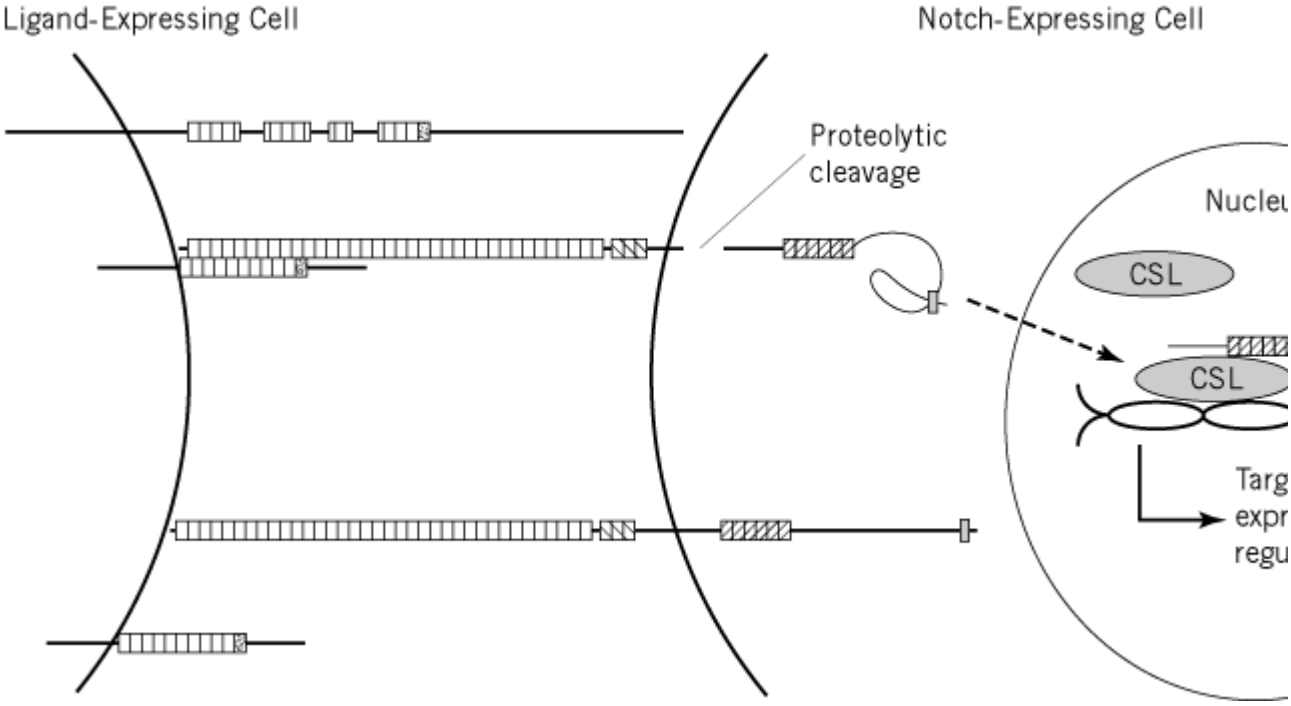
An additional shared component in the Notch pathway has been demonstrated by studies in *Drosophila*, *C. elegans*, and vertebrates. These are the homologous CSL proteins, which encode nuclear DNA-binding proteins (3, 4). CSL proteins appear to act both as repressors and activators of transcription, providing a link for the Notch pathway to alterations in gene expression (5-7).

2. Activation of the Notch Receptor

Interestingly, almost all identified Notch proteins contain nuclear localization signals in their intracellular domain (see **Nuclear import /export**). In addition, the intracellular domains of most Notch proteins, when expressed alone in cells and untethered to the membrane, enter the nucleus and cause **phenotypes** in cells similar to the one caused by overactivation of the Notch pathway. Furthermore, the intracellular domains of some Notch proteins bind physically to CSL proteins and activate transcription of target genes. These findings have led to the proposal that the interaction of Notch with its ligands results in the proteolytic release and translocation of the intracellular domain into the nucleus (Fig. 2 and Ref. 8). The amount of intracellular domain that enters the nucleus to signal *in vivo*, however, appears to be extremely low and requires very sensitive assays to detect (9, 10). One common transcriptional target in both vertebrates and *Drosophila* for the Notch-CSL protein complex is the *Enhancer of Split* complex (7, 11). This complex encodes seven proteins related to basic helix-loop-helix proteins, as well as a protein that shares homology with G**TP-binding proteins**. Another target of Notch signaling in *Drosophila* is the *vestigial* gene, which is

activated by Notch signaling at the dorsal-ventral boundary in the wing to stimulate cell proliferation. Other targets of Notch-mediated signaling are likely to exist but have yet to be identified (eg, 12). Intriguingly, during some cell–cell interactions, Notch proteins do not require CSL proteins to signal (7, 12, 13). But how Notch proteins signal independently of CSL proteins is unknown at this time.

Figure 2. Hypothetical model for activation of the Notch signaling pathway. The Notch receptor can bind to either Delta neighboring cell. Ligand binding leads to proteolytic release of the intracellular domain of Notch from the membrane. A intracellular domain is translocated into the nucleus, where it interacts with a CSL protein. This interaction leads to a cor the transcriptional activity of target genes of the Notch pathway.



3. Pleiotropy of Notch-mediated signaling

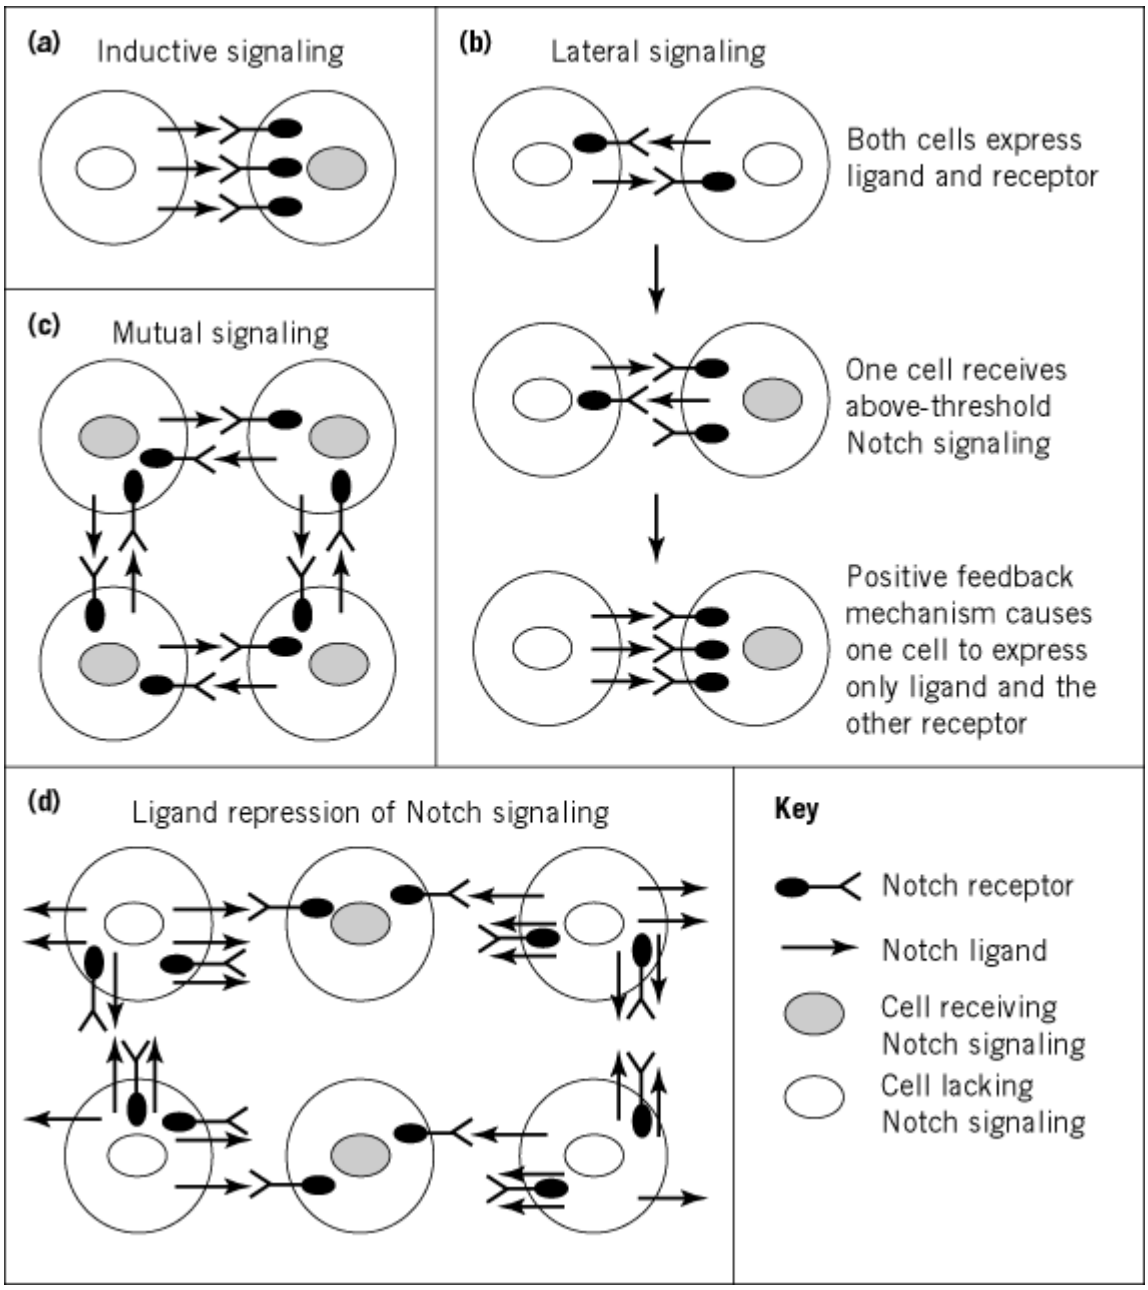
Notch was originally identified in *Drosophila* as a "neurogenic" gene involved in the segregation of neuroblasts and epidermal cells in the embryonic neuroectoderm. However, **temperature-sensitive mutants** in *Drosophila Notch* and *C. elegans Notch* homologues, specific mutations in *Notch* homologues, and expression and misexpression studies have uncovered an amazing diversity of cell-fate decision and patterning processes that Notch receptors mediate in *Drosophila, C. elegans*, and vertebrate development. For example, in *Drosophila*, Notch signaling has been implicated in the establishment of distinct cell types in the mesoderm, endoderm, Malpighian tubules, eye, and ovary. In addition, Notch signaling is crucial to the organization of the *Drosophila* dorsal-ventral wing boundary, which is a patterning process that directs wing growth and wing margin formation (eg, 14). In *C. elegans*, the two Notch-like proteins GLP-1 and LIN-12 similarly mediate numerous cell-fate decisions, and GLP-1 plays a central role in an important patterning process, the maintenance of mitotic nuclei in the distal end of the *C. elegans* ovary. In vertebrates, Notch signaling is involved in cell-fate specification during neurogenesis, hematopoiesis, and muscle cell development (3, 15-17). In addition, Notch signaling is necessary for the segmentation of somites, a critical process in patterning the segmental organization of vertebrate embryos (18, 19). Furthermore, studies of human diseases have shown that altered forms of Notch signaling can lead to T-cell lymphoblastic leukemia and to a developmental disorder called Alagille syndrome, which results in developmental abnormalities in the liver, kidney, heart, eye, vertebrae, and facial structure (reviewed in 20).

Intriguingly, particular mutations in the human Notch receptor, *Notch3*, have also been implicated in the adult onset disease CADASIL, which causes vascular alterations and leads to repeated strokes and dementia (21). The late onset of this disease suggests that Notch signaling may play an unknown function in differentiated cells of adult tissues.

4. Diverse interactions between Notch and its ligands

Reflecting the numerous cell-fate and patterning processes mediated by Notch signaling, the ligands for Notch are used in diverse ways to activate and sometimes even repress the Notch receptor. In some developmental contexts, Notch and its ligands are arranged in what is known as an inductive interaction. In inductive cell–cell interactions, the signaling and receiving cells are not equivalent to one another, and one cell or tissue selectively signals to the other (Fig. 3**a**). An example of this is germ-line induction in *C. elegans*: the Notch-like protein GLP-1 is selectively expressed in the receiving germ-line tissue, and the ligand LAG-2 is restricted to the signaling distal-tip cell.

Figure 3. Diverse interactions between the Notch receptor and its ligands. (**a**) In inductive signaling, the signaling and receiving cells are not equivalent to one another at the onset of the interaction. The signaling cell expresses only the ligand, and the receiving cell expresses only the Notch receptor. In lateral signaling, (**b**) interacting cells are initially equivalent to one another, and both express ligand and receptor. A stochastic fluctuation in signaling results in one cell receiving above-threshold Notch signaling. This triggers a feedback mechanism that reinforces this signaling difference such that one cell ultimately expresses only ligand and the other only receptor. In mutual signaling, (**c**) a group of cells express ligand and receptor, and all signal one another. This type of signaling may be used to coordinate patterning processes or cell-fate decisions within groups of cells. High levels of Notch ligand can inhibit Notch signaling within the same cell in which they are expressed (**d**). The mechanism for this inhibition is not understood, but it may be mediated by direct interactions between Notch and its ligands within the same cell.



Notch and its ligands also mediate lateral signaling, where the signaling and receiving cells are initially equivalent to one another in developmental potential and signaling ability. In this type of interaction, it appears that random fluctuations in signaling activity are reinforced and strengthened through feedback mechanisms so that one cell becomes the signaler and the other cell the receiver (Fig. 3**b**). An example of this is the interaction between the anchor cell (AC) precursor and the ventral uterine (VU) precursor cell during *C. elegans* development. Both cells are initially equivalent in their ability to become either the AC or the VU cell, and both express the Notch-like receptor LIN-12 and the ligand LAG-2. Interactions between these cells result in the activation of a feedback mechanism, such that one cell ultimately expresses only the ligand LAG-2 (signaling cell, which becomes the AC) and the other cell expresses only the Notch-like receptor LIN-12 (receiving cell, which becomes the VU).

Notch and its ligands can also be expressed and activated in groups of cells. This type of interaction is known as mutual signaling (Fig. 3**c**). An example of this occurs during the early development of the *Drosophila* nervous system in the ventral neurogenic ectoderm. All cells in this region express

both Notch and the ligand Delta. Usually, only a subset of the cells delaminate from the neurogenic ectoderm and become neuroblasts; in embryos lacking either Notch or Delta, however, most cells in the neurogenic ectoderm delaminate as neuroblasts. It appears that nearly every cell in the neurogenic ectoderm has the potential to become a neuroblast but that neighboring cells interact through Notch–Delta signaling to inhibit this potential, thus restricting the number of cells that develop as neuroblasts.

In some developmental contexts, high levels of Delta or Serrate inhibit Notch signaling within the same cell in which they are expressed (Fig. 3**d**). An example of this type of interaction is found at the *Drosophila* dorsal-ventral wing boundary. High levels of Delta or Serrate within cells adjacent to the wing boundary inhibit these cells from receiving Notch signaling (22). This ensures that Notch signaling is activated only in cells at the boundary that do not express ligands for Notch. How ligands for Notch inhibit Notch signaling within the same cell is not fully understood, but evidence suggests that the inhibition could be mediated by direct interactions between the ligand and receptor within the same cell. Thus, the levels of ligand present on a cell may be a critical component in controlling whether neighboring cells can signal one another with the Notch pathway.

5. Additional regulators of the Notch pathway

Several other molecules have been identified as important regulators of the Notch pathway. A protein called Numb was first identified in *Drosophila* as playing a role in the generation of the different cell types that are required to build neuronal sensory organs located in the epidermis. Protein localization studies found that Numb is distributed asymmetrically during cell divisions in cells that construct the sensory organ. Interestingly, Numb appears to affect the generation of distinct cell types by binding to the intracellular domain of Notch, which inhibits Notch signaling. Therefore, Numb creates a signaling interaction between neighboring sister cells from a cell division very similar to inductive signaling, where one cell is the signaler and the other the receiver (see Fig. 3**a**).

Genetic studies have indicated that many interactions occur between the Notch pathway and another important cell–cell signaling pathway called the Wnt/**Wingless** pathway. During some interactions, these pathways appear to act synergistically; in others, however, they act antagonistically to one another. Interestingly, the *disheveled* gene product, a cytoplasmic protein and member of the Wnt/Wingless signaling pathway, may mediate direct antagonistic interactions between these two pathways. The Disheveled protein can bind to the intracellular domain of Notch and inhibit Notch signaling during the specification of *Drosophila* wing margin bristles.

Another protein that regulates the Notch pathway is Fringe, which is a secreted protein that appears to function in the extracellular space between cells. In *Drosophila*, Fringe can modulate interactions between Delta and Serrate and with Notch by blocking the ability of Serrate to activate Notch and potentiating the ability of Delta to activate the receptor (23, 24). Several vertebrate Fringe homologues have been identified as well, and they appear to mediate a similar function (25).

6. How does the Notch pathway control the generation of many cell types?

One of the most puzzling questions about Notch signaling is how this one pathway is involved in the formation of so many distinct cell types and patterning processes during development. Experiments in vertebrates and *Drosophila* have demonstrated that, during many Notch-mediated cell–cell interactions, Notch signaling appears to block the ability of cells to respond to differentiation signals or regulatory factors, maintaining cells in an undifferentiated state (15, 26). For example, in the *Drosophila* compound eye, inappropriate activation of Notch signaling in the presumptive R7 cell, at the time this cell is receiving the differentiation signal to become R7, inhibits this cell from differentiating as an R7 cell. Instead, after Notch signaling subsides, this cell differentiates into a cone cell, the default fate for this cell when it does not receive the R7 differentiation signal. Therefore, Notch signaling may be crucial in the establishment of many different cell types in controlling whether and when cells can respond to specific differentiation cues.

Notch signaling, however, does not always inhibit differentiation in cells. During *C. elegans* development, the Notch pathway mediates the formation of numerous cell types, yet there is currently no evidence that Notch signaling guides the generation of distinct cell types by inhibiting differentiation. Indeed, during the development of the vulva and uterus, Notch signaling appears to act as a differentiation signal in the generation of specific cells that contribute to the formation of both these tissues (27, 28). Furthermore, during *Drosophila* wing development, activation of Notch leads to the expression of growth and patterning genes (eg, 29), a finding inconsistent with the notion that Notch signaling is keeping these cells in an undifferentiated state. Therefore, although, in many cell–cell interactions, Notch signaling functions to establish distinct cell types by regulating the ability of cells to differentiate, Notch signaling does not always function in this manner. To gain a deeper understanding of how Notch signaling affects the establishment of numerous cell types and patterning process, it will be necessary to identify additional target genes regulated by Notch signaling and elucidate how these genes mediate the differentiation and patterning of distinct cell types.

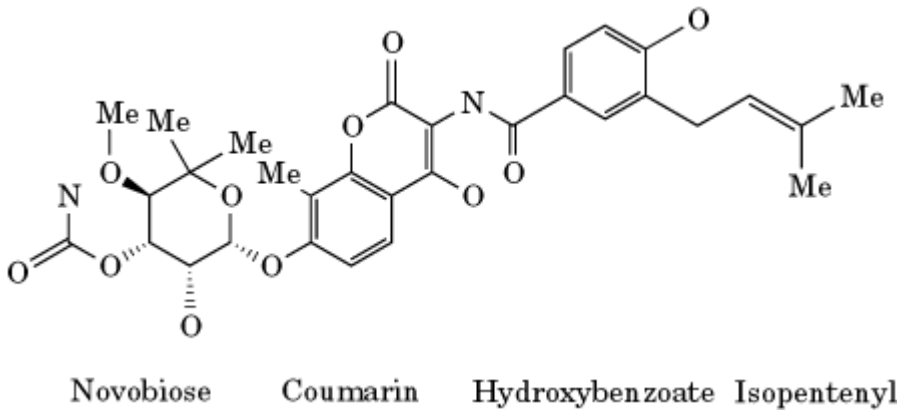
Novobiocin

Novobiocin is an antibiotic of the aminocoumarin class that was originally discovered in 1955 (1). It is produced by bacteria of the species *Streptomyces spheroides* and *Streptomyces niveus* (2). Novobiocin is composed of a noviose sugar linked to a substituted coumarin and a prenylated 4-hydroxybenzoic acid (Fig. 1). Because of its pronounced side effects, novobiocin is not the antibacterial treatment of choice in the clinic (3). Nevertheless, it has regained some interest recently due to its synergistic effect with some antitumor drugs (4, 5).

Figure 1. The chemical structure of novobiocin.



The antibacterial activity of novobiocin is based on its inhibition of bacterial type-II DNA topoisomerases (see DNA Topology). The type-II DNA topoisomerases are essential cellular enzymes that, together with the type-I DNA topoisomerases, determine DNA superhelicity and are involved in **chromosomal** condensation and segregation (6, 7). Using the energy derived from ATP hydrolysis, type-II topoisomerases introduce a double-stranded cut into a duplex DNA, pass a second

duplex through the opening, and then reseal the cut. In prokaryotes, the type-II topoisomerases DNA gyrase and DNA topoisomerase IV are both tetramers of two subunits (8). The A subunit of DNA gyrase (ParC in topoisomerase IV) harbors the DNA breakage-reunion activity, and the B subunit of DNA gyrase (ParE in topoisomerase IV) is responsible for ATP hydrolysis.

The bacterial-type II topoisomerases are the targets of several antibiotic compounds. Quinolones interact with the A subunit, coumarins (eg, novobiocin) and cyclothialidines (9) with the B subunit. Novobiocin (10, 11) and the cyclothialidines (12) block the ATPase activity of the B subunit of DNA gyrase by binding to the ATP-binding site. The detailed binding mode of novobiocin and of an ATP analog to a 24-kDa N-terminal fragment of the *Escherichia coli* DNA gyrase B protein has recently been determined by X-ray crystallography (13). The structure shows that ATP and novobiocin have partially overlapping binding sites. Therefore, novobiocin is a **competitive inhibitor** of ATP binding to the gyrase B subunit. An extensive **hydrogen-bonding** network is formed between novobiocin and the enzyme. Most of the bonds are contributed by the novobiose sugar group that forms hydrogen bonds with Asn46, Ala47, and Asp73. In addition there are several hydrogen bonds to ordered water molecules, which in turn hydrogen bond to Val43, Val71, Asp73, Gly77, and Thr165. The coumarin ring of novobiocin forms two hydrogen bonds to Arg136, and it is also involved in **hydrophobic** interactions with Arg76 and Pro79. The prenylated hydroxybenzoate moiety of novobiocin is not required for DNA gyrase inhibition (14) and shows few interactions with the enzyme. This group is important, however, for the antibacterial activity of novobiocin, possibly by influencing uptake of the compound by bacterial cells. The crystal structure of chlorobiocin, a close homologue of novobiocin, bound to the 24-kDa N-terminal fragment of the gyrase B subunit is also known (15). This information is very helpful in understanding differences in the affinity of various novobiocin derivatives, and it could be exploited in rational drug design.

The occurrence of resistance to novobiocin is a frequent phenomenon. Mutation of the gyrase B subunit gene that leads to an altered gyrase B subunit is the most widespread mechanism of novobiocin resistance. A summary of the known mutations leading to novobiocin resistance is given in Table 1. It is obvious that the conserved residue Arg136 (*E. coli* numbering) is most often involved in resistance development. This residue has also been mutated in two coumermycin A-resistant strains of *Borrelia burgdorferii* (16). The susceptibility of these strains to novobiocin has not been tested, but coumermycin-resistant strains are normally cross-resistant to novobiocin. Arg136 forms two hydrogen bonds with the coumarin ring in the crystal structure of the 24-kDa N-terminal fragment of *E.coli* gyrase B with novobiocin. Therefore, involvement of this residue in resistance development is not surprising (13). The effects of mutation of Arg136 on the structure of the 24-kDa N-terminal fragment and on the binding affinity and the binding mode of novobiocin have recently been described (17). Mutation of Arg136 decreases the ATPase and supercoiling activity of the DNA gyrase B subunit (18), but the residual activity of the enzyme is still sufficient to fulfill the essential task of DNA gyrase. Novobiocin-resistant mutants of gyrase B must still retain sufficient activity to carry out the essential role of DNA gyrase, so it is not surprising that the mutated residues are not directly involved in binding ATP but instead surround the ATP-binding site.

Table 1. Mutations in the gyrB Gene from Novobiocin-Resistant Strains

Organism	Mutation of Gyrase B[a]	Increase in MIC[b] or IC50[b]	References
Escherichia coli	R136L	>8×	27
	R136C	12×	18, 27
	R136S	13.2×	18

	R136H	11.6×	18
	G164V	>3×	18, 28
Staphylococcus aureus	G85S (G77)	32×	29
	I102S (I94)	32×	29
	S128L (V120)	8×	29
	R144I (R136)	64×	29
	I102V, T173N (T165)	32×	29
	S128L, A108S (A100)	32×	29
	R144I, I175T (V167)	250×	30
	R144I, I102S		
Streptococcus pneumoniae	S127L (V120)	128×	31
Haloferax	D82G (G81), S122T (S121), R137H (R136)	No data	32

[a] The numbers in brackets refer to the residue in *E. coli* homologous to the mutated residue in the respective species. The amino acid residues are indicated by their one-letter abbreviations.
[b] MIC: Minimal inhibitory concentration; IC_{50}: 50% inhibitory concentration.

In addition, gyrase B resistance to novobiocin can also result from an active process of efflux from the cell. Recent results have demonstrated that the baseline level of resistance of *Haemophilus influenzae* and *Pseudomonas aeruginosa* to novobiocin is caused by multidrug efflux pumps that actively extrude novobiocin (19, 20). The novobiocin-producing organism *Streptomyces sphaeroides* protects itself against the toxic effects of novobiocin by producing two gyrase B subunits, one of which is resistant to the drug (21). Two loci that confer novobiocin resistance have been identified in *Streptomyces niveus* (22). Both loci also hybridize to DNA from *S. sphaeroides* but they do not encode a gyrase because they do not hybridize to the DNA gyrase gene.

Novobiocin is widely used in basic research, to study the effects of DNA topology on **gene expression**. DNA topology is influenced by many parameters, such as osmolarity and temperature. Novobiocin is used to mimic the consequences of such parameters on DNA topology. By exposing cells to novobiocin, it was demonstrated that DNA relaxation leads to increased expression of the sigma factor that governs the **heat-shock** response and to a concomitant induction of the production of heat-shock proteins (23, 24). Similarly, it was shown that DNA **supercoiling** also regulates the expression of genes that respond to osmotic pressure (25). Furthermore, the inhibition of DNA gyrase by novobiocin leads to an increase in the expression of the genes that encode the enzyme (26).

Nuclear Envelope

The nuclear envelope separates the nucleoplasm from the **cytoplasm**. The envelope regulates (1) the import of proteins into the nucleus, (2) the export of **ribonucleoproteins** (RNP), such as those of messenger RNA and the large and small subunits of ribosomes, and (3) the timing of DNA replication. The nuclear envelope consists of two lipid bilayers, the inner and outer nuclear membranes, which together separate the nuclear compartment from the cytoplasm. The outer membrane is continuous with the endoplasmic reticulum (ER). In fact, ribosomes are often found on the cytoplasmic surface of the nuclear envelope. The space between the outer and inner membranes is called the perinuclear space . It is continuous with the ER **lumen**. In typical cells, several thousand nuclear pore complexes perforate the envelope to mediate the **nuclear import** and export of molecules that range in size from small ions to large macromolecular complexes. The inner and outer nuclear membranes fuse to form the pore membrane, a separate membrane domain of the envelope that circumvents the lateral sides of the nuclear pores complex. Just beneath the inner nuclear membrane and in contact with it is the nuclear lamina, a meshwork of **intermediate filament**-type proteins. The lamina in vertebrate somatic cells consists of **lamins** A, B, and C. The lamina provides support and shape to the envelope and is considered a component of the nuclear matrix. Metabolically active cells increase their envelope surface area with folds or blebs that extend into the cytoplasm (eg, the multiple blebs within the **oocyte** nuclear envelope of Xenopus).

Nuclear pore complexes mediate bidirectional transport between the nucleus and the cytoplasm. They were first described by Callan and Tomlin in electron microscopic examination of amphibian oocyte nuclei (1). Their three-dimensional architecture and arrangement within the envelope were determined by Hinshaw et al. (2). An individual pore complex has a combined mass of approximately 124 megadaltons and consists of four ultrastructural elements: (1) two eight-membered spoke-ring assemblies on the cytoplasmic and nuclear sides; individual pore complexes display eight-fold symmetry, and they measure about 120 nm in diameter; (2) a plug that fills the center of the spoke-ring assembly; it may function as the central transporter; (3) lateral components of the nuclear pore complex that are anchored to the envelope by protein gp210 (3, 4); in addition, aqueous channels form between the pore membrane domain and the sides of the pore complexes (2); (4) filaments that extend from the pore complex into the cytoplasm, plus a basket-like structure that extends into the nucleoplasm on the other side; these peripheral structures may function in docking incoming proteins and outgoing RNP complexes (see Nuclear Pore Complex).

The continuity between the ER membrane, the outer nuclear membrane, the pore membrane, and the inner nuclear membrane suggests that proteins integrated into the ER membrane might potentially diffuse into separate membrane domains of the nuclear envelope. The outer nuclear membrane, for example, is quite similar to the ER membrane in integral membrane composition, so newly-synthesized proteins can integrate into the ER membrane and then diffuse into the outer nuclear membrane. Yet the pore membrane and the inner membrane remain unique with respect to their integral proteins (5), and how these proteins localize there remains an intriguing problem (6). The inner membrane contains a putative lamin B **receptor** (LBR) of ~58kDa that may mediate the assembly of the lamina and anchor the lamina to the underside of the inner membrane.

The LBR is a good case study of how integral proteins could make their way to the inner nuclear membrane. The LBR is synthesized in the cytoplasm without a cleavable ER **signal sequence** . It integrates into the ER membrane using eight hydrophobic transmembrane **domains** that are positioned well downstream of the amino terminus. Upon integration, its amino terminus of 204 residues (in chickens) remains in the cytoplasm. The receptor is thought to diffuse from the ER membrane to the outer nuclear membrane, past the pore membrane, and finally into the inner

membrane. The pore membrane is thought to form lateral aqueous channels with the pore complex (2). These lateral channels permit **passive transport** of water, ions, and small molecules, of course. More importantly, however, they may be large enough to permit the passage of cytoplasmic protein domains as integral membrane proteins diffuse through the pore membrane domain on their way to the inner membrane. These cytoplasmic domains may be as large as 40 to 60 kDa. Once the receptor diffuses to the inner membrane, its amino terminus faces the nucleoplasm. Then this terminus binds lamin B, DNA, and other nuclear proteins. The amino terminus of the LBR is required for proper localization because the LBR amino terminus is sufficient to localize unrelated (nonenvelope) transmembrane fusion proteins to the inner nuclear membrane (5). The first transmembrane domain of LBR can localize independently to the inner nuclear membrane (7).

Other proteins that localize to the inner nuclear envelope include the *Drosophila* otefin protein (8), the lamina-associated proteins (LAPS), which may play a role in nuclear envelope reassembly (9), and the SREBP-1 protein, a membrane-bound, cholesterol-regulated transcription factor. Like LBR, SREBP-1 has an amino-terminal domain that binds DNA (10). Alternatively, some proteins may localize to the inner membrane by first associating with a cytoplasmic carrier protein via their signal sequence for **nuclear import**. Then the carrier protein delivers the protein to the nuclear pore complex. Other proteins might associate with the inner membrane by first binding the lamina or envelope-associated chromatin, but there are also other possibilities (6).

The nuclear envelope disassembles at **mitosis**, and **phosphorylation** of the lamin proteins by maturation promoting factor (MPF or cyclin B/p34 ^{cdc2} kinase) may be the most significant factor. Upon disassembly, the envelope membranes form two populations of **vesicles** (see *later*), the pore complexes disassemble, and the lamina matrix depolymerizes. Lamins A and C remain associated, but soluble. On the other hand, lamin B and the LBR associate with one class of nuclear membrane vesicles, another class derives from the nuclear pore membrane domain, and it retains protein gp210 (11, 12). These disassembled materials disperse into the cytoplasm to form a pool of materials reconstructing functional envelopes in the daughter cells. Reassembly of the envelope occurs at **telophase** in stages (6, 13). First the membrane vesicles containing lamin B bind to the chromosomes, most likely through ligand–receptor types of interactions. Then the vesicles fuse, which requires ATP, GTP, soluble cytoplasmic factors, and free Ca^{2+} (6). Finally, nuclear pore complexes and the lamina reassemble from pools of disassembled components. As the interphase ensues, the envelope grows by the adding of membrane from the ER and newly synthesized lamins and pore components.

The nuclear envelope may also control the timing of DNA replication (14). For example, during mitosis when the nuclear envelope normally disassembles, a cytoplasmic licensing factor is thought to gain access to the chromatin. In the next interphase, DNA replication is thought to initiate at the sites where the licensing factor has bound. More licensing factor is synthesized during the interphase, but it is excluded from the nuclear compartment by the nuclear envelope. The licensing factor that originally mediated DNA replication is degraded after the **S phase**, preventing DNA replication a second time. Upon envelope breakdown, licensing factor made in the previous interphase again gains access to the chromatin to mediate the next round of DNA replication. The replication licensing factor has been fractionated into separate components. Chief among these components are the minichromosome maintenance (MCM)/P1 proteins that bind chromatin before the S-phase and are indispensable for DNA replication. As expected for a licensing factor, the MCM/P1 proteins are present at relatively few foci in G1 and the S-phase before DNA replication, and they are excluded from replicated chromatin.

Finally, the nuclear envelope has been traditionally included as a part of the interphase nuclear matrix. In this capacity, the nuclear envelope organizes interphase chromatin to assist nuclear reassembly, regulation of **gene expression**, chromatin condensation, and meiotic chromosome pairing in oocytes.

Nuclear Import, Export

The nuclear envelope separates the nucleus from the **cytoplasm** and consists of two membrane bilayers that are perforated by nuclear pore complexes. Two-way nucleocytoplasmic transport across this barrier is crucial in **eukaryotes** for cells to function and survive. Transport includes the export of messenger RNA, the large and small subunits of ribosomes, transfer RNA, and small nuclear **ribonucleoprotein** particles (pre-snRNP) that continue to assemble in the cytoplasm before reentering the nucleus. Nuclear proteins synthesized in the cytoplasm must translocate into the nucleus through the pores. Passive diffusion of water, small ions, and small molecules (eg, **nucleotides**) must also occur. This article primarily addresses the import of nuclear proteins, but recent evidence suggests that nucleocytoplasmic import and export are two sides of the same coin (1). They are intimately related by the nuclear pore complex through which import and export must occur and also by the regulatory proteins involved in **energy transduction** (eg, Ran and its associated regulators) and the protein import factor known as importin a.

1. Mechanism

The nuclear import of small proteins (<40kDa whose diameters are no greater than 230 Å) is

generally believed to occur by diffusion through the pore complexes, and the migration rate is inversely proportional to size. The transport of histone proteins and some other small nuclear proteins may be an exception to this general rule, however, because histone H_1 (~21kDa) is believed to cross the nuclear envelope by a facilitated, receptor-mediated **active transport** type of mechanism (2).

Selective import of nuclear proteins larger than 40 kDa, however, requires a nuclear localization signal (NLS) and an energy-dependent mechanism of active transport at the pore complexes. Two types of NLS have been identified: (1) a simple basic motif and (2) a larger, bipartite signal. The best characterized simple NLS is the **SV40 virus** large T Antigen, which has the amino acid sequence -Pro-(Lys-)$_3$Arg-Lys-Val, -PKKKRKV- in one-letter code (3). When fused to cytoplasmic proteins, this simple NLS is sufficient to transport them into the nucleus (4). Bipartite NLS sequences include two short basic motifs that are separated by spacer segments of about 10 amino acid residues, as observed in nucleoplasmin (5). The NLS functions as a ligand. The rate of nuclear uptake of bovine serum albumin (BSA) covalently coupled to the SV40 NLS is saturable, thus indicating a ligand/receptor-mediated mechanism of nuclear protein targeting (6).

The mechanism of nuclear protein uptake depends on cytoplasmic factors, specifically, importins a and b (1, 7), also known as karyopherin a and b (8). Importin a binds the NLS-containing proteins directly through its NLS-binding **domain**. Importin a forms a heterodimer with importin b, which then mediates docking the complex to the nuclear pore or to fibers that extend from the pore into the cytoplasm. Docking is temperature-insensitive and energy-independent (9). The importins, however, are sensitive to **N-ethylmaleimide**, a thiol-alkylating compound that blocks the docking reaction. In docking, importin b binds nucleoporins, a family of proteins that reside at or within the pores. Nucleoporins p62/p58/p54 in rat cells, or Nup1 and Nsp1 in yeast, for example, may serve as docking sites for the complex of importin-NLS containing proteins (10). **Posttranslational modification** of the nucleoporins introduces O-linked *N*-acetyl-glucosamine residues (11) (see O-Glycosylation. The lectin wheat germ agglutinin (WGA) binds these sugar moieties and inhibits nuclear protein uptake. WGA does not inhibit by preventing the importins from binding nucleoporins, but by preventing the second step, namely, the actual translocation of the karyophilic protein through the pore complex.

Although understanding of the precise translocation mechanism is still in flux, translocation through the pore is known to be energy-dependent. Specifically, the GTP/GDP-binding Ran/TC4 protein is a critical player (see GTP-Binding Proteins). Interestingly, most of the Ran protein within a cell (80–90%) is contained within the nucleus as GTP-Ran. Its **guanine exchange factor** is the chromatin protein, RCC1 (regulator of chromatin condensation, Prp20 in yeast). The remaining Ran protein within the cell is cytoplasmic, existing as GDP-Ran. The GTPase activating protein, RanGAP1 (Rna1 in yeast), is also cytoplasmic. Although its precise function and associations remain unknown, this cytoplasmic GDP-Ran is necessary for karyophilic protein translocation through the pores (12). Besides Ran, the Ran-interacting factor, NTF2/p10, is another necessary factor which binds p62 of the pore complex to regulate GTP/GDP binding of Ran (13). In one model for nuclear import (14), GDP-Ran is needed to help tether the complex of importin a/importin b/NLS-bearing karyophilic protein to the pore complex by an interaction between importin b and the nucleoporins. After movement through the pore, this complex is in the nucleus and an environment rich in GTP-Ran. Now GTP-Ran competes with importin a for overlapping binding sites on importin b (8). As a consequence, importin a, with its bound NLS-bearing protein, dissociates from importin b. Importin b remains attached to the nuclear side of the pore and is thought to exit the nucleus quickly. Once within the nucleus, importin a releases the NLS-bearing protein, perhaps in exchange for RNP proteins, such as the 5′-cap binding complex that escorts capped **small nuclear RNAs** out of the nucleus (15). Therefore the export of RNAs may be directly linked to protein import via importin a.

Several nuclear proteins shuttle between the nucleus and the cytoplasm. These include the proteins Nopp140, NO38, and nucleolin of the nucleolus. The significance of shuttling of nucleolar proteins

has yet to be established, but one possibility is that ribosomal subunits are escorted out of the nucleus and that the ribosomal proteins are transported into the nucleus on the return trip and eventually to the nucleolus. In addition to nucleolar proteins, some of the more abundant hnRNA-associated proteins shuttle: namely, A1, A2, D, I, and K (16) (see Transcription). HnRNP protein A1 contains a nuclear export signal (NES) sequence, a 38 -residue domain near the carboxyl end of the protein sequence. It directs export of the protein (17) and also its import (18). The NES of hnRNP protein A1 and of HIV-1 Rev may function in RNA export, but those of other nuclear proteins (eg, hsc70, protein kinase inhibitor) may serve other defined nuclear shuttling activities (19).

Nuclear Matrix

The nuclear matrix is a three-dimensional fibrogranular latticework of ribonucleoprotein (**RNP**) and chromatin that permeates the nucleus of **interphase** cells. Its overall function is to organize the nuclear architecture and to regulate genetic function. The precise nature of the matrix has been

elusive, perhaps because of its multiple interactions in DNA replication, **gene transcription**, RNA splicing, and messenger RNA (mRNA) transport. Although its precise functions remain uncertain, significant progress has been made in ultrastructural and molecular analyses to provide at least strong evidence for its existence. The first mention of the nuclear matrix was made by Fawcett (1) to describe the interchromosomal material that previously had been called simply "nuclear sap." The RNP fibrogranular portion of the matrix was first defined by the **EDTA**-regressive staining technique developed in the late 60's and early 70's to distinguish **RNA**-containing nuclear structures from **DNA**-containing chromatin (2). Berezney and Coffey (3-5) were the first to isolate the nuclear matrix and then to characterize potential matrix proteins by **SDS-PAGE** analysis. The matrix has been defined operationally, and several modifications to the original technique, developed in the last twenty years, yield different matrix characteristics. Consequently, there are corresponding differences in descriptions of the matrix.

One particular method of matrix preparation, significant for retaining accurate nuclear morphology, was developed by Deppert (6) and by Penman (7). The nuclear matrix is prepared by treating whole cells grown on coverslips with **Triton** X-100, extracting the genomic chromatin with **DNase I** digestion, and then reextracting the cells with 0.2 to 0.6 M **ammonium sulfate** (8). Such *in situ* preparations, as they are called, retain the nuclear lamina, the residual nucleolus, and the fibrogranular RNP matrix. In addition, Penman and co-workers (7) perfected whole mount and resinless thick-section techniques for electron microscopy to assess the three-dimensional matrix. Another modification included using the detergent 3,5-diiodosalicylate (LIS) to extract nuclei (9, 10). Such preparations are called nuclear scaffolds, rather than matrices, because LIS extraction replaces the high salt extraction, and minimizes protein rearrangements while efficiently removing histone proteins.

The matrix is ubiquitous in eukaryotic cells ranging from yeast to human. Ultrastructurally, the matrix consists of at least the residual nuclear envelope and its **nuclear pores** and lamina, the residual nucleolus, certain regions of euchromatin that attach to the matrix, and the fibrogranular RNP matrix, which is often called interchromatin fibers and perichromatin granules. The matrix also contains 10 to 25% of the total nuclear proteins, and some tightly bound DNA and RNA remain after **nuclease** treatment and extraction (8, 11).

Using **two-dimensional gel** analyses, Fey and Penman (12) detected more than 200 potential nuclear matrix proteins. Some of these are common to all cell types. Others are specific to a particular type of cell or tissue or to particular stages of differentiation, including oncogenesis. Among the common nuclear matrix proteins are the three **intermediate filament**-like lamin proteins, A, B, and C. The nuclear mitotic apparatus protein (NuMA), of more than 200 kDa, may be an important structural component of the matrix (13-16). Like intermediate filament proteins, NuMA can form a coiled-coil structure (17, 18). Other common proteins include the **hnRNP** U protein, nuclear actin, the nucleolar protein B23, and a set of related proteins called matrins (8). Protein kinases A, B, C, and CKII have been linked to the nuclear matrix, suggesting regulatory roles for the matrix in signal transduction (8). **Topoisomerase II** and an attachment region binding protein (ARBP) are matrix proteins that associate with the chromatin (see later).

Several studies have shown that different cell types share these common proteins, but that they also contain their own unique matrix proteins (12, 19-21). The protein composition of the matrix changes upon differentiation of fetal rat calvarial osteoblasts (22-25) and when they become malignant (26-28).

In their studies on mitotic chromosomal structure, Laemmli's laboratory demonstrated, after nuclease treatment and high salt extraction (29), that mitotic chromosomes consist of residual proteinacious scaffolds and that large radial chromatin loops are anchored to these scaffolds (30). As mitotic chromosomes decondense in the early interphase, these radial loops are thought to maintain their attachment to the interphase nuclear matrix. The DNA elements that attach to the mitotic scaffold and to the interphase matrix are AT-rich sequences that easily unwind with the introduction of

negative **supercoils** (see Matrix Attachment Regions, or MARS). A special AT binding protein (SATB1) specifically binds the unwound AT-rich regions of the MARS (31), perhaps to anchor the elements to the matrix.

Several functional roles have been ascribed to the nuclear matrix. DNA replication has been linked with the matrix, because **DNA polymerase** a, primase, and other DNA replication factors have been found in prepared matrices (8). An intriguing hypothesis suggests that between 50,000 to 100,000 bidirectional DNA replication units (replicons) are affixed to the nuclear matrix in relatively few (150 to 300) clusters, called clustersomes (8). Bidirectional replication occurs as looped chromatin domains reel through the stationary replication machinery (8, 32). The clustersome model was supported by studies in which **biotin**-labeled dUTP was incorporated into newly synthesized DNA during the **S-phase** of permeabilized culture cells. Staining with streptavidin tagged with a fluorescent marker revealed distinct replicative granules whose number and size matched the values predicted for clustersomes. To demonstrate that replicons are in fact attached to the matrix, matrices were prepared *in situ* before staining with streptavidin. The staining pattern was identical to that observed in the nonextracted cells, thus indicating that the replicative factories are associated with defined matrices. Interestingly, the number and size of the stained replicative granules are again similar after DNA synthesis is carried out in matrices that retained chromatin fragments.

The nuclear matrix has also been linked to transcription (33), primarily because several transcription factors have been found associated with the nuclear matrix (34) and transcription foci have been immunolocalized to **HeLa** cell nuclear matrices (35). Analogous to the stationary DNA replicative factories described in the preceding paragraph, stationary transcription factories have also been proposed (35).

Splicing of heterogeneous nuclear RNA (hnRNA) has been intimately linked to the nuclear matrix. Interchromatin fibers and perichromatin granules constitute the bulk of the matrix of the interphase nucleus, and it was found by immunolocalization that they contain many of the splicing factors, such as **small nuclear RNAs** (snRNA) with trimethyl caps, snRNPs, and the SR family of proteins (36) (see RNA Splicing). Over 70% of the hnRNA is retained in matrices prepared in the presence of **ribonuclease inhibitors** (11). Many of the hnRNP proteins originally identified by Dreyfuss et al. (37) (eg, proteins A2, B1, C1/C2) constitute the matrix (38). The hnRNP U protein is abundant in prepared nuclear matrices, and in addition to its role in processing nascent heterogeneous nuclear RNA, it preferentially binds DNA MAR elements. For this reason, the hnRNP U protein has been called the scaffold attachment factor (SAF-A) (38).

Finally, the matrix may play a role in the actual transport of transcripts from their site of synthesis on the gene to the nuclear pore complex (another component of the matrix), where they are transported out of the nucleus and into the **cytoplasm**. **Exons** and **introns** of specific transcripts have been detected on curvilinear tracks within the nucleus (39, 40) and in prepared matrices (41). In all likelihood these curvilinear tracks consist of the interchromatin fibrils observed in thin-section electron micrographs.

Nuclear Overhauser Effect (NOE)

Regardless of the complexity of the experimental design that produced them, the intensities of signals in a nuclear magnetic resonance (NMR) spectrum depend on the populations of molecules in the various allowed nuclear spin energy states immediately before the analyzing RF pulse is applied. In the simplest case, these populations are the Boltzmann populations, characteristic of the system at thermal equilibrium. Under such conditions, the relative intensities of signals from various chemically different groups of molecule spins are proportional to the relative number of spins of each type. But in a variety of circumstances, including an experimental design more complex than a single RF pulse, the number of molecules in some or all of the permitted nuclear energy states may differ from those present at thermal equilibrium. In this event, the intensity of a signal observed in the spectrum will be changed. The change in signal intensity is called a nuclear Overhauser effect, or NOE. There are several ways of expressing the NOE quantitatively. Most commonly used (1) is the equation

$$f_I\{S\} = I_p/I_0 - 1 \qquad (1)$$

where $f_I\{S\}$ indicates the NOE on the signal(s) from spin I when there is a perturbation of level populations associated with spin S. I_0 is the normal intensity of the signal(s) for spin I observed from a sample at thermal equilibrium before the analyzing RF pulse, and I_p is the intensity of the same signal when there has been a perturbation of spin S before the analyzing pulse. The value of $f_I\{S\}$ depends on the gyromagnetic ratios of spins I and S, how these spins move in the sample, the strength of the magnetic field used for the NMR experiment, and the details of how the energy level populations associated with spin S are perturbed during the course of an experiment. Importantly, $f_I\{S\}$ depends on the distance between spins I and S. Values of $f_I\{S\}$ ranging from 0.5 to –1.0 are possible when both I and S are protons. The first value corresponds to a 50% enhancement of the intensity associated with spin I, and the latter represents the disappearance of the signal intensity for this spin.

A change in NMR signal intensity can arise in molecular situations where two or more spins interact strongly with each other, such that perturbation of the level populations of one of the spins by RF pulses or by some other way ultimately results in the perturbation of the level populations corresponding to the other spin. It should be apparent that the NOE is strongly related to relaxation, those natural processes in any sample that tend to return the populations of the spin energy levels to their Boltzmann (thermal) equilibrium values if these level populations have been altered in some way. (See NMR (Nuclear Magnetic Resonance).) Consequently, the formation and disappearance of a NOE will be time-dependent.

The power of experiments that produce NOEs lies in that the bulk of the interactions that lead to relaxation are strongly dependent on the distance between interacting spins. Thus, observation of NOEs can provide internuclear distance data that ultimately can be used to deduce information about the three-dimensional structures of biopolymers. The distance dependence of the NOE is strong. In the case of ^{1}H- ^{1}H interactions, NOEs are typically observed only when the distance between the spins is 0.22–0.55 nm, with the effect observed at 0.55 nm being less than 1% of that when the internuclear distance is 0.22 nm.

When molecules move slowly in the sample, an additional phenomenon complicates the NOE experiment. “Slow motion” conditions in this context arise when molecules have masses in excess of about 5 kDa or when solutions are highly viscous. The complication is called spin diffusion; it occurs because the magnetization transfers or level population alterations mentioned above become rapid between all protons. Under these conditions, magnetization that originates with one spin of the molecule may be transferred not only to a nearby proton but also to more distant protons. Thus, distance information that is implicit in the NOE may be obscured.

It is also possible to create NOEs because of interactions between various coherences that can be formed as a result of the application of RF pulses to the sample. These experiments, called rotating-frame NOEs, or ROEs, exhibit a different dependence on the details of molecular motions than the NOEs described above. The NOE and ROE experimental results are thus complementary. The formation of the ROE is also time-dependent and must compete with the decay of spin coherence by transverse relaxation. (See also NOESY Spectrum, ROESY Spectrum, Distance Geometry, Simulated Annealing.)

Nuclear Pore Complex

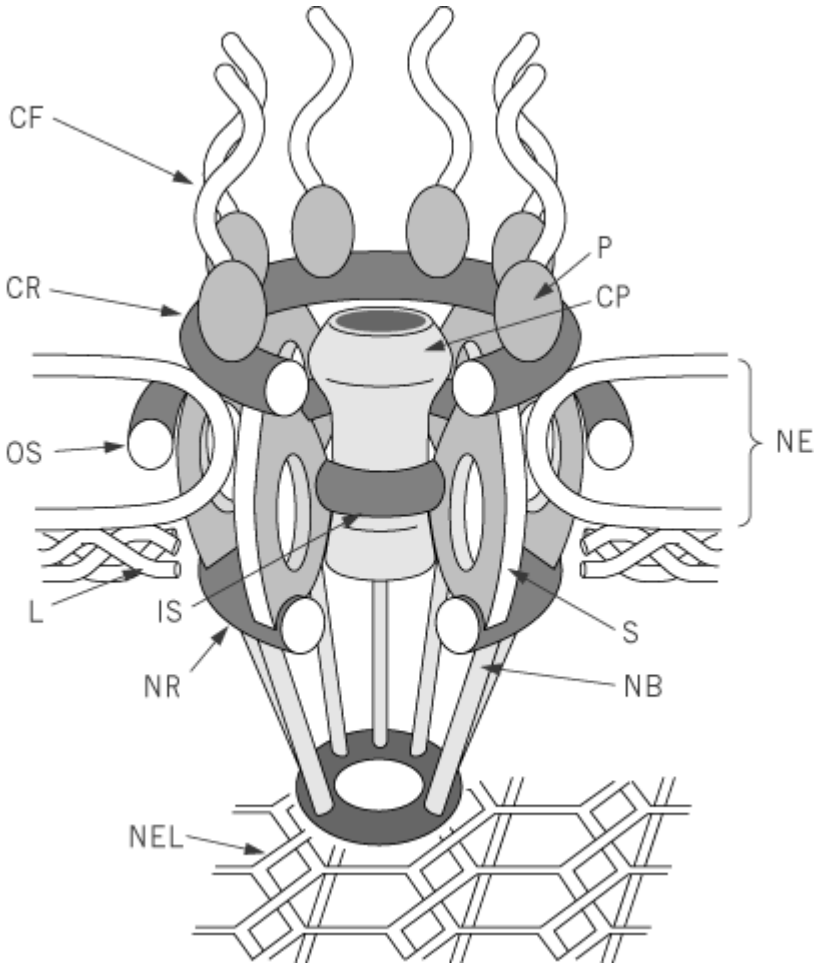
The nuclear pore complex is the **organelle** within the nuclear envelope that mediates the export of messenger RNA, transfer RNA, and the subunits of ribosomes, which are synthesized or assembled in the nucleus but function in the **cytoplasm**. The pore complex also mediates the **nuclear import** of

proteins and protein complexes (eg, snRNP particles) that are synthesized and assembled in the **cytoplasm** but destined to function in the nucleus. The number of nuclear pore complexes varies considerably, depending on the cell type. Their number generally reflects the biosynthetic activity of the cells. For example, the nuclear envelope of the ***Xenopus oocyte*** has the highest known concentration of pores per unit area of nuclear envelope (60 pores mm^{-2}), whereas quiescent chick **erythrocytes** have two to four pores mm^{-2}.

1. Pore Structure

Nuclear pore complexes were first described by Callan and Tomlin (1) in their electron microscopic analysis of the nuclear envelope in amphibian oocytes. Architecturally, the nuclear pore is a huge (124 megadaltons), beautifully elaborate, symmetrical organelle within the nuclear envelope (Fig. 1). The entire complex can be graphically divided into four main component types: (*1*) eight-membered ring complexes, (*2*) the central plug, (*3*) cytoplasmic filaments, and (*4*) a filamentous nuclear basket (cage). There are two similar eight-membered ring complexes per pore, which associate through apparently **homotropic** interactions to create twofold symmetry of the complex within the plane of the envelope and are designated as the nucleoplasmic and cytoplasmic rings. The ring complexes are anchored to the nuclear envelope where the inner and outer membranes fuse together. Each ring consists of eight spoke-ring subunits of 10 to 25 nm arranged in eightfold symmetry when viewed from the surface of the envelope (3). Each spoke-ring segment consists of subcomponents that contribute to the formation of the overall complex. Some contribute to formation of the rings, and columnar and lumenal portions of each spoke-ring segment help anchor the ring complexes within the nuclear envelope. A spoke protrudes from each columnar subcomponent to help form the central annulus. Spokes from the cytoplasmic ring interact with spokes from the nucleoplasmic ring. The central annulus forms an hourglass-shaped channel of 42 nm at the peripheries and between 9 and 10 nm at the narrowest point. This channel transports macromolecular complexes as large as 23 nm (see later). Eight aqueous channels form on the periphery of the complex between the columnar subcomponents and the nuclear envelope. These aqueous channels permit passive diffusion of ions and small molecules across the envelope. Extending into the cytoplasm from the cytoplasmic ring are eight long, cylindrical filaments that may serve as docking sites for proteins that must enter the nucleus. Extending into the nucleoplasm from the nucleoplasmic ring are eight filaments that join together at their ends by yet another component to form a distal annulus within the nucleoplasm. This annulus may contact the nuclear matrix to play a role in the export of nuclear products.

Figure 1. A schematic model of the vertebrate nuclear pore complex. The cytoplasmic face is shown uppermost, and certain facing portions have been omitted for clarity. Structures are drawn approximately to scale with the pore transversing the membrane of ~90 nm thickness. The diameter of the outer spoke ring (OS) is ~120 nm. Filamentous structures (CF and NB) extend from both the cytoplasmic and nuclear faces, with the former attached to particles (P) and the latter forming a basketlike structure. The overall architecture is octagonal: based on eight equally spaced spokes (S) that are sandwiched between two rings (CR and NR). The spokes are attached to an inner spoke ring (IS) that encompasses a central plug (CP). The buttresses connecting the CP with the IS are omitted. The spokes appear to transverse the pore membrane for connection to an outer ring (OS) in the nuclear envelope (NE) lumen. Well defined lamina (L) and nuclear envelope lattice (NEL) structures also seem to have connections to the nuclear pore complex. (Figure from Rout and Wente, ref. 2, 1994. Reprinted with permission).



At least 100 different proteins (nucleoporins) are thought to constitute the nuclear pore complex, and approximately forty have been identified. They can be subdivided into pore membrane proteins (poms) and phenylalanine/glycine-rich (FG) proteins. Poms are integral nuclear membrane proteins closely associated with the pore complex, such as the 16 to 24 copies of protein gp210 that reside around the periphery of the pore complex. They anchor the pore complex within the envelope, and the bulk of the gp210 resides within the lumen of the envelope. Other poms include the yeast Pom152p and the mammalian pom121. FG proteins found in yeast, such as *NUP1*, *NUP2*, and *NSP1*, are so-called because of their repeated -X-Phe-X-Phe-Gly- (or -XFXFG-) sequences. A related -Gly-Leu-Phe-Gly- (or -GLFG-) repeated sequence is also found in yeast proteins *NUP100*, *NUP116*, *NUP49*, and *NUP145* . The functions of the repeated motifs remain unknown. Deleting them does not perturb the cell's viability nor localization of the protein to the complex. Several metazoan nucleoporins also have been identified. Some of these have been localized to the spoke-rings that face the cytoplasm and their extending filaments (nup214/CAN, p180, and p75), some to the central plug or spoke-ring structures (p62, p58, p54), and at least one to the nuclear basket (nup153). Interestingly, outside of the FG-repeat domains, no extensive homologies have been found between yeast and metazoan nucleoporins. Metazoan FG nucleoporins are modified **posttranslationally** by addition of *N*-acetylglucosamine through O-glycosylation of serine and threonine residues. The function of this glycosylation also remains unknown, but it makes it possible to probe specifically for nucleoporins and to block transport using the wheat germ agglutinin (WGA), a lectin that specifically binds O-linked *N*-acetylglucosamine.

2. Pore Function

The pore complex transports macromolecules into and out of the nucleus and permits diffusion of

small molecules across the nuclear envelope (see Nuclear Import, Export). Briefly, proteins that are destined for the nucleus translocate across the envelope by a **facilitated diffusion** mechanism, as in the case of small proteins such as histones (4), or an **active transport**, ATP-driven mechanism, as in the case of proteins larger than approximately 40 kDa. Large proteins usually have a short nuclear localization signal (NLS) within their linear amino acid sequence. Two types of signals are known. One is a simple basic sequence, rich in lysine residues, typified by the NLS found in the **SV40 virus** large T Antigen(namely, -Pro-Pro-Lys-Lys-Lys-Arg-Lys-Val-). Fusion proteins that consist of a normal cytoplasmic protein linked to this NLS translocate into the nucleus. Another characterized NLS is a bipartite sequence in which two short segments of basic residues are separated by approximately ten amino acid residues (5).

Transport of nuclear proteins harboring NLS sequences occurs in two steps (6). The first step is an energy-independent docking that occurs initially with the cytoplasmic filaments extending from the envelope pore complex and then with the central annulus. Cytoplasmic factors, known as importins a and b (7, 8), bind NLS sequences of proteins destined to function in the nucleus and deliver them to the filaments. Association occurs between the importins and the FG nucleoporins described previously. The docking protein may be nup214 of the filaments. Docking can be blocked by WGA, which specifically binds the O-linked *N*-acetylglucosamine residues on nucleoporins that constitute either the filaments (ie, nup214) or the central annulus of the pore complex. The second step is translocation of the docked proteins, which requires GTP hydrolysis (9-11). Translocation requires Ran/TC4, a Ras-like GTPase, and its specific guanine nucleotide exchange factor, called RCC1. The precise mechanism of the active transport remains uncertain, however, and other factors may be required, such as the recently described nuclear factor II (NTFII), which transiently associates with the pore complex protein p62 and Ran/TC4 (12). ATP hydrolysis is necessary for nuclear protein uptake, but again, the actual reason remains uncertain.

The nuclear pore complex is also required for nuclear export of messenger RNA (mRNA), transfer RNA (tRNA), ribosomal subunits, and prespliceosomal complexes that mature in the cytoplasm before reentering the nucleus (13, 14). The export mechanisms of these gene products are still largely unknown. Although export of mRNA must include docking, unwinding, and then translocation, it is known that the mRNA leaves the nucleus bound to protein. The nuclear cage must be intimately involved in the export process (15). Blobel's “gene gating” hypothesis (16) suggests that nuclear pores and the nuclear lamina influence (by specific binding of chromatin) the three-dimensional gene organization within the nucleus, so that transcribed genes are positioned for efficient transport of their RNA products through the pores. Tracks of **polyA**-containing mRNA have been detected in nuclei between the sites of RNA synthesis and the nuclear pores, lending support to the gating hypothesis. These tracks may be the perichromatin fibrils, which contain several **RNA splicing** components (17). Despite these uncertainties, pre-mRNA does not interact with the pore complex until all the splicing reactions are complete. HnRNP proteins (eg, A1, A2, and B1) may play a positive role in this export because a non-RNA-binding domain has been identified in their linear amino acid sequence as a nuclear export signal (NES) (14). When fused to unrelated proteins, the NES in A1 (called M9) confer bidirectional import and export (shuttling) of the fusion protein (18, 19). Other nuclear proteins contain export signals that are unrelated to the M9 sequence. For example, the activation domain of the HIV Rev protein is leucine-rich and is a strong NES that mediates the export of Rev with its bound, *un*spliced HIV RNA (14). The NES in Rev is similar to the NES in transcription factor IIIA (TFIIIA), which binds and exports 5S rRNA (20).

The nuclear pore complex disassembles into individual components during **mitosis**. Pore disassembly is concomitant with mitotic disassembly of the nuclear lamina and the vesiculation of the envelope membranes. Pore reassembly begins in **telophase** and is initiated by nucleoporins and poms aggregating within the plane of the re-forming envelope. Pore assembly itself is probably incremental, and individual components arrive at the site of reassembly from a stored mitotic pool. Fusion of the inner and outer membranes occurs at the site of pore assembly. Later in the cell cycle during the **S-phase**, pore complexes are added as the nuclear envelope grows in size. Again addition may be incremental as in telophase. Alternatively, cytoplasmic annulate lamellae, which consist of

membrane and pore-like structures, may contribute additional membrane and pores to the growing nuclear envelope.

Nucleoids

Nucleoids are prepared cell **nuclei** used to discern the structure and function of the nucleus. They have been used to characterize nuclear chromatin, nascent **RNA**, nuclear proteins, and nuclear structures, such as the nuclear matrix, lamina, and nuclear pore complex. Originally, the term

"nucleoid" was used to describe the nuclear body within **bacteria** that contains the centrally located chromosomes. These bacterial nucleoids were isolated from **spheroplasts** using solutions containing 0.1 to 2.0 *M* salt and a chelating agent (1, 2). Subsequently, the term has come to include nucleoids from **eukaryotes** prepared similarly. Eukaryotic nucleoids have been isolated by gently lysing cells with 0.4 to 2.0 *M* NaCl, the chelating agent EDTA (133 m*M*), and the nonionic detergent **Triton** X-100 (0.67%, *v/v*). Cell lysis gently occurs over a 15-min period, and the nucleoids are enriched by **sucrose gradient centrifugation** (3). A "nucleoid cage" is formed by remnants of the cytoskeleton. The plasma membrane and cytoplasmic **organelles** are absent, but within the nucleoid cage is the nuclear cage. This inner nuclear cage consists of the nuclear envelope and the entire genome, although the histone proteins may be lost, depending on the salt concentrations used during lysis. Although intact, approximately 55% of the genome spills out of the nuclear material to form a shroud of intact chromatin loops that surrounds the nucleoid cage. The nuclear cage of the nucleoid contains residual **nucleoli**, nuclear particles, and fibrous aggregates that may be related to the chromosome scaffold described by Paulson and Laemmli (4).

When nucleoids are treated with low concentrations of ethidium bromide (5 µg/mL), negative **supercoils** within the genomic DNA relax, and the DNA diffuses from the nucleoid to form a fluorescent halo around the nucleoid periphery. When the ethidium concentration is increased to 100 mg/mL, however, the halo of DNA is resorbed back into the nucleoid (5), because of the introduction of positive supercoils (6). If the DNA is nicked before adding excess ethidium bromide, it fails to retract back into the nucleoid, presumably because it is impossible to introduce positive supercoils. The observation that chromatin spools out and then back again as the DNA is positively supercoiled by ethidium bromide indicates that chromatin exists as closed looped domains. These early observations also suggested the presence of a nuclear matrix to which certain regions of the chromatin are anchored. Nucleoids were further used to demonstrate specific complexes within the nuclear matrix that are responsible for DNA replication and **RNA transcription** .

Experimental observations using nucleoids have received criticism in that artifactual associations between DNA or RNA with nuclear structures may arise due to the high salt conditions used in lysis. Jackson (7) provides arguments that such artifacts may be minimal: (1) the chromatin loops retain their size and the positions of genes on the loops remain constant; (2) preparation of nucleoids does not severely affect the apparent specificity of nascent RNA association with the nuclear matrix (8); (3) DNA, RNA, or ribonucleoprotein particles added before or after nucleoid purification in the presence of 2 *M* NaCl fail to associate with the nuclear cage (8); (4) no gross redistribution of DNA and RNA occurs during nucleoid preparation. Regardless of criticisms, nucleoids provided initial sources for studying nuclear matrices that many now accept as the structural support for nascent DNA replication, RNA transcription, pre-**mRNA splicing**, and RNA transport (9) (see Nuclear Matrix).

Nucleolar Organizer

Nucleolar organizers are secondary constrictions within the mitotic chromosomes of **eukaryotes**. The primary constriction occurs at the centromere. The nucleolar organizer genetic locus contains tandemly repeated **genes** that encode the 42 S to 47 S precursor of ribosomal RNA (pre-rRNA) (see Nucleolus, Ribosomes). As the name implies, the nucleolar organizer gives rise to the nucleolus in the **telophase** of **mitosis**. During the late telophase, **RNA polymerase I** begins to transcribe rRNA genes once again, and the newly synthesized rRNA likely nucleates the assembly of the nucleolus by recruiting prenucleolar bodies to the transcription site.

Transcription of the 45 S rRNA genes is one of the primary events for nucleolar assembly. This was beautifully demonstrated by Karpen *et al.* (1), who inserted rRNA genes (ie, nucleolar organizers) within ectopic sites in ***Drosophila*** chromosomes by **P-element**-mediated integration. As a result, nucleoli were observed at ectopic sites of the polytene chromosomes. This work indicated that transcription of the ribosomal genes is necessary to initiate nucleolar assembly on the chromosome, but perhaps not sufficient. At least some of the nucleolar constituents used in the preceding interphase are retained in the cytoplasm during mitosis. In the late telophase, these constituents preassemble into extrachromosomal particles before or concomitant with the initiation of ribosomal gene transcription. These preassembled nucleolar particles, or prenucleolar bodies as they are called, contain at least the small nucleolar RNA, snoRNA U3, and the nucleolar proteins fibrillarin, nucleolin (C23), and NO38 (or B23) (2), all of which play a role in pre-rRNA processing. Although formation of the prenucleolar bodies is independent of transcription, fusion of the prenucleolar bodies to the organizer regions depends on rRNA transcription (3). Once the particles fuse with the nucleolar organizers, the resulting nucleoli grow in the early interphase because of increased rates of rRNA synthesis and the influx of other components necessary for ribosomal production (eg, ribosomal proteins). See Nucleolus for a more complete description of nucleolar structure and function.

Historically, Heitz (4) concluded that the number of secondary constrictions within certain chromosomes of *Drosophila funebris* is proportional to the number of nucleoli. He called these regions “sine acid thymonucleinico” (SAT, without DNA). It is now known that the mitotic nucleolar organizer regions retain a significant proportion of nucleolar-specific proteins relative to rDNA, as the chromosomes condense in prometaphase. These proteins include the **RNA polymerase I** complex, DNA **topoisomerase I**, and the transcription factors UBF and the SL1 complex (5). Together, these various proteins form a set that makes it possible to stain selectively for nucleolar organizers.

McClintock (6) actually coined the term “nucleolar organizer” to describe the satellite segment at the tip of **maize** chromosome 6 (the “nucleolar chromosome”) that organizes the assembly of the nucleolus beginning in the telophase. If the terminal satellite element of chromosome 6 is broken into two equal portions by X-rays, her studies demonstrated that each portion gives rise to a nucleolus of normal size. McClintock's observation suggests that not all ribosomal genes within the normal nucleolus may be active. Subsequent work with *Drosophila* (7, 8) and *Xenopus* (9)

established that the tandemly repeated ribosomal genes reside at these nucleolar organizer regions. Nucleolar organizers occur on one or as many as six chromosomes, depending on the organism (10). Nucleolar gene clusters have been found on **autosomes** in some organisms and on sex chromosomes in others (eg, the X- and Y-chromosomes of *Drosophila*). Interestingly, ribosomal gene clusters are often found near **telomeres** on the shorter arm of the chromosomes that normally carry the nucleolar organizers. One possibility for this close association between the telomere and the nucleolar organizer is to reduce the adverse phenotypic affects of **unequal crossing over** between repeated rRNA genes on nonhomologous chromosomes (11, 12). Nucleolar organizers are found in humans on chromosomes 13, 14, 15, 21, and 22. All are **acrocentric** chromosomes.

Nucleolus

The primary function of the nucleolus is to biosynthesize ribosomes, both the large and small subunits. The nucleolus is the most conspicuous **organelle** within the nucleus. Because of its prominence, light microscopists have studied the nucleolus for more than 200 years. Fontana described the nucleolus as early as 1774, and there was a review of its literature in 1898 by Montgomery. Although much has been learned, the nucleolus is still imperfectly understood.

1. Overview

Assembly of large and small ribosomal subunits requires 18S, 5.8S, 28S, and 5S ribosomal **RNA** molecules (rRNA) and approximately 85 structural ribosomal proteins. The 18S, 5.8S, and 28S rRNA, but not 5S, are transcribed within the nucleolus by **RNA polymerase I** as parts of a large precursor transcript, pre-rRNA (47S in mammalian cells, 42S in Xenopus, and 35S in **yeast**) (see Ribosomes). RNA spacer sequences reside in front of the 18S region, between the 18S and 5.8S

regions, and between the 5.8S and 28S regions. The pre-rRNA is processed within the nucleolus by several endonuclease-catalyzed cleavages to yield mature 18S, 5.8S, and 28S rRNA. Although still imperfectly understood, these cleavage reactions require several nucleolar-specific proteins and small nucleolar RNAs (see later). Processing of the 45 S pre-rRNA occurs concomitantly with ribosomal subunit assembly. The 5 S rRNA is transcribed by RNA polymerase III from multiple copies of a **gene** that resides outside the nucleolus. After biosynthesis, the 5S RNA must migrate through the nucleoplasm to the nucleolus. Most of the ribosomal proteins translocate into the nucleus from their site of synthesis in the cytoplasm. Then they associate with the maturing rRNA in the nucleolus during assembly of the ribosomal subunits. The small ribosomal subunit consists of 18S rRNA and small subunit-specific ribosomal proteins (S-proteins), and the large ribosomal subunit consists of 5.8S and 28S rRNA, the incoming 5S rRNA, and large subunit-specific ribosomal proteins (L proteins) (1). Small and large subunits move from the nucleoli to the nuclear envelope through a nuclear pore complex and into the cytoplasm. The subunits unite to form intact ribosomes once they associate with messenger RNA to participate in synthesizing new protein (see Translation).

The number of nucleoli per nucleus varies, depending on the cell type. Yeast cells, for example, contain one nucleolus that is relatively large compared with the volume of the nucleus, and most metazoan cells contain one or a few nucleoli. On the other hand, amphibian oocytes contain hundreds of nucleoli per nucleus because of selective rDNA amplification during the early pachytene stage of meiosis I (2). The number of nucleoli also varies during the cell cycle. For example, nucleoli disassemble at the onset of **mitosis**, and they reappear beginning in the **telophase** by a process called nucleologenesis. In the late telophase/early **interphase**, a new cell displays several small nucleoli. The number reflects the number of nucleolar organizers that are characteristic of the species. As the new cells mature through the interphase, their nucleoli fuse to form larger nucleoli, and the number of nucleoli actually declines.

1.1. Nucleolar Ultrastructure

The interphase nucleolus consist of three ultrastructural subdivisions: the fibrillar center (FC), the surrounding dense fibrillar regions (DFR), and the peripheral granular regions (GR) (1, 3). The DFR are darker than the FC when stained with uranyl acetate and viewed by electron microscopy. As the name implies, the GR consist of small granules believed to be the still immature ribosomal subunits (see later). The overall nucleolar morphology varies in different cell types because of differences in the relative sizes and distributions of these three subdivisions (3). For example, nucleoli within metabolically active cells contain DFR that are cast into nucleolonemae, which appear in the electron microscope as darkly-stained, anastomosing thread-like structures. Each thread is surrounded by lightly staining material. Conversely, nucleoli in a few cell types constitute a second morphological class and appear compact, with uniform RNA-containing structures. The third classification includes ring-shaped nucleoli in which RNA-containing structures form a peripheral ring around **chromatin**-like fibrils (3). Nucleolar morphology is influenced by the particular physiology of a given cell type. For example, the multiple nucleoli within transcriptionally active **oocytes** from *Xenopus* (stage IV) show pronounced nucleolonemae, but greatly reduced GR, perhaps because of rapid ribosomal subunit biosynthesis and export from the nucleus. Conversely, nucleoli in mature and relatively quiescent stage VI oocytes display collapsed DFR (eg, no anastomosing nucleolonemae) and very prominent GR (4).

The FCs clearly contain the DNA encoding the rRNA, and they may well be the interphase homologue of mitotic nucleolar organizers, the genetic loci that contain tandemly repeated ribosomal genes (see later). The precise function of the FC is controversial. RNA polymerase I (5, 6) and **topoisomerase I** (7) have been detected in the FC, thus suggesting a potential for transcription. Using selective ***in situ*** **hybridization** and **immunolabeling** techniques to detect both rDNA and rRNA within the FC, Thiry (8, 9) argued that transcription must occur within these centers. Hozák *et al.* (10), however, proposed an alternative model in which active transcription units radiate from condensed DNA within the FC. In this latter model, the transcription units occupy the borders between the FC and the DFR. Regardless of the precise site of transcription, the dense fibrillar

regions are the sites for early pre-rRNA processing and initial ribosomal subunit assembly. This assembly is a vectoral process, and maturation of the large and small ribosomal subunits continues on into the GR. Certain ribosomal proteins associate early in the DFR, and others associate in the GR. Finally, ribosomal subunits pass out of the nucleus into the cytoplasm, where final assembly with a few more ribosomal proteins takes place before they are competent to function in mRNA translation (1).

1.2. Ribosomal RNA Gene Organization and Expression

Genes that encode the large 45S pre-rRNA are tandemly repeated head-to-tail within genomes of most, if not all, **eukaryotic** organisms. Intergenic spacer (IGS) DNA sequences separate the individual genes. There are approximately 200 copies of ribosomal genes per haploid genome in humans, 100 in mouse, 500 to 600 in *Xenopus laevis*, 150 in ***Drosophila*** *melanogaster*, and 140 in the budding **yeast** *Saccharomyces cerevisiae* (1). Heitz (11, 12) and McClintock (13) demonstrated that the secondary constrictions in mitotic chromosomes are the genetic loci that initiate nucleolar formation as cells leave mitosis and enter the interphase. McClintock actually coined the term "nucleolar organizer" to describe these secondary constrictions. Now we know that the tandemly repeated pre-rRNA genes reside at these loci and that transcription of these genes initiates formation of nucleoli during the late telophase (see Nucleolar Organizer). Mutations that map to the nucleolar organizers reduce the number of rRNA genes or eliminate nucleoli altogether. For example, the bobbed (*bb*) mutation on the X-chromosomein *Drosophila* is a partial deletion of the tandem rDNA repeats. Flies homozygous or hemizygous for the mutation display pleiotropic effects of slow development, reduced fertility, and shortened (bobbed) bristles. In *Xenopus*, the anucleate mutation O_{nu} fails to synthesize rRNA because it lacks ribosomal RNA genes. Finally, McClintock (13) described a chromosomal deletion in **maize** that eliminates the nucleolar organizer and also the ability to form nucleoli.

One of the most informative techniques for elucidating nucleolar gene ultrastructure is the spreading of nucleolar chromatin in solutions with low salt and high pH for electron microscopic examination (14-16). These so-called "Miller spreads" show that nucleolar chromatin consists of nascent rRNP fibrils (rRNA associated with protein) which project from the tandemly repeated ribosomal genes. RNA polymerase I complexes pack the active ribosomal RNA genes, and the RNP fibrils remain attached to these complexes during preparation. As a result, the RNP fibrils display a gradient in length. The shortest fibrils are closest to the transcription initiation site, and the longest fibrils approach transcription termination. The gradient of RNP fibrils looks like a "Christmas tree" where the RNA polymerase I-coated gene is the tree trunk that supports the RNP branches. Interestingly, the 5′-end of each RNP fibril contains a relatively large RNP particle (see later for function). These particles have been called the "ornaments" on the Christmas trees.

The organization of a typical rRNA gene in higher eukaryotes is as follows beginning at the transcription start site: the 5′-external transcribed spacer (5′-ETS) region; the 18S rRNA region; the first internal transcribed spacer (ITS1); the 5.8S rRNA region; the second internal transcribed region (ITS2); the 28S rRNA region; and finally a short 3′-external transcribed spacer (3′-ETS). The *Xenopus* rDNA gene is described here because it is well characterized. The nascent transcript encoded by the *Xenopus* genes is 7,625 nucleotides long and has a **sedimentation coefficient** of 40S. Individual genes are separated by intergenic spacers (IGS) of variable length. For the vast majority of rRNA genes in *Xenopus*, transcription initiates at the **promoter** just upstream of the ETS and stops within the IGS at a site 235 bp downstream of the 28S region at the site called T2, yielding a 40S pre-rRNA transcript. The T1 site is at the very end of the 28S region, and it arises from initial posttranscriptional trimming of the 3′-ETS back to this site (17). The intergenic spacers in *Xenopus* contain several duplicated promoters and enhancers (18). Occasionally, transcription initiates at a distant upstream IGS promoter, reads through the other downstream promoters and enhancers (thus silencing these promoters), and then terminates at T3, a site approximately 60 bp upstream of the next rDNA proximal gene promoter (eg, 215 bp upstream of the transcription start site of the next gene). This secondary transcription unit is fully contained within the IGS. IGS transcription may

positively enhance transcription of this next gene by terminating at T3 and then handing the polymerase complex over to the adjacent downstream promoter (19, 20). Although the actual site of transcription termination has been debated, electron microscopic examination verifies that the vast majority of rDNA transcription units terminate transcription at the T2 site, at least in *Xenopus* (21).

Despite length differences in regions that encode either the mature rRNA themselves or the transcribed spacers, the overall genetic organization is similar in other eukaryotes (1). Many species of *Tetrahymena*, however, contain an **intron** within the 28S region. This is a group I intron originally characterized as self-splicing (22; see **Catalytic RNA**). Many of the *Drosophila* rRNA genes also contain one of two types of introns in the 28 S region. One type (a transposable element) appears only in 50% of the X-chromosome ribosomal genes. The other type appears in the ribosomal genes of both the X- and Y-chromosomes but at a frequency of 15%. Yeast has the same overall ribosomal gene structure as the higher eukaryotic cells, except that the primary transcript is shorter than in vertebrates (35S versus 40 to 45S). Yeast produces a 25S mature ribosomal RNA instead of a 28S transcript. Finally, the intergenic sequences in *S. cerevisiae* and *discoideum* contain 5S genes that are transcribed by RNA polymerase III but in the direction opposite to that of the main rDNA repeats.

Besides RNA polymerase I, several transcription factors (TF) are required for efficient rDNA expression (19). The upstream binding factor (UBF, a protein of 97 kDa in humans) contains a triple a-helical **domain** characteristic of the **HMG proteins** in chromatin. On its own, UBF binds promiscuously to both rDNA enhancers and promoters. UBF forms a stable complex with another factor, called SL1 in humans and rats, which then selectively binds the rDNA promoter. Transcription is initiated when an active RNA polymerase I complex recognizes the UBF-SL1 complex situated on the proximal promoter. Another transcription initiation factor, called TIF-IC in mouse cells, regulates the ability of polymerase I to recognize the UBF/SL1 complex. Topoisomerase I is relatively abundant within nucleoli. Its primary function is thought to aid RNA polymerase I transcription by relieving torsional stress generated within the DNA by the process of transcription. Low concentrations of actinomycin D (0.05 to 25 μg/ml) selectively inhibit RNA polymerase I transcription and strip the nascent RNP fibrils from the transcription units. This has been used to study nucleolar transcription, structure, and function (23).

Multiple copy, tandemly repeated genes encode the 5 S ribosomal RNA that assemble within the large ribosomal subunit. As mentioned above, the 5 S genes in *Saccharomyces, Dictyostelium*, and a few other organisms are closely linked to the rRNA genes within the same repeating units. The 5S genes in most other organisms are located on other chromosomes without a nucleolar organizer. In addition, the clusters of 5S genes are scattered between several loci in many organisms (1). The number of 5S genes within an organism usually exceeds the number of 45S rRNA genes. *Xenopus*, for example, has over 20,000 5S genes per haploid genome. The 5S genes are transcribed by RNA polymerase III and are regulated by transcription factors IIIA, IIIB, and IIIC. TFIIIA binds an intergenic control region of the 5S genes to direct the binding of TFIIIC. The 5S genes are small, 120 bp in total length. Therefore, the bound TFIIIA/C complex directs TFIIIB to bind just upstream of the transcription start site. RNA polymerase III finally associates with TFIIIB to initiate transcription. Interestingly, TFIIIB consists of three proteins, one of which is the **TATA binding protein** found in RNA polymerase II transcription initiation complexes. The 5S transcripts follow a rather circuitous route to the nucleoli. Monomeric ribosomal protein L5 binds 5S rRNA in the nucleus, and together they migrate out to the cytoplasm. They reenter the nucleus and then associate with the nucleolus, where they join in ribosomal assembly (24).

1.3. Nonribosomal Nucleolar Proteins

Besides RNA polymerase I, UBF, SL1, and topoisomerase I, which regulate 45 S rRNA gene transcription, many other nonribosomal nucleolar proteins are involved with pre-rRNA processing (25).

1.3.1. Fibrillarin

To date vertebrate fibrillarin (Nop1 in *S. cerevisiae*) is the best characterized in terms of function. Vertebrate fibrillarin has a molecular mass of 34 kDa. It localizes mostly to the DFR, either to discrete foci within the DFR or to rings that surround the FC. This sublocalization suggests functional compartmentalization of fibrillarin within the DFR. Fibrillarin is conserved throughout eukaryotes. The amino-terminal portion contains a glycine/arginine-rich domain (called a GAR or RGG domain). Nearly half of these arginine residues are dimethylated, a **posttranslational modification** reserved for many nuclear RNA-binding proteins that contain RGG domains (26). Fibrillarin also contains a consensus RNA-binding domain (CS-RBD) in its center (27). Fibrillarin closely associates with many small nucleolar RNA (snoRNA) involved in either cleavage or base modification of the pre-rRNA. The best characterized fibrillarin association is with snoRNA U3 to form the RNP complex necessary for the first cleavage event within the ETS region of the pre-rRNA (see later).

1.3.2. Nucleolin

Vertebrate nucleolin is a phosphoprotein of molecular mass 90–110 kDa that is abundant in rapidly dividing somatic cells (28, 29) and in developing amphibian oocytes (30), where rates of ribosomal production are maximal. Although nucleolin shuttles between nucleoli and the cytoplasm (31), the greatest **steady state** concentration of the protein remains within the nucleolar DFR. Lesser amounts are found in the GR, and very little if any nucleolin resides in the FC. Vertebrate nucleolin consists of modular **domains** (32). The amino-terminal third contains alternating acidic domains (containing glutamic acid, aspartic acid, and phosphorylated serine residues exclusively) and basic domains (containing lysine residues). The serines within the acidic regions are phosphorylated by casein kinase type II enzymes during the interphase (see **Phosphorylation**). The basic domains, on the other hand, contain mitotic $p34^{cdc2}$/cyclin B (MPF, maturation promoting factor) phosphorylation sites whose sequence is -Thr-Pro-(Ala or Gly)-Lys-Lys- (ie, -TP $^{A}/_{G}$KK-). Differential phosphorylation within the amino-terminal domain of nucleolin may regulate nucleolar assembly and function during interphase and also nucleolar disassembly during mitosis. The carboxyl-terminal two-thirds contains four consensus RNA-binding domains (CS-RBD), each about 80 amino acid residues long. The fourth CS-RBD is followed by a GAR (or RGG) domain of about 100 residues very near the carboxyl terminus. As in several other nuclear RNA-binding proteins (see previous discussion), the arginine residues within this GAR domain are dimethylated. Despite intense investigations of nucleolin, its precise nucleolar associations and functions remain uncertain. Nucleolin has been called a ribosome assembly factor (29). By sucrose gradient centrifugation, Herrera and Olson (33) showed that nucleolin associates with nascent rRNA, and it is believed that nucleolin binds nascent pre-rRNA *in vivo*. Recent experiments (34) showed that nucleolin decorates the RNP fibrils of Miller-spread CHO nucleolar chromatin, and it was shown by SELEX amplification that nucleolin preferentially binds a stem-loop structure consisting of a 4- to 5-bp stem and an eight-nucleotide loop containing a specific UCCCGA sequence motif. Interestingly, the six-nucleotide motif recovered by SELEX is also present in pre-rRNA, presumably at sites of nucleolin interaction (34). Binding to the motif is thought to be by one or more of nucleolin's CS-RBDs. Nucleolin's GAR domain may also function in RNA binding. It binds single-stranded DNA and RNA *in vitro*, and it displays RNA **helicase** (unwinding) activity.

Homologues of vertebrate nucleolin have been found in yeast. NSR1 in *S. cerevisiae* is an abbreviated version of the vertebrate protein. It also contains alternating acidic and basic domains at its amino terminus, but only two CS-RBD, followed by a GAR domain very near the carboxyl terminus. Gar2+ is the nucleolin homologue in *S. pombe* . Although the function of vertebrate nucleolin remains obscure, genetic **knockout** of these yeast homologues (35-37) disrupts processing of 18 S rRNA, causes a relative decrease in the abundance of 40 S small ribosomal subunits, and slows cell growth. These latter findings indicate that NSR1 and gar2+ have at least an associative role in pre-rRNA processing.

1.3.3. Nopp140, SRP40

Rat Nopp140 (SRP40 in yeast) is another nucleolar-specific phosphoprotein that contains alternating

acidic and basic domains (38). Its acidic domains are extremely rich in serine residues that are also phosphorylated by casein kinase II. Its basic regions are similar to those of nucleolin, and it has substantial numbers of alanine, valine, lysine, and proline residues. Several potential MPF sites that have the amino acid sequence - $^{T}/_{S}$PKK- are apparent in these basic domains. Similar to nucleolin, the highest steady-state concentrations of Nopp140 reside within the DFR, and to a lesser extent within the GR (39). One of Nopp140's distinguishing characteristics, however, is its ability to shuttle from nucleoli to the cytoplasm along nuclear tracks that begin within the DFR (39). Nopp140 was first identified as a nuclear localization signal (NLS)-binding protein (40). The supposition is that Nopp140 acts as a nucleolar **chaperone** by shuttling NLS-containing proteins into the nucleolus. Nopp140 specifically binds wild-type NLS sequences (not mutated versions) but only when the acidic regions are fully phosphorylated. The dephosphorylated version of Nopp140 does not bind wild-type NLS.

1.3.4. NO38, B23, Nucleophosmin, and Numatrin

Similar to nucleolin, vertebrate NO38 (M_r of 38,000; also called B23, nucleophosmin, and numatrin) is a putative ribosomal assembly factor (29) and a nucleolar shuttling protein (31). Early reports showed that NO38 is enriched in the GR, but now it appears that NO38 localizes to both the DFR and GR (41). The function of NO38 also remains poorly understood. NO38 preferably binds single-stranded versus double-stranded nucleic acids. It binds RNA just as readily as it binds DNA. It binds nucleic acids cooperatively, and it destabilizes RNA helices (42). Interestingly, two **isoforms** of NO38 exist in rat (called B23.1 and B23.2), the isoforms result from alternative splicing of mRNA transcribed from one gene copy, and the B23.1 protein contains an additional 5-kDa tail at its carboxyl terminus that is not present in B23.2 (43). B23.1 is the predominant form that binds nucleic acids, and it resides within nucleoli. Conversely, B23.2 binds nucleic acids only weakly, and it resides within both the cytoplasm and the nucleoplasm but not within nucleoli. The functional significance of the two isoforms remains unknown but intriguing. Also like nucleolin, NO38 contains -Thr-Pro-Ala-Lys- (-TPAK-) sequences that are phosphorylated by MPF (44), thus suggesting that mitosis-specific phosphorylation of NO38 may help disassemble nucleoli (see later).

1.3.5. Other proteins

Several other nucleolar proteins have been identified, mostly in yeast (45). The yeast Ssb1 protein contains an RNA-binding CS-RBD, and a GAR domain, followed by an acidic region. It copurifies with snR10 and snR11 small nucleolar RNA, but its role in pre-rRNA processing remains unknown. Gar1 in *S. cerevisiae* is closely associated with 18 S rRNA processing and, as its name implies, also contains a glycine/arginine-rich domain. Nop2p in *S. cerevisiae* (46) is very similar to vertebrate p120, which is closely associated with cell proliferation (47). Nop3p is another GAR-containing nucleolar protein in *S. cerevisiae*. When it is genetically depleted, yeast cells show abnormal processing of pre-rRNA, when the 27SB intermediate (precursor of the 25S mature rRNA) and the 23S intermediate (precursor of the 18S mature rRNA) both accumulate. This results in a drop in producing both small and large ribosomal subunits and in slow growth (48). Nop4p in *S. cerevisiae* is required for formation of the 60 S large ribosomal subunit (49). Nop77p is a yeast nucleolar protein that mediates interactions between Nop1 (fibrillarin) and pre-rRNA (50). Sof1p is yet another protein associated with Nop1 and U3 in 18 S rRNA processing. Several nucleolar RNA-dependent helicases in yeast (Spb4p, Drs1p, Dbp3p, and CA9) are necessary for 40S and 60S ribosomal subunit assembly (49). Pop1 and Snm1 associate with the 7-2/MRP RNA in 5.8S processing (see later). The interplay in processing between all of these proteins with the pre-rRNA and with the small nucleolar RNA (see later) remains imperfectly understood.

1.4. Small Nucleolar RNA and Pre-rRNA Processing

The nascent pre-rRNA transcript (47S in mammals) is processed by a series of exo- and endonucleolytic cleavage reactions to yield intermediates of discrete size before the formation of mature 18 S, 5.8 S, and 28 S ribosomal RNA (51). The transcript is modified posttranscriptionally by methylation of bases at conserved sites and by the conversion of specific **uridine** residues to pseudo-uridine. The assembly with in-coming ribosomal proteins to form the ribosomal subunits is

concurrent with cleavage and base modification. Several small nucleolar RNAs (snoRNA) have been identified that play either direct or associative roles in the processing reactions (45, 52). SnoRNAs in turn interact with nonribosomal nucleolar proteins (many described above) to form RNP complexes that engage in cleavage or base modification.

Initial cleavage of the mammalian 47S pre-rRNA at the 3′-T1 site yields the abundant 45S intermediate. The best characterized cleavage event, however, occurs within the 5′-ETS region of the primary transcript (53-55). U3 (56) and fibrillarin associate closely within the RNP complex known as “terminal balls” (54) that is positioned on the 5′-ETS (57). This terminal complex makes the first site-specific endonucleolytic cleavage in the processing of the 18S RNA (58). Miller spreads of nucleolar transcription units clearly show a relatively large RNP complex situated at the 5′-end of even the shortest fibrils. This RNP complex assembles on the 5′-ETS sequence specifically in the vicinity of cleavage sites at nucleotide 412 in human, 649 in mouse, or 782 in rat (57). Besides its association with the 5′-ETS cleavage, U3 is also associated with ITS1 and ITS2 cleavage reactions. Processing of 18S is inhibited by depletion of U3 (59), U14 and snR10 in yeast (60, 61), or of U14 and U22 in *Xenopus*. The 7-2/MRP snoRNA in yeast, with its associated Pop1 protein, plays a role in cleavage within ITS1 to liberate the yeast 5.8S rRNA. The U8 snoRNA in *Xenopus* mediates cleavage events within ITS2 and the 3′-ETS for proper excision of the 5.8S and 28S regions (62, 63).

SnoRNAs display conserved sequence elements that determine their conserved three-dimensional structures (45). For instance, the highly characterized U3 snoRNA contains conserved motifs designated boxes A, B, C, C', and D. Boxes A, B, and C are unique to U3. Boxes A and B interact with rRNA, and box C associates with fibrillarin. Boxes C' and D of U3 are common to many other snoRNAs that constitute a class called C/D snoRNA (box C' of U3 is simply called C in these other snoRNAs). This box C (C' in U3) is a conserved motif of six nucleotides that is six nucleotides downstream of the 5′-end of the snoRNA. Box D, on the other hand, is a conserved motif of four nucleotides that is just upstream of the 3′-end of the snoRNA. The 5′- and 3′-ends of the snoRNA form a short terminal **double helix**. Complementarity does not extend into boxes C and D, so they remain single-stranded and positioned next to the terminal helix. In the case of U14, boxes C and D are necessary for proper intron processing, stability, and accumulation (64). Interestingly, the majority of C/D snoRNAs are thought to associate with fibrillarin, again via box C.

More than fifty snoRNAs have been identified (65). Whereas snoRNA U3, U8, and U13 are encoded by their own independent genes, many of these other snoRNAs are encoded as introns of several different pre-mRNA molecules. For example, mouse U14 was the first snoRNA identified as part of an intron within the gene encoding the 70-kDa cognate **heat shock** protein hsc70 (66). Interestingly, many snoRNAs are transcribed as introns of pre-mRNA that encode proteins necessary for ribosomal assembly or factors necessary for protein translation (45). For example, snoRNA U17 in *Xenopus* is repeated in each of six introns of the pre-mRNA that encodes ribosomal protein S8 (67), and snoRNA U24 in humans and chickens is contained within an intron of the ribosomal protein L7 pre-mRNA. Both U20 and U23 in humans, mice, rats, hamsters, frogs, and fish are contained within introns of the nucleolin pre-mRNA. Expression of intronic snoRNA within these various pre-mRNA suggests a potential mechanism to coordinate synthesis of pre-rRNA processing components, ribosome structural proteins, and even translation factors. The intron processing mechanism that removes the snoRNA from the intron remains obscure. In the case of U14, the snoRNA region of the intron forms a loop whose ends are held together by a short double-helical stem of about seven base pairs. This helix actually spans what will be the final 5′-and 3′-ends of the snoRNA. An endonucleolytic cut within the stem is necessary to liberate the snoRNA from the rest of the intron. Characteristic of the intronic snoRNA, the cut is staggered, leaving a 3′-overhang of one base.

Although snoRNA U3, U8, U14, and U22 associate with fibrillarin in various pre-rRNA cleavage events, the processing roles for many of these other C/D snoRNAs have only recently been described (65, 68), and these results provide exciting discoveries about posttranscriptional methylation of the pre-rRNA. Just upstream of the D box in a particular snoRNA is a single-stranded region that is

complementary to a specific pre-rRNA segment, either within the 18S, 5.8S, or 28S regions, but not to any of the spacer regions. The D box, together with an upstream helix formed between the snoRNA and the complementary segment of the pre-rRNA, directs the methylation specifically of the fifth nucleotide upstream of the D box. Methylation occurs on the **ribose** ring as 2′-O-methylation. Approximately 105 conserved methylation sites are known within the rRNA. Therefore, the majority of the C/D snoRNAs are guide RNAs, perhaps in association with fibrillarin, for site-specific methylation of the mature ribosomal RNA. Methylation creates **hydrophobic** sites within the rRNA that may direct proper RNA folding, processing, and subsequent interaction with incoming ribosomal proteins as ribosomal subunits assemble.

1.5. Nucleolar Cycle

The cycle of nucleolar assembly and disassembly is intimately linked to the cell cycle. The nucleolus disassembles during the prometaphase of mitosis and begins to reassemble during the telophase. The onset of mitosis is controlled by tight regulation of MPF, or cyclin B/p34^{cdc2} kinase. Once activated, MPF phosphorylates many different cellular substrates. At least two nucleolar proteins, nucleolin and NO38, are direct substrates for MPF (44). The phosphorylation sites in hamster nucleolin are the threonine residues within nine -TP $^{A}/_{G}$KK- motifs found within the basic domains of the amino terminus. At least one other nucleolar protein of known sequence, Nopp140, displays potential MPF phosphorylation sites. The current supposition is that MPF-specific phosphorylation of key structural proteins within the nucleolus contributes to nucleolar disassembly.

Another prominent factor in nucleolar disassembly may be the shutdown of rDNA transcription. Interphase nucleoli partially disassemble when actinomycin D blocks rDNA transcription (23). Transcription of the pre-rRNA genes normally begins to decline in the **prophase**. This decline may result from tight compaction of rDNA into the nucleolar organizer regions of the mitotic chromosomes. **Immunofluorescence** studies of mitotic cells show that at least fibrillarin and nucleolin, two proteins involved with pre-rRNA processing and packaging, diffuse into the cytoplasm (the nuclear envelope has disassembled by this time) upon nucleolar disassembly. SnoRNA U8 also diffuses to the cytoplasm (69). The lack of pre-rRNA transcripts may contribute to the diffusion of RNA processing components. Interestingly, RNA polymerase I and the transcription factors UBF and SL1 all remain bound to the nucleolar organizer regions of the chromosomes (70).

Nucleolar reassembly (nucleologenesis) begins during the telophase with the appearance of prenucleolar bodies. These particles contain fibrillarin, NO38, nucleolin, Nopp140, and the snoRNA U3, but no rRNA. All are factors closely associated with the processing of pre-rRNA. As rDNA transcription by polymerase I resumes in the telophase, these prenucleolar bodies coalesce with the nucleolar organizers to reconstitute intact nucleoli by the interphase. By the early interphase, there may be several functional nucleoli, which may fuse to form fewer but larger nucleoli. Interestingly, the prenucleolar bodies share morphological and compositional similarities with coiled bodies (71), originally described in 1903 as accessory bodies of nucleoli in nerve cells (72). Coiled bodies contain fibrillarin, ribosomal protein S6, DNA topoisomerase I, and snoRNA U3, but no rRNA. In addition, coiled bodies contain the specific p80 coilin protein and snRNPs normally involved with pre-mRNA splicing. The precise relationship between prenucleolar bodies and coiled bodies remains imperfectly understood.

Nucleoplasm

The terms nucleoplasm and karyoplasm have been used interchangeably for more than one hundred years. According to E. B. Wilson (1), karyoplasm (nucleoplasm) is "¼ the nuclear substance in contradistinction to the cytoplasmic." Today we know that the nucleoplasm includes the nucleolus, euchromatin and heterochromatin, a myriad of ribonucleoprotein particles such as **spliceosomes**, interchromatin granules and fibers, coiled bodies, and the nuclear matrix, which has often been referred to as the "ground substance." These nuclear contents are separated from the cytoplasm by the nuclear envelope. For detailed descriptions of these components, see Nucleus.

Nucleoplasmin

Nucleoplasmin is an acidic, thermostable protein found in the **nuclei** of amphibian **eggs** that binds histones H2A and H2B and transfers them to DNA to form nucleosome cores *in vitro* (1-7), suggesting that nucleoplasmin is required for nucleosome assembly inside eggs. However, nucleoplasmin is not a component of the nucleosome, nor does it possess steric information required for nucleosome assembly; this information resides in the histones. These unusual properties of nucleoplasmin led to the term **molecular chaperone** (6), a usage subsequently extended to a much wider range of proteins involved transiently in assembly processes (8). Subsequent work has revealed a related function of nucleoplasmin in decondensing sperm chromatin on fertilization of the egg, resulting in the replacement of the protamine proteins of sperm chromatin by the histone proteins of the zygote (5, 9-11), in the reactivation of genes in somatic nuclei incubated in egg extracts (12), and in the binding of transcription factors to nucleosome cores (13).

Cell-free extracts of Xenopus *laevis* eggs convert added purified DNA to a regularly repeating chain of nucleosomes, using either the endogenous pool of histones or exogenous sources of purified histones. In contrast, separated DNA and histones form insoluble aggregates when incubated together directly at physiological ionic strength (0.1–0.2 *M* NaCl). It is the nucleoplasmin present in the cell-free extracts that prevents the formation of these aggregates, by binding transiently to histones via electrostatic interactions before the histones are transferred to DNA (6). In support of this view is the observation that complexes of histones H2A and H2B with nucleoplasmin occur in soluble extracts of *Xenopus* eggs and **oocyte** nuclei, and that the histones of these complexes can be transferred to DNA *in vitro* (13, 14). Homologues of nucleoplasmin have been detected in somatic cells (15, 16) but the specificity of some of the immunological methods used have been questioned

(5), and their possible role in nucleosome assembly in such cells is not established. Nucleosome assembly in adult somatic cells is linked to DNA replication, unlike the case for *Xenopus* eggs, and involves the action of other protein assembly factors (see Nucleosome). Nucleoplasmin appears to be specialized to function as a store of maternally synthesized histones for chromatin assembly during early embryogenesis.

The detailed mechanism of nucleoplasmin action is unknown, but it does not appear to require the hydrolysis of ATP, unlike the action of some other molecular chaperones such as the **chaperonins**. An important aspect is the reduction of the high positive charge density on the histone surface by the binding of the negatively charged nucleoplasmin (17). In effect, nucleoplasmin acts as an "electrostatic filter" that reduces the high positive charge density of histones and thus inhibits the tendency for unspecific aggregates to form between histones and DNA. This transient inhibitory role of nucleoplasmin allows the self-assembly properties of the histones with DNA to predominate over the incorrect interactions generated by their high densities of opposite charge. The same property is amplified to regulate the disassembly of DNA complexes with other basic proteins; massive hyperphosphorylation of nucleoplasmin during oocyte maturation allows the decondensation of the tight protamine-DNA complexes in sperm chromatin (5, 10).

Nucleoprotein

Nucleoprotein is a complex of **DNA** and protein. In the eukaryotic nucleus, DNA is organized by the histone proteins into the nucleoprotein complex known as chromatin. The recognition that

nucleoprotein structures represent the functional form of genes has taken many decades to develop. Toward the end of the nineteenth century, numerous investigators formulated the theory that chromosomes determine inherited characteristics. These studies were almost entirely based on cytological observations with the light microscope. Although chromosomes are clearly only in the nucleus, the influence of components of the cytoplasm on inherited characteristics was examined by forcing embryonic nuclei into regions of the cytoplasm where they would not normally be found. These experiments and others led Morgan to propose the theory that differentiation depends on variation in the activity of genes in different cell types. The genes were clearly in the chromosomes, but their biochemical composition remained completely unknown (1).

The last quarter of the nineteenth century also saw the recognition of **RNA** (first identified as yeast **nucleic acid**) and of DNA (thymus nucleic acid) and the discovery of histones. Albrecht Kossel isolated nuclei from the erythrocytes of geese and examined the basic proteins in his preparations, which he named histones. The apparent biochemical simplicity of DNA and the obvious complexity of protein in chromosomes led investigators mistakenly to regard the latter component as the major constituent of the elusive genes. Only the gradual acceptance of experiments on the capacity of DNA alone to change the genetic characteristics of the cell led to the recognition of nucleic acid as the key structural component of a gene (2).

The elucidation of the **double-helical** structure of DNA, with its immediate implications for self-duplication, opened up the new approaches of molecular biology to clarifying the nature of genes. Although it was recognized that the double helix contains the requisite information to specify a genetic function, how this information was controlled was not understood. The apparent heterogeneity of histones due to **proteolysis** and the various **posttranslational modifications** of these proteins suggested that they might be important in regulating genes. Eventually methodological improvements for isolating and resolving the different histones demonstrated that the histones are highly conserved in eukaryotes and that only a few basic types exist. This lack of variety implied that histones themselves were unlikely to be the determinants of gene specific transcription. However, a key role for histone modification remained central to prevailing ideas of transcriptional regulation.

A major breakthrough came in the 1970s when a combination of methodologies, including **nuclease** digestion (see **DNase I sensitivity)**, protein–protein **cross-linking**, electron microscopy and sedimentation velocity centrifugation, determined that chromatin consists of a repetitive fundamental nucleoprotein complex, which came to be called the nucleosome. The integrity of the nucleosome depends on highly specific histone–histone interactions and the recognition by the histones of DNA structural features induced as the nucleosome is assembled. The core histones are present as an octamer, consisting of two molecules of H2A, H2B, H3 and H4. Histones H3 and H4 assemble a tetramer, $(H3, H4)_2$, that wraps DNA so that two dimers of H2A and H2B stably associate. Once two turns of DNA are wrapped around the octamer, a fifth linker histone, such as histone H1, is stably incorporated to complete the assembly process. Although all nucleosomes maintain these architectural features, there are many variations built on this common theme.

In a series of insightful experiments, Grunstein and colleagues determined that changes in nucleosomal packaging had pleiotropic effects on genetic activity. Subsequent work established that very specific modifications in histone structure could either activate or repress specific genes. This led directly to the resurgence of interest in understanding genetic activity in the natural chromosomal environment, which has characterized much of the research in eukaryotic transcriptional regulation over the past few years.

The new-found interest in the role of nucleoprotein complexes, such as chromatin, in transcriptional regulation has been fueled by progress in two specific areas. Structural studies led to the recognition that the histones are isomorphous with components of the **transcriptional** machinery . These observations provided an architectural foundation for examining the specific roles of histones and transcription factors in the assembly and function of regulatory nucleoprotein complexes. It was

shown that specific modifications to nucleosomal architecture through histone **acetylation** and removal of histones H2A/H2B or H1 alleviate the repressive effects of chromatin assembly . In certain instances, chromatin assembly also stimulates the transcription process. Thus the potential roles of nucleosomal proteins in gene control became more interesting. Biochemical purification of histone acetyltransferases and deacetylases provided an even closer link between chromatin and the transcriptional machinery. It was discovered that histone acetyltransferases are components of large macromolecular complexes, known as coactivators , which are targeted at specific promoters by transcriptional activators. Therefore a direct link was established between histone acetylation and transcriptional activation. Histone deacetylases were found within corepressor complexes that turn genes off. Once again, histone chemistry became an important variable to consider in transcriptional control.

Now it is recognized that to understand transcriptional control or any other regulated event in the nucleus, it is necessary to define the nucleoprotein structure within which the DNA is utilized. Aside from the characterization of specific architecture, we must also determine how that structure might change. Nucleoprotein complexes are not static, but dynamic. Targeted histone modifications within regulatory nucleoprotein complexes have emerged as a means of modulating the stability of repressive chromatin structures and the transcription process itself. The observations made using simple model systems are having an increasing impact on our understanding of both development and disease. It is now probable that our increasing knowledge of both nucleoprotein complex structure and function in the nucleus will provide many avenues for future advances in the biotechnological and medical fields.

Nucleoside Diphosphate Kinase

For the first 35 years after its discovery in the early 1950s, nucleoside diphosphate kinase (NDP kinase) was considered the quintessential "**housekeeping** enzyme," responsible only for the transfer of the g-phosphate from a variety of nucleoside triphosphates to any common nucleoside diphosphate . Initially, NDP kinase was discovered as a partner in the succinyl-CoA synthetase reaction, using GTP synthesized by that enzyme to drive the synthesis of ATP from ADP. Later, it was recognized that the enzyme can participate in the biosynthesis of all common ribo- and deoxyribonucleoside triphosphates from the respective diphosphates and a phosphate donor (usually ATP) (see Nucleotides, Nucleosides, And Nucleobases). The past decade, however, has revealed a bewildering array of regulatory and developmental roles ascribed to NDP kinase, as well as additional catalytic capabilities.

1. NDP Kinase Reaction

NDP kinase functions via a phosphoenzyme intermediate. The reaction begins with transfer of the g-phosphate from the nucleoside triphosphate substrate—N_1TP in reaction (1) to a specific histidine residue of the enzyme. After dissociation of the resultant diphosphate (N_1DP), the second substrate (N_2DP, the phosphate acceptor) binds, and phosphate is transferred from the enzyme, yielding N_2TP, the nucleoside triphosphate product. Thus, the enzyme displays classical ping-pong kinetics (see Kinetic Mechanisms, Enzyme):

$$N_1TP + E \rightleftharpoons N_1NP + E \sim P \quad (1)$$

$$E \sim P + N_2NP \rightleftharpoons E + N_2TP \quad (2)$$

The enzyme is quite efficient, with k_{cat} values over 1000 sec $^{-1}$. The equilibrium constant for the reaction is close to 1. Because of this, and because ATP is the most abundant nucleoside triphosphate in most cells and organelles (see Adenylate Charge), the primary role of the enzyme has been considered to be the synthesis of the other seven triphosphates from the respective diphosphates and ATP.

Steady-state kinetic analysis revealed that the enzyme is rather nonspecific with regard to both phosphate acceptor and donor. However, recent pre-steady-state kinetic analysis of a human NDP kinase has revealed more specificity than was previously thought. This analysis depended on, first, a change in intrinsic tryptophan fluorescence accompanying phosphorylation of the enzyme and, second, the stability of the phosphoenzyme intermediate, which permitted its isolation for analysis of enzyme dephosphorylation by N_2DP. As shown in Table 1, the second-order rate constants for the formation of $E \sim P$ varied 17-fold among the five triphosphates tested, whereas the dephosphorylation rate constants varied 145-fold among the eight phosphate acceptors tested. In general, **purines** are better substrates than **pyrimidines**, and ribonucleotides are better substrates than deoxyribonucleotides.

Table 1. Rate Constants for Phosphorylation and Dephosphorylation of Human NDP Kinase

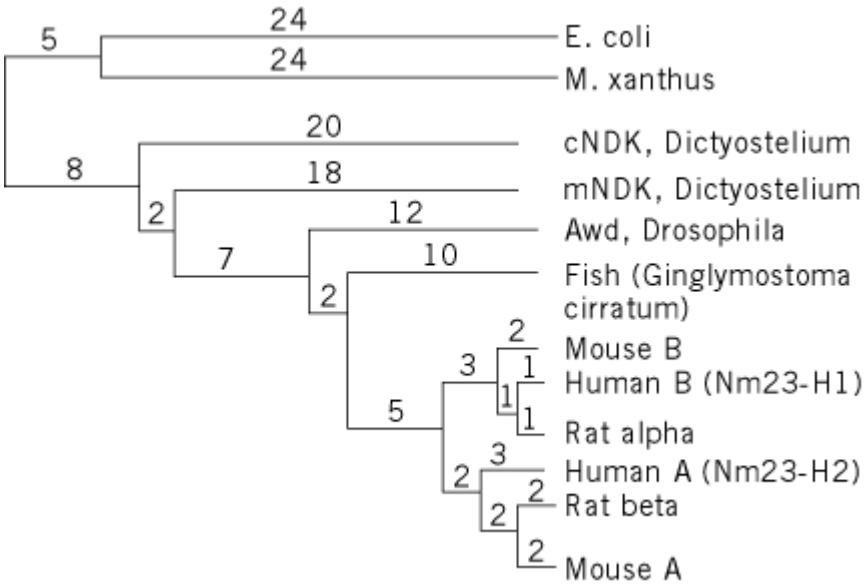
	Second-Order Rate Constant ($\times 10^{-6} M^{-1} s^{-1}$)			
Base	**rNTP**	**dNTP**	**rNDP**	**dNDP**
Adenine	7.9	—	17.9	4.5
Guanine	12.2	—	29.1	10.3
Uracil	2.0	—	3.8	1.3
Cytosine	0.7	—	1.3	0.2
Thymine	—	2.3	—	4.3[a]

[a] Data for rNTPs and dNTPs refer to enzyme phosphorylation rates; data for rNDPs and dNDPs refer to dephosphorylation of the phosphoenzyme.Source of the data: ref. 2.

2. Structure of NDP Kinase

The NDP kinase protein has been rather highly conserved through evolution, and there is about 43% amino acid sequence identity between the human enzyme and that of *Escherichia coli*. Figure 1 summarizes relationships among some of the known NDP kinase sequences. Although the primary structure is highly conserved, the quaternary structure is not; the enzymes of eukaryotic origin are homohexamers whereas the prokaryotic enzymes have a homotetrameric structure. Subunit molecular weights range from 15 to 18 kDa. Interestingly, preliminary data suggest that at least one mitochondrial **isoform** of a eukaryotic NDP kinase might not have a hexameric structure.

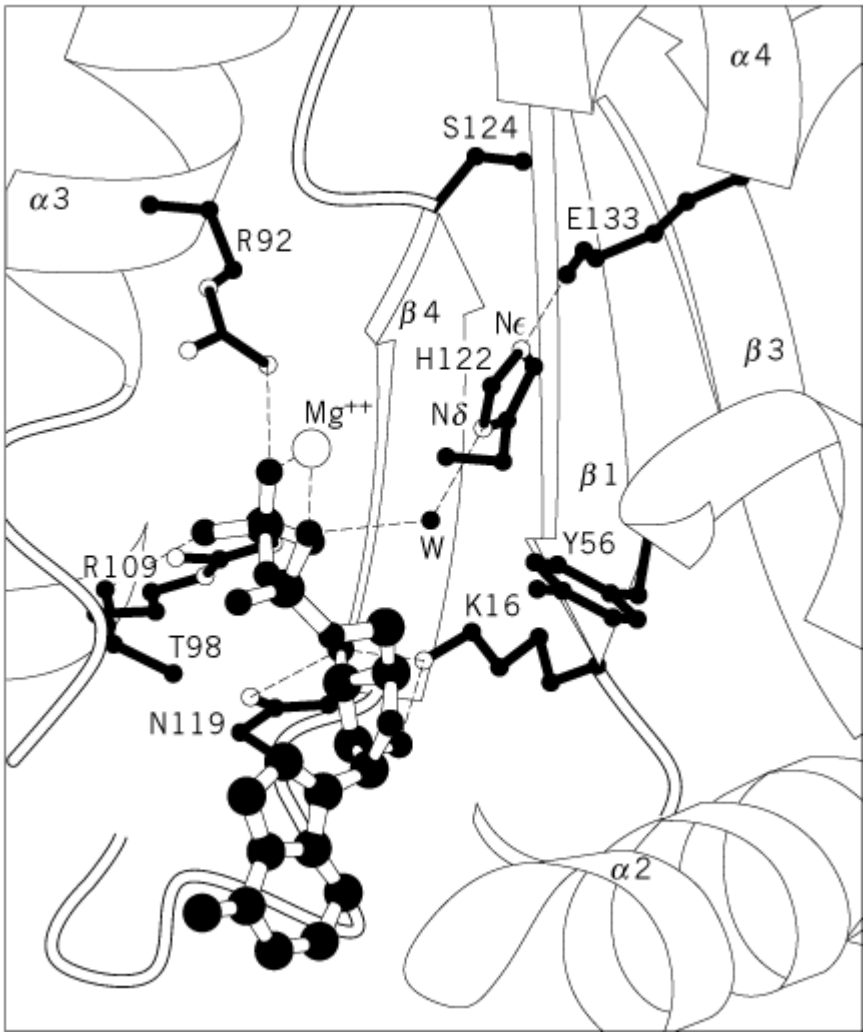
Figure 1. A phylogenetic tree illustrating the evolutionary relationships among NDP kinase amino acid sequences. The numbers above the horizontal lines represent evolutionary time in arbitrary units. The vertical lines indicate the positions of common ancestors. Reprinted with permission from H. Troll, T. Winckler, I. Lascu, N. Müller, W. Saurin, M. Véron, and R. Mutzel (1993) *J. Biol. Chem*. **268**, 25469–25475.



X-ray crystallography structures have been described for the NDP kinases from *Dictyostelium discoideum* (4, 5), *Drosophila melanogaster* (6), and human tissue (7). The tertiary structures are similar. The *Dictyostelium* structure has been determined complexed with ADP and with dTDP. Figure 2 shows the active-site structure of the ADP-enzyme complex. The nucleotide is bound near His122, the residue that becomes phosphorylated during the reaction. The b-phosphate interacts with two **arginine** residues and a threonine that are conserved in all known NDP kinases, and the ribose 2′ and 3′ hydroxyls similarly have polar interactions with Lys19 and Asn119, which are also conserved. Of considerable interest, the purine base forms no polar contacts with the enzyme, nor does thymine in the dTDP-enzyme complex. The absence of specific contacts involving the purine or pyrimidine base accounts for the relatively low nucleotide specificity of the enzyme. However, the structure explains a distinct aspect of specificity that the enzyme does display. Bourdais et al (8) reported that the diphosphates of the anti-HIV drugs azidothymidine, dideoxyadenosine, and dideoxythymidine are very poor substrates. This finding points up the importance of the interaction between the enzyme and the sugar 3′ hydroxyl, which is missing in these analogues, a feature that may be significant in design of more effective antiviral nucleoside drugs.

Figure 2. Structure of the active site of *Dictyostelium* NDP kinase with bound ADP. ADP is shown with open bonds, with the purine base at the bottom of the figure. Amino acid side chains are shown in black; W is a water molecule. Reprinted with permission from A. Tepper, H. Dammann, A. A. Bominaar, and M. Véron (1994) *J. Biol. Chem*. **269**,

32175–32180.



The structure of the ADP-NDP kinase complex suggests a model for the transition state leading to the phosphoenzyme intermediate (4). Amino acid residues involved in both binding and catalysis, shown in Figure 3, are residues that are conserved in all NDP kinases analyzed to date.

3. Additional Functions of NDP Kinase

Several recent developments have graphically demonstrated that the NDP kinase protein does more than simply synthesize nucleoside triphosphates from diphosphates. Some of these additional roles are hinted at by the existence of specific protein–protein interactions involving NDP kinase. Other functions have been traced by genetic analysis to the structural genes for NDP kinase. It is evident that NDP kinase lies at the heart of a number of developmental, genetic, and metabolic control systems.

3.1. Human *nm23* Genes and Metastatic Cancer

Analysis of a closely related series of murine tumor cell lines revealed the existence of a gene, named *nm23* (nonmetastatic clone no. 23), whose action correlated with the potential of the cell lines to develop metastatic tumors after implantation in mice. Lines of low metastatic potential expressed the gene at high levels (9). Sequence analysis revealed the *nm23* gene to be the structural gene for an NDP kinase. Human cells contain two major Nm23 proteins, Nm23-H1 and Nm23-H2 (NDP kinase **isoforms** A and B, respectively). Action of the A isoform is specifically associated with metastasis. The NDP kinase enzymatic activity of the protein is not essential for this activity because some mutant forms of the protein that lack kinase activity still retain the metastatic suppression activity. Since the original cloning and analysis of the two human *nm23* genes, two additional members of the NDP kinase protein family, less closely related to each other and to Nm23-H1 and -H2, have been described in human tissues.

Important clues to the biochemical activity involved in tumor suppression are beginning to accumulate (10). NDP kinase has a protein kinase activity, being able to transfer phosphate from its catalytically important histidine residue to other proteins, including histidine residues on ATP citrate lyase and succinyl-CoA synthetase, and aspartate or glutamate residues on a number of human membrane proteins. Using a cell motility assay with breast cancer cells, Wagner et al (10) explored the activities of a series of *nm23-H1* mutants. Mutations that abolished motility suppression activity also interfered with the phosphorylation of Asp and Glu residues in the membrane proteins, with minimal effects on the protein histidine kinase activity. Thus, the suppression of metastasis correlates closely with the transfer of phosphate to acidic amino acid residues. This activity is similar to that seen in two-component regulatory systems in bacteria; indeed, *E. coli* NDP kinase also can transfer phosphate from histidine to protein aspartate residues, and evidence strongly suggests regulatory roles for this activity (11).

3.2. Wing Development and the *Prune* Gene in *Drosophila*

In *Drosophila*, NDP kinase is encoded by the *awd* gene (abnormal wing development). Mutations in this gene are normally not lethal, but one particular mutation, a Pro-to-Ser substitution at residue 97,

is lethal when in combination with a mutation in the *prune* gene. *Prune* controls eye color, by somehow regulating the activity of GTP cyclohydrolase, an enzyme involved in the synthesis of the pteridine eye pigments. However, the *prune* gene itself evidently encodes a small protein similar to the mammalian GTPase-activating proteins involved in **Ras**-mediated signal transduction pathways (12). *In vitro* experiments with one such protein (13) suggest that NDPK can use a protein-GDP complex as a substrate, with direct conversion of the bound GDP to GTP occurring in the absence of dissociation from the protein. Similar findings have been described for mammalian NDP kinases (14) but, to date, interactions of this type have not been unambiguously demonstrated *in vivo*.

The Pro-to-Ser mutation that makes *awd* lethal in combination with *prune* is called the *kpn* mutation (killer of prune). The proline residue involved lies in a loop that participates in subunit contacts. When the same mutation was engineered into the *Dictyostelium* NDP kinase , the mutant enzyme was found to undergo ready dissociation from its hexameric structure to folded monomers that retained some enzymatic activity. Lascu et al. (15) speculated that comparable dissociation occurs *in vivo* in *kpn* mutant cells and that the conditional lethality of the mutation derives from a deleterious effect of these monomers, still unknown.

Similar conclusions have been drawn from analysis of a natural mutation in human NDP kinase A (Nm23-H1), which is found in several aggressive neuroblastoma tumors (16). This mutation involves a Ser-to-Gly substitution at position 120. *In vitro*, the mutant enzyme was found to be quite unstable, and when it renatured, an intermediate accumulated that had the properties of a molten globule. Whether the accumulation of such a folding intermediate at abnormal levels *in vivo* might somehow contribute toward the tumor phenotype is an exceedingly interesting, unanswered question.

3.3. Control of *c-myc* Gene Transcription

Postel et al (17) proposed that human NDP kinase B also serves as a transcription factor for the *c-myc* proto-oncogene. This role was identified by screening a cervical cell carcinoma cDNA library with DNA containing binding sites for PuF, the purine-binding transcription factor. Sequence analysis of a positive clone revealed the PuF gene to be identical to *nm23-H2*, the structural gene for NDP kinase B. The enzyme has been shown to activate c- *myc* transcription *in vitro* and to bind preferentially to pyrimidine-rich single-stranded DNA (18). This is a specific activity of the B isoform, whereas the metastatic tumor suppression described earlier is associated with the A isoform. Nevertheless, it is intriguing to consider whether there is a common element in the actions of these two proteins with respect to tumorigenesis and **tumor suppression**.

4. Protein–Protein Interactions Involving NDP Kinase

As befits a protein involved in a range of biological processes, NDP kinase has been shown to interact with numerous proteins. In *Pseudomonas aeruginosa*, NDP kinase copurifies with succinyl-CoA synthetase (19), which is consistent with the idea that one role of NDP kinase is to generate ATP from the substrate-level phosphorylation step of the citric acid cycle. The possible connection with substrate-level phosphorylation is seen also in frog heart preparations, where NDP kinase was found to copurify with five proteins (20), including glyceraldehyde 3-phosphate dehydrogenase, creatine kinase, pyruvate kinase, and vimentin.

Relatively little attention has been paid to the role of NDP kinase in DNA precursor biosynthesis. One system that has been explored is bacteriophage T4-infected *E. coli*, in which all the reactions in dNTP and DNA synthesis are catalyzed by phage-coded enzymes, except for the synthesis of dNTPs from the respective NTPs. In this system, the NDP kinase of the host bacterium, encoded by the *ndk* gene, forms part of a multienzyme complex for dNTP synthesis (21). Affinity chromatography with immobilized *E. coli* NDP kinase as the affinity ligand reveals specific interactions with several T4 phage proteins, including dihydrofolate reductase, ribonucleotide reductase, and single-strand DNA-binding protein (22). However, NDP kinase is dispensable, because an *E. coli* strain bearing a targeted deletion of the *ndk* gene is viable, and it supports phage T4 growth (23). Interestingly, these mutant cells have abnormal nucleoside triphosphate pools—in particular, a twentyfold elevation of

the dCTP level—and, probably as a result, an elevated spontaneous mutation rate. Lu and Inouye (24) searched in the *ndk* deletion strain for an enzyme capable of synthesizing nucleoside triphosphates from the respective diphosphates, and they made the surprising observation that adenylate kinase, the product of the *adk* gene, possesses this capacity. Because adenylate kinase was previously known only to catalyze the ATP-dependent phosphorylation of AMP or dAMP to the respective diphosphate, this is a novel activity of the *adk* protein, representing another important but incompletely understood aspect of the biochemistry of nucleoside diphosphate kinase.

Nucleosome

The nucleosome is the basic repeating subunit of chromatin (1), which has a regulatory role in gene transcription as well as serving to package DNA. It consists of about 166 bp of DNA wound in two left-handed superhelical turns around a wedge-shaped histone octamer (a tetramer, $H3_2H4_2$, of histones H3 and H4, flanked by two H2A.H2B dimers), a length of linker DNA which may vary from effectively zero (yeast, mammalian cortical neurons) to 74 bp (sea urchin sperm) and defining the repeat length of the chromatin (~170 to 40 bp), and one molecule of linker histone (H1 or one of its variants; see Histones). Nucleosomes are responsible for the familiar beaded appearance of chromatin seen in the **electron microscope**. The nucleosome is a wedge-shaped disk, about 110 Å in diameter and about 55 Å high, with a pseudo-dyad axis of symmetry close to which the entering and exiting DNA duplexes lie.

Nucleosomes (and runs of two, three, etc, nucleosomes) may be excised from chromatin by cleavage in the more accessible linker DNA using, for example, the double-stranded endonuclease micrococcal nuclease (**Staphylococcal nuclease**) and then fractionated by sedimentation velocity centrifugation through sucrose gradients. Further digestion of mononucleosomes with micrococcal nuclease, which has exonuclease as well as endonuclease activity, proceeds in two stages. First, the DNA is trimmed to ~166bp, at which point histone H1 presents a barrier to further digestion and a metastable particle termed the “chromatosome” is produced. Further digestion of the chromatosome trims the DNA further, causing loss of histone H1, presumably as its binding site close to the nucleosome core is invaded, and then trims the DNA back to 146 bp, where contacts with the octamer block further digestion. The limit product of digestion is the nucleosome core particle whose structure is now known at high resolution (see text below). Protection by histone H1 in the chromatosome was believed to be symmetric, with 10 bp protected at each end of the core particle. It now appears, however, that it may be asymmetric (2, 3), with 20 bp protected at one end of the core particle and none at the other (assuming that the addition of linker histone did not shift the dyad by one helical turn).

The exact location of H1 in the nucleosome has been controversial (summarized in Ref. 4), because there is not yet any direct structural information for a chromatosome. The general view from several lines of evidence was that the globular domain of H1 bound close to, or over, the dyad axis, on the outside of the DNA gyres, and that it contacted two duplexes through two DNA binding sites (see Histones) that were shown (5) to be required for correct binding to two duplexes and to chromatin. However, results obtained for a nucleosome reconstituted on to *Xenopus* 5S rRNA gene, which contains a strong nucleosome positioning sequence (see Chromatin), suggested a fundamentally different picture, with the globular domain bound away from the dyad axis and *inside* the DNA gyres, contacting only one duplex (6). It may be that this is a unique feature of the 5S nucleosome, although this would be a little surprising. Current evidence (summarized in Ref. 7) suggests that, for at least the majority of chromatosomes (a bulk population from chicken erythrocytes), the globular

domain of H5 makes two DNA contacts, one of which is indeed near the dyad. Helix III, the "recognition helix" in the globular domain (by analogy with the homologous structures of HNF3g and cyclic AMP receptor protein; see Histones), contacts one of the exiting/entering duplexes, about one helical turn from the end of the chromatosomal DNA, and the second site makes a contact that is in the vicinity of the dyad (Fig. 1). This location is such that the basic *C*-terminal domain of H1 would be directed toward the linker; a linker location of this domain is suggested by electron microscopy of mononuclesomes (8). It has been argued (7) that the globular domain could well be binding to the 5S nucleosome in the same way, if assumptions about the position of the octamer in that system were to prove to be incorrect; however, the possibility remains that the 5S nucleosome is different.

Figure 1. The location of the globular domain of histone H5 in the 166-bp chromatosome. The recognition helix (magenta) makes a contact one double-helical turn from the end of the DNA (region shown in green) and the second binding site on the opposite face of the domain contacts the central gyre, close to the pseudodyad (3 bp around the dyad shown in red). (Based on the data in Ref. 11. Drawing courtesy of S. Muyldermans.) See color insert.

1. Nucleosome Core Particle

The length of DNA in nucleosome core particles produced by limit nuclease digestion as described above is relatively homogeneous, allowing particles with sequences representing essentially the entire genome to be crystallized (despite the mixed DNA sequences, histone variants, and post-translational modifications). The year 1985 saw the publication of an X-ray crystallography structure of the 206,000 Da nucleosome core particle to 7 Å resolution, which confirmed the general shape and arrangement of histones and DNA inferred from earlier studies using electron microscopy and **single-particle reconstruction** analysis. Determination of the structure of the histone octamer (free of DNA) to 3.1 Å resolution in 1991 (see Histones) allowed some of the details of protein–DNA interactions to be inferred, but the full picture has become available only in the 2.8 Å structure of the nucleosome core particle (9) published in 1997 (Fig. 2). To obtain this resolution, highly homogeneous nucleosome core particles were reconstituted (see Chromatin) from synthetic 146-bp palindromic DNA and homogeneous recombinant histones produced in *Escherichia coli*. This is also the largest piece of DNA whose structure has been determined.

Figure 2. Nucleosome core particle structure at 2.8 Å resolution. (**a**) *Left*: A view down the superhelical axis; *right*, view perpendicular to the superhelical axis. The pseudo-twofold axis is aligned vertically with the DNA center at the

top in each case. The DNA is shown in brown and turquoise; H3, H4, H2A, and H2B are shown in blue, green, yellow, and red, respectively. (**b**) The histone octamer structure in the nucleosome core, formed by removing the DNA from the nucleosome core particle image in (**a**). (**c**) Histone tails between DNA gyres shown in a space-filling model. The colors are as in (**a**). Note that the H2B (red) and H3 (blue) *N*-terminal tails pass through channels in the DNA superhelix (white) formed by aligned minor grooves. [(**a**) and (**c**) reproduced from ref. 9, with permission; (**b**) reproduced from Ref. 12, with permission. See color insert.

H2B

The DNA in the core particle is wound in 1.65 superhelical turns on a left-handed helical ramp on the octamer surface; the remaining 10 bp at each end are essentially straight due to contacts between neighboring molecules in the crystal, to give pseudocontinuous double helices. The core particle has a pseudodyad axis of symmetry that coincides with the dyad axis of the octamer and passes between the two H3 molecules. One base pair in the 2.1 Å structure sits on the dyad, so the DNA of the two "halves" of the particles (73 and 72 bp) are not identical, despite the initial choice of a palindromic sequence in an attempt to obtain a nucleosome core particle with exact two-fold symmetry! The DNA superhelix is not uniformly bent, as was already known, due to the nature of the local histone–DNA interactions, the sharpest distortions being at positions 15 bp and 40 to 50 bp on either side of the dyad (positions±1.5 and ±4 to 5 relative to the dyad as position 0). The overall helical periodicity of the DNA in the core particle is 10.2 bp per turn, but varies in detail along the DNA.

The organization of histones is very similar to that seen in the structure of the histone octamer on its own at 3.1 Å resolution (10), with histone folds arranged in handshake motifs (Fig. 2 **a**). The histone folds organize the central 121 bp of DNA; the remaining 13 bp at each end are organized by *N*-terminal **a-helical** extensions to the folds in the two H3 molecules and adjacent residues from the *N*-terminal tail domain. Each histone-fold dimer in the octamer organizes 27 to 28 bp, with 4-bp stretches between contacts. Each dimer has three independent DNA-binding sites: two contributed by the loops at each end of the dimer, and one formed by the two *N*-termini of a-helices of each histone fold at the dimer apex. Histone–DNA contacts include extensive salt bridges and hydrogen bonds from both main chains and side chains of the histones to the phosphate backbone, together with nonpolar contacts with DNA sugar groups, and electrostatic interactions of the positively charged *N*-termini of a-helices in the histone folds with DNA phosphate groups. Such interactions might be expected for proteins that can bind to a variety of DNA sequences; the number of specific base contacts in the core particle structure is very small (one of them being a nonpolar contact of the 5-methyl group of a thymidine in the major groove). Strikingly, **arginine** side chains contact the minor groove each of the 14 times it faces inwards.

A surprising finding was that the *N*-terminal tails (see Histones), which are the most variable regions between species and which are the sites of post-translational modification, notably acetylation (see Histone Acetylation), are directed outward from the core particle, exiting between the DNA gyres; they are therefore well-placed to make contacts with other nucleosomes or other proteins. Some of the tails are visible in Figure 2**a**; Figure 2**b** shows the DNA stripped away to show the extended histone tails and the histone folds in the octamer. The four H3 and H2B tails exit through the narrow channels formed by perfectly aligned minor grooves of adjacent gyres of the DNA superhelix (Fig. 2**c**), the alignment being a consequence both of the change in the twist of the DNA from 10.6 bp in solution to 10.2 bp in the core particle and local adjustments to the twist. H4 and H2A tails exit in minor grooves either on the "top" or the "bottom" of the core particle. The accessible histone tails in chromatin are known to be targets for transcription-linked histone acetyltransferases (see Histone Acetylation) as well as recognition sites for proteins that lead to a more repressive chromatin structure (eg, SIR proteins, giving **silenced** regions at yeast **telomeres** and mating type loci) and for at least one chromatin remodeling complex (NURF) (see Chromatin). Histones are thus not simply packaging proteins but also have a gene regulatory function. DNA could be weakly bound to the outside of the core particle (but with low occupancy; otherwise they would have been seen in the core particle structure), and acetylation could well prevent this. Such a weak effect alone is unlikely, however, to account for the enhancing effect of acetylation on transcription *in vivo*, although it could perhaps account for results of some *in vitro* assays in which acetylation can increase the access of transcription factors to mononucleosome DNA (see Histone Acetylation). The nature of the crystal contacts hints at possible roles for the tails. The basic H4 tail, which has been implicated in a variety of biological functions, contacts an acidic patch on the surface of a neighboring octamer. Residues 16 to 25 of H4 (the most internal/proximal acetylation site is at position 16) make multiple

interactions with acidic side chains on H2A and H2B in an adjacent nucleosome in the crystal. Model building shows that a similar interaction could occur in the solenoid model for chromatin higher-order structure (9) (see Chromatin). Acetylation might then result in disruption of higher-order structure, with the relaxed structures being more accessible to transcription factors, remodeling complexes, and the transcriptional apparatus (see Chromatin). Residues 16 to 24 of H4 are also known to be necessary for interaction with Sir3 in yeast silencing and heterochromatin formation, and in this case the suggestion is that the internucleosomal contact is replaced by an interaction with Sir3 (9).

Nucleotide-Binding Motif

The nucleotide-binding motif is a structural and functional **domain** that is frequently observed in protein structures that bind nucleotides. It has a characteristic sequence that can usually be observed in the primary structure. There are two classes of the motif; the classical dinucleotide-binding fold and the classical mononucleotide-binding fold. The former binds dinucleotides such as NAD and FAD, and the latter binds mononucleotides such as ATP (and is also called the ATP-binding motif).

The dinucleotide motif was first identified by Rao and Rossmann, who identified two b–a–b–a–b units (b is a **b-strand** and a is an **a-helix**) forming a six-stranded parallel **b-sheet** surrounded by four a-helices in the structures of lactate dehydrogenase (LDH) and malate dehydrogenase (Fig. 1) (1). Both bind NAD; each half of the dinucleotide interacts with one b–a–b–a–b unit. A single b–a–b–a–b unit is called a Rossmann fold. The adenine moiety of NAD (or FAD) binds to the first of the two

b–a–b–a–b– units, and the nicotinamide (or flavin) binds to the second. The first three elements of **secondary structure** in the adenine-binding motif, b1–aA–b2, are involved in the predominant interactions with adenine and have a common structure and related sequences (1). This "fingerprint" sequence consists of conserved small **hydrophobic** residues in b1, followed by a glycine-rich region (–Gly–X–Gly–X–X–Gly, where X is any residue), conserved small hydrophobic residues in helix aA, and an Asp or Glu at the end of helix aA. The first two glycine residues are in a loop connecting b1 and aA; the third glycine is in helix aA. The glycine residues adopt conformations forbidden to other residues and allow close packing of the b-strands and helix and a close approach between the adenine pyrophosphate and the *N*-terminal end of the aA-helix. The phosphate group is thought to interact favorably with the partial positive charge at the *N*-terminal end of the aA-helix dipole. The conserved Asp/Glu residue interacts with the ribose hydroxyl. This signature sequence of ~30 residues was derived from the tertiary structures of known NAD-binding proteins, but it can also be used to predict NAD- or FAD-binding proteins from their primary structure.

Figure 1. Schematic representation of the backbone structure of the nucleotide-binding domain of malate dehydrogenase (1). b-Strands are shown as arrows and a-helices are shown as coils. The bound dinucleotide (NAD) is shown as a ball-and-stick model. The two b–a–b–a–b– units that interact with the each half of the mononucleotide are shown in green and purple. The b1–aA–b2 region that interacts with the adenine portion of NAD is shown in yellow. This figure is generated using Molscript (2) and Raster3D (3, 4). See color insert.

The fingerprint sequence is slightly different for binding the dinucleotide NADP, where the 2′ ribose hydroxyl of NAD is phosphorylated. In this case, the third glycine (in the aA-helix) is replaced by Ala so that the close approach of aA and the b-strands is prevented. This provides additional space for binding the 2′-phosphate. Furthermore, the conserved Asp/Glu of the NAD/FAD sequence is replaced by Arg to interact with the 2′-phosphate.

The classical mononucleotide or ATP-binding motif, typified by adenylate kinase, is also an a/b

protein fold but has a five-stranded parallel b-sheet with a very different connectivity from the dinucleotide fold. Once again, the bound nucleotide binds to a b1–aA–b2 region that has a characteristic fingerprint sequence: Gly–X–X–Gly–X–Gly–Lys. In this case, however, the glycine-rich sequence corresponds only to the loop between b1 and aA, so that all three glycine residues form part of the loop (in contrast to the dinucleotide sequence, where the third glycine is part of helix aA). The loop forms a large pocket that accommodates the phosphate of the mononucleotide (it is also called the P-loop), and the glycine amides and the side chain of the conserved lysine residue interact with the phosphate.

Nucleotides, Nucleosides, And Nucleobases

Nucleotides are the monomeric constituents of **nucleic acids**, as well as structural elements of most **coenzymes** and many activated metabolic intermediates. This article describes the structure, nomenclature, and chemical and physical properties of nucleotides that serve as nucleic acid constituents.

1. Definitions

A nucleotide is a substance that, on hydrolysis, yields per mole at least 1 mole of a nitrogenous base, a sugar, and orthophosphate. A nucleoside yields 1 mole each of a nitrogenous base and a sugar. The term *nucleobase* refers to those nucleotides found in nucleic acids—adenine, guanine, cytosine, and uracil in RNA, and adenine, guanine, cytosine, and thymine in DNA, plus the quantitatively minor bases found in both nucleic acids. Other bases, such as the nicotinamide found in NAD^+ and $NADP^+$, occur as parts of coenzymes or as parts of metabolically activated biosynthetic intermediates, such as uridine diphosphate glucose.

A mononucleotide is a nucleotide that, on hydrolysis, yields 1 mole each of a base and a sugar plus at least 1 mole of orthophosphate. The term nucleoside diphosphate usually refers to a mononucleotide which, on hydrolysis, yields 1 mole each of a base and a sugar plus 2 moles of orthophosphate; similarly, a nucleoside triphosphate yields 3 moles of orthophosphate per mole of

nucleotide. A dinucleotide yields, on complete hydrolysis, 2 moles each of base and sugar, plus at least 1 mole of orthophosphate; a trinucleotide yields 3 moles each of base and sugar, plus 2 or more moles of orthophosphate.

Figure 1 shows the structures of the five common nucleobases (in their most frequent **tautomeric** configuration) and several nucleosides, mononucleotides, and oligonucleotides, as well as the numbering systems used. Note that, in all nucleotides found in nucleic acids, a glycosidic bond links N-9 of a purine base or N-1 of a pyrimidine base to C-1, the carbonyl carbon, of either ribose or 2-deoxyribose. By convention, all positions in the sugar of a nucleoside or nucleotide are given primed numbers. Thus, the adenine nucleotide recovered from digestion of DNA with certain enzymes would be named 2′-deoxyadenosine 5′-monophosphate, identifying the position of the phosphate esterified to the sugar, as well as the carbon of the sugar that is in the reduced, or deoxy, configuration. Note that some modes of nucleic acid digestion will yield 2′- or 3′-nucleotides, in which the phosphate is esterified to positions 2′ or 3′ of the sugar, respectively. Also, in the 3′,5′-cyclic nucleotides, **cyclic AMP** and **cyclic GMP**, which play multiple roles in biological signal transduction, the phosphate is esterified simultaneously to carbons 3′ and 5′. Because the nucleic acid biosynthetic intermediates are nucleoside 5′-phosphates, or 5′-nucleotides, these structures are shown predominantly. Table 1gives the names and common abbreviations of the nucleotide constituents of nucleic acids and the cyclic nucleotides.

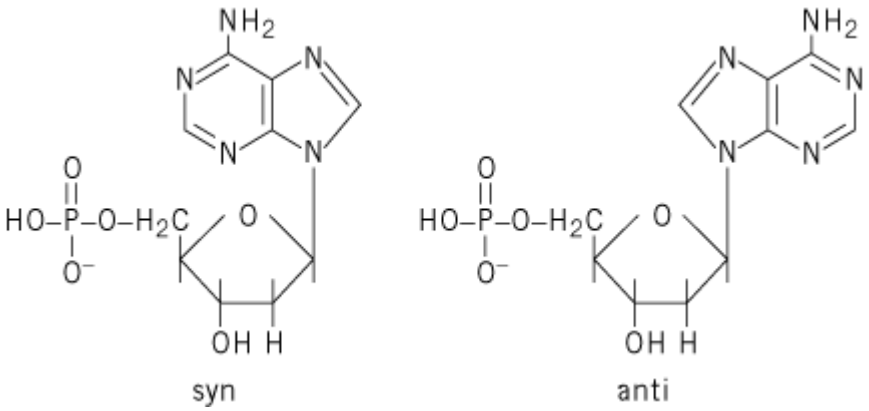
Guanosine 3′,5′-monophosphate, 3′,5′-cyclicguanylic acid	cGMP, Guo-3′,5′-P, 3′,5′-GMP

[a] Thymine occurs as a minor base constituent of tRNAs. However, because the thymine ribonucleotides do not occur in nature, nucleotides containing thymine are called either *thymidine* or *deoxythymidine nucleotides*. No consistent preference for either nomenclature has emerged.

One additional structural feature of nucleotides relates to the somewhat hindered rotation about the glycosidic bond, which leads to two rather stable orientations of bases with respect to the sugar, termed *syn* and *anti* (Fig. 2). Because it is more compact to draw, most of the structures shown here are represented as *syn*, but the *anti* configuration predominates in nucleic acids (see Z-DNA).

Figure 2. dAMP in the *syn* and *anti* configurations.



2. Chemical and Physical Properties of Nucleotides

Because of the phosphate group or groups on nucleotides, these substances are highly acidic and exist as anions at physiological pH. The primary and secondary pK_a values for the phosphate groups of nucleoside 5′-monophosphates are about 1 and 6, respectively. The amino groups on adenine, guanine, and cytosine rings are extremely weak bases, undergoing protonation with pK_a values of 2 to 4.5. Because of variations in these values, and the absence of a ring amino group in uracil and thymine (see Table 2 and ref. 2), one can adjust the pH to values at which different nucleotides have different net negative charges, thereby permitting their ready separation by electrophoresis or ion-exchange chromatography (2).

Table 2. Properties of Nucleoside Monophosphates

Nucleotide	pK_a of ring –NH_2	UV absorbance maximum, nm	Measured at pH	ε_m, l^2/mole-cm×10^{-3}
AMP	3.8	257	2	15.0
CMP	4.5	280	2	13.2
GMP	2.4	256	1	12.2
UMP	—	262	2	10.0
dAMP	4.4	258	2	14.3
dCMP	4.6	280	2	13.5
dGMP	2.9	255	1	11.8
dTMP	—	267	2	10.2
cAMP	N.R.	256	2	14.5
cGMP	N.R.	256.5	1	11.35[b]

[a] N.R., not reported.

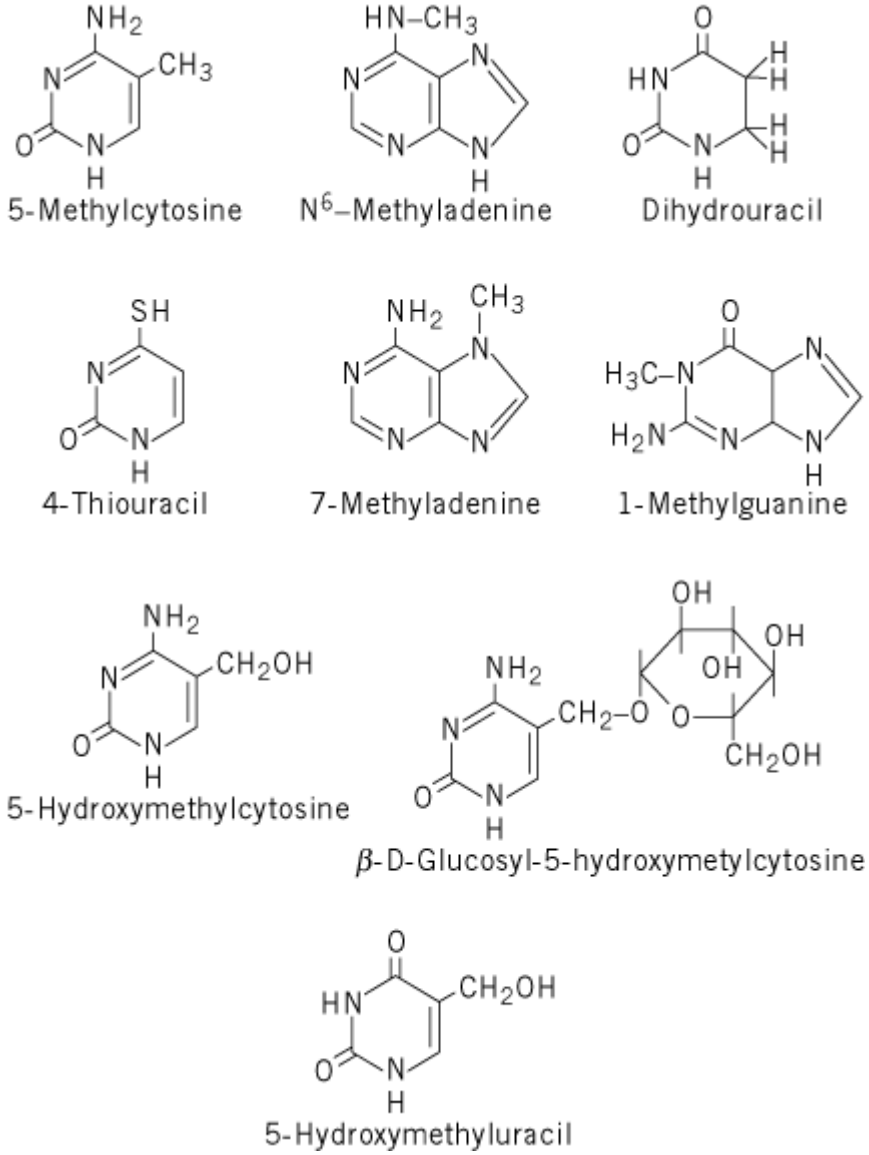
[b] Data for cyclic nucleotides are from Ref. 10. Other data are from Ref. 1.

The aromatic character of the purine and pyrimidine rings leads the nucleotides to **absorb** ultraviolet light with characteristic absorption spectra, as indicated in Table 2. This allows ready detection, identification, and quantification of nucleotides and nucleotide derivatives. Because of ionization of the purine and pyrimidine rings, the ultraviolet absorption spectra are quite dependent on pH, and this has made identification and quantification methods even more specific and sensitive.

3. Naturally Occurring Modified Nucleotides

In addition to the five "standard" nucleobases (adenine, guanine, cytosine, thymine, and uracil), most nucleic acids contain modified bases (see Transfer RNAand DNA Structure). The most widespread is 5-methylcytosine, which is present at up to 5% of the cytosine level in most eukaryotic DNA (Fig. 3). The most abundant methylated base in prokaryotic DNA is N^6-methyladenine (see Methyltransferase, and Mismatch Repair). A variety of modified bases, some but not all of them methylated, are found in RNA, most abundantly in transfer RNA. A few of these are shown in Figure 3.

Figure 3. Structures of prominent modified nucleobases found in nucleic acids.

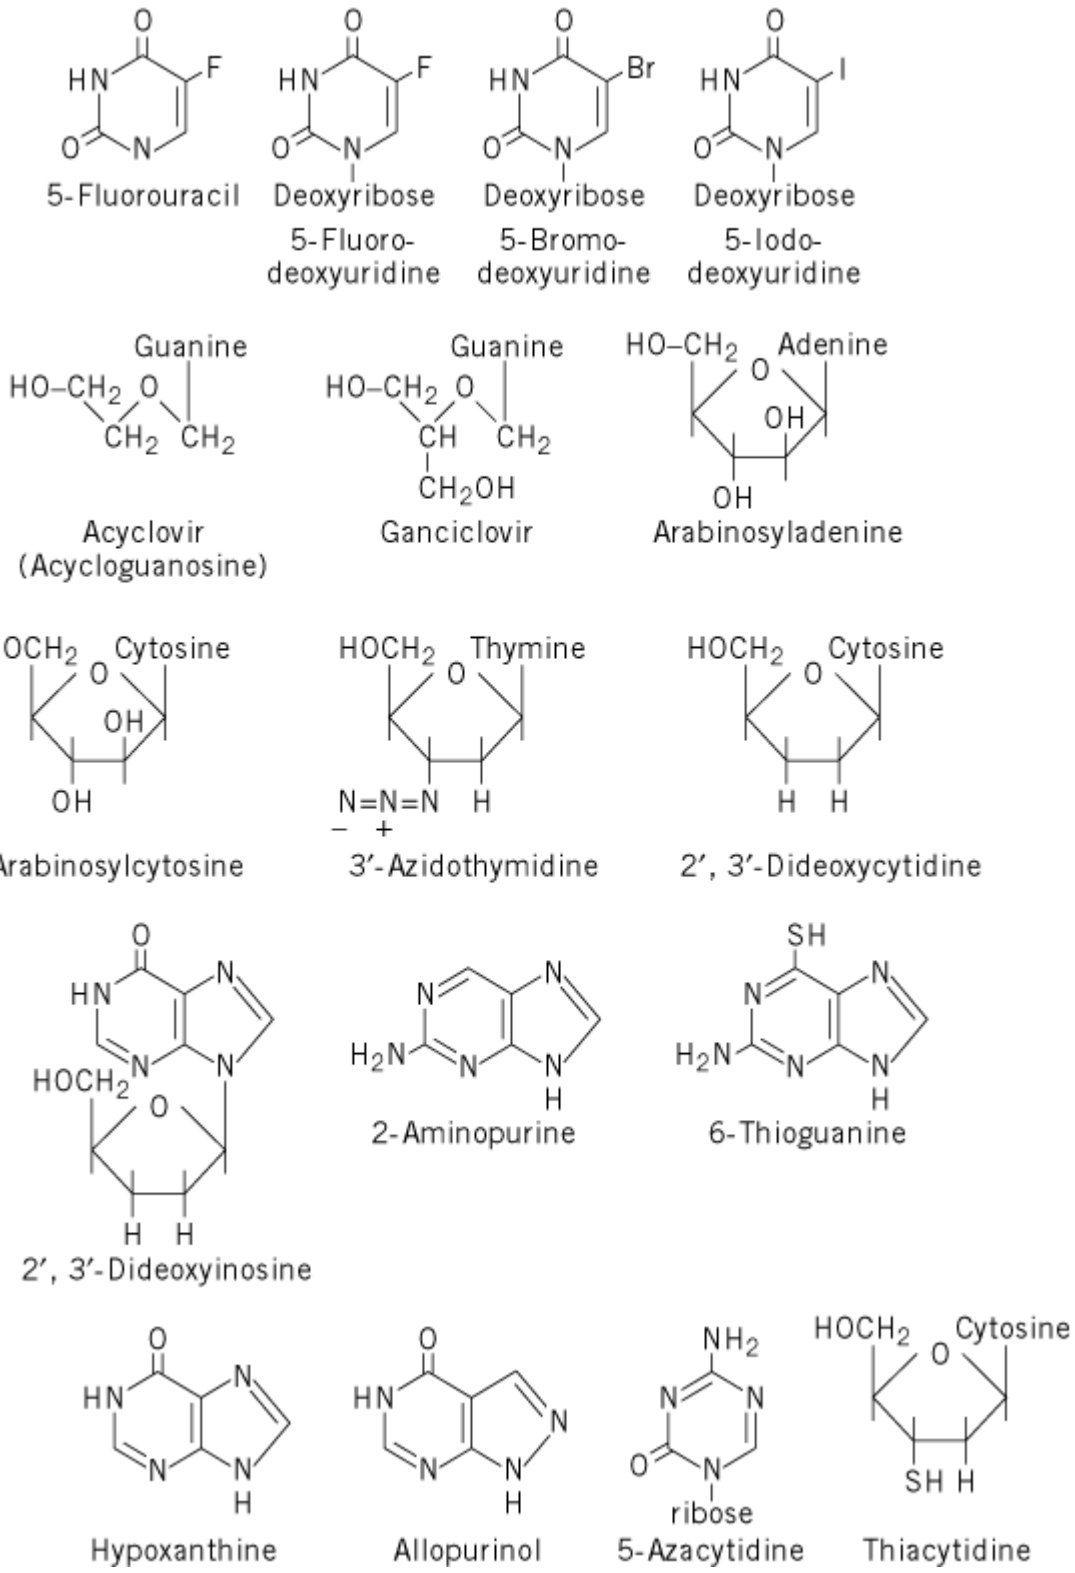


In addition to the above modified bases, which are quantitatively minor in most systems studied, there are several bacteriophages whose DNA contains modified bases as major constituents. Most prominent among these are the T-even coliphages, which contain four forms of 5-hydroxymethylcytosine, completely substituted for cytosine (Fig. 3): the base itself, with no further modifications, and the base glycosylated at the hydroxymethyl position with glucose in either the a or b configuration, or with cellobiose (glucosyl-1,4-b-D-glucose). Several phages infecting *Bacillus subtilis* contain 5-hydroxymethyluracil completely replacing thymine, and bacteriophage XP-12, which infects Xanthomonas oryzae, contains 5-methylcytosine completely replacing cytosine. 5-Hydroxymethyluracil has also been found as a minor constituent of DNA subjected to oxidative damage; it results from oxidation of thymine residues (3).

4. Synthetic Nucleoside and Base Analogues

A large number of nucleoside and nucleobase analogues have been synthesized and developed as anticancer, antiviral, antibacterial, and antiparasitic drugs (4-6). Many of these analogues act by intracellular conversion to deoxyribonucleotide analogues, which selectively block DNA replication (because deoxyribonucleotides have no significant metabolic roles other than as DNA constituents). A few of the most prominent of these analogues are shown in Figure 4 and discussed briefly here.

Figure 4. Nucleobase and nucleoside analogues of biological or medical significance.



4.1. Halogenated Pyrimidines

The earliest-developed useful synthetic nucleobase and nucleoside analogues were 5-fluorouracil (FUra) and **5-fluorodeoxyuridine** (FdUrd), both of which were synthesized during the 1950s and shown to have potent antitumor activity; both agents are still in use today. Both the base and the nucleoside act by uptake into target cells, followed by intracellular conversion to 5-fluorodeoxyuridine 5′-monophosphate (FdUMP), an analogue of deoxyuridine monophosphate, which binds covalently to thymidylate synthase, thereby blocking the synthesis of dTTP and hence

the replication of DNA.

Because of their negative charge, nucleotides are not readily transported through cell membranes. With most nucleobase or nucleoside drugs, the active form of the drug is a nucleotide analogue—FdUMP in the example under discussion. Thus, in order to use nucleic acid precursors successfully as drugs, the biochemical pharmacologist must be aware of the nucleotide biosynthetic salvage enzymes in target cells (see Salvage Pathways To Nucleotide Biosynthesis), so that a precursor is administered that can be converted to the active nucleotide. One must be concerned also with degradative enzymes. For example, nucleoside phosphorylase can cleave fluorodeoxyuridine to 5-fluorouracil plus deoxyribose-1-phosphate, a reaction that would limit the effectiveness of the drug by decreasing its availability for conversion to the active FdUMP.

Closely related to 5-fluorodeoxyuridine are the other halogenated pyrimidines, 5-bromodeoxyuridine (BrdUrd) and 5-iododeoxyuridine (IdUrd). The bromine atom of BrdUrd has a van der Waals radius similar to that of a methyl group; thus, it is readily phosphorylated by thymidine kinase and ultimately converted to the nucleoside triphosphate BrdUTP, which is a close dTTP analogue and is readily incorporated into DNA. BrdUrd has limited therapeutic utility, but it is widely used as a research reagent, for density-labeling experiments involving DNA; the heavy bromine atom imparts a significantly higher buoyant density to BrdUrd-substituted DNA than to thymidine-containing DNA. Moreover, BrdUrd is a potent chemical mutagen because bromouracil in DNA occasionally base-pairs with guanine and not with thymine in DNA ((6); also, see Mutagenesis). By contrast, IdUrd is a fairly useful antiviral drug, used in treating eye infections caused by the large DNA virus, **herpes** simplex. The genome of this virus encodes a thymidine kinase of broad specificity that readily phosphorylates IdUrd to the monophosphate, and then to the diphosphate. Thus, this nucleotide is more readily incorporated into DNA of virus-infected cells, where its presence can damage the viral genome, than in uninfected cells.

4.2. Arabinosyl Nucleosides

These compounds, of which the adenosine and cytidine analogues are most useful therapeutically (6), contain arabinose, which is the 2-epimer of ribose. AraA is a fairly effective antiviral agent, being used to treat viral encephalitis, among other conditions. The triphosphate of araA, araATP, is a rather specific inhibitor of DNA polymerases encoded by herpes viruses. AraC is used in chemotherapy of leukemias and some solid tumors. AraC is phosphorylated initially by deoxycytidine kinase, ultimately being converted to araCTP, a potent inhibitor of replicative DNA polymerases. A problem in the use of araC is its fairly facile deamination by cytidine deaminase, yielding the weakly effective arabinosyluracil. Therapeutic activity of araC can be potentiated by coadministration of a cytidine deaminase inhibitor. In the same sense, the efficacy of araA is often enhanced by coadministration of an adenosine deaminase inhibitor, because this enzyme converts arabinosyladenine to arabinosylhypoxanthine.

4.3. 6-Thioguanine

This guanine analogue is widely used in **somatic cell** genetics. Its conversion to a toxic nucleotide is carried out by hypoxanthine guanine phosphoribosyltransferase (HGPRT). Since the structural gene for HGPRT is sex-linked, mammalian genomes contain only one copy of the gene, making this gene a convenient selectable marker for studies on mutagenesis and for generating hybridoma cell lines for monoclonal antibody production. HGPRT-negative mammalian cell mutants become resistant to the lethal effects of 6-thioguanine, because of their inability to anabolize the analogue.

4.4. Allopurinol

This hypoxanthine analogue is a successful drug for treating gout (7). It is an effective inhibitor of xanthine oxidase, which converts hypoxanthine to xanthine, and xanthine to uric acid in the catabolism of purine nucleotides. Thus, allopurinol often inhibits the buildup of the insoluble uric acid, allowing excess purines to be excreted as the more soluble hypoxanthine and xanthine.

4.5. 5-Azacytidine

This cytidine analogue has a nitrogen atom at position 5 of the modified pyrimidine ring. It has been useful in studies of the biological significance of **DNA methylation** because it is metabolized similarly to cytidine. When incorporated into DNA as the dCMP analogue, however, the pyrimidine ring cannot be methylated at position 5. Thus, a G·mC base pair is effectively demethylated in subsequent rounds of replication, allowing investigators to investigate the epigenetic changes that occur as a result.

Nucleus

The nucleus is the center for **genetic** inheritance and **gene expression** within the cells of **eukaryotes.** It contains a myriad of reactions that occur within several macromolecular compartments and particles. This article provides an overview of nuclear structure and function. Many of the more specific topics are treated in more detail in their entries.

1. Genomic Inheritance

The nucleus is the most conspicuous **organelle** within eukaryotic cells. Although earlier microscopists made note of what must have been nuclei(1), historians attribute the discovery of the nucleus to Robert Brown in 1833 because of his careful descriptions of orchid cell nuclei(2). Once the nucleus was firmly established by Brown as a constant entity within cells, Hertwig and Strasburger in 1884 independently described the nucleus as the organelle of cellular inheritance. These and other late nineteenth and early twentieth century researchers theorized that inheritance is based on segregation of the nuclear chromosomes (3, 4).

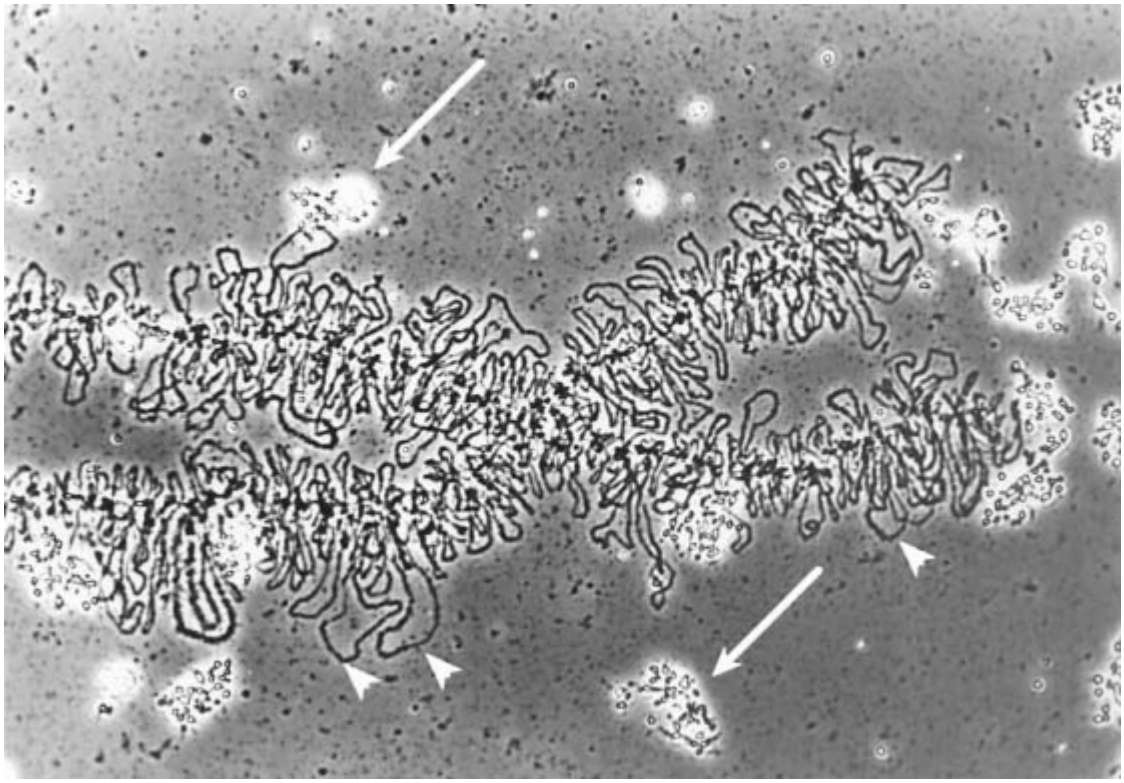
Most eukaryotic cells contain one nucleus, but there are many examples of multinucleated cells or syncytia (eg, differentiated muscle cells, the early ***Drosophila*** embryo). Conversely, mature mammalian red blood cells lack nuclei. Nuclei differ in size depending on the cell type: the **yeast** (*Saccharomyces cerevisiae*) nucleus is approximately 2 μm in diameter, a typical mammalian nucleus is 4 to 6 μm, and nuclei (germinal vesicles) in mature amphibian **oocytes** are about 600 μm

in diameter. Most nuclei are spherical, but multilobed nuclei are common, such as those found in polymorphonuclear leukocytes or mammalian epididymal cells. The nucleus is bordered by a double-membrane nuclear envelope that contains **nuclear pore complexes** for macromolecular import and export from and to the cytoplasm.

The nucleus is the repository for the complex eukaryotic genome. It normally consists of unique, middle-repetitive, and highly repetitive sequences, defined by renaturation kinetics(5) (see **C_0t curve**). Generally, unique DNA includes single-copy **genes** and unique but nontranscribed sequences. Middle-repetitive DNA contains genes with multiple copies, such as those found in the tandem arrays of repeated genes for histones or the 47S RNA precursor for ribosomes and the spacer sequences that separate the individual genes within these clusters. Highly repetitive sequences include relatively short DNA elements that constitute, for example, the centromeres of chromosomes. Highly repetitive, noncentromeric sequences have also been detected. Examples include the 5S ribosomal genes (over 20,000 copies per haploid ***Xenopus*** genome), the L1 transposable elements that constitute about 4% of primate genomes, and the *Alu* pseudogene/transposable elements that constitute about 5% of the human genome .

The eukaryotic cell must efficiently package all of its genomic DNA (which in human cells has a combined linear length of more than one meter) within a nucleus with a diameter of only 5 μm. Yet the manner in which the DNA is packaged must also accommodate the complex processes of DNA replication, recombination, DNA repair, and transcription . Chromatin is the term used to described the packaged genome. It consists of genomic DNA, a nearly equal mass of histone proteins, a relatively small amount of non-histone chromosomal protein, and some nascent RNA. The most basic structural unit of chromatin is the nucleosome, which consists of approximately 146 bp of genomic DNA wrapped around a complex of eight histone molecules. In the presence of histone H_1, nucleosomes condense to form a solenoid with a diameter of 30 nm and six nucleosomes per turn. The solenoid is cast into looped domains that are attached to the interphase nuclear matrix by adenine/thymine-rich DNA elements called matrix attachment regions (MARS). Such compacted chromatin is then organized into one or more chromosomes. The complexity of chromosomal structure within the nucleus is well illustrated by the lampbrush chromosomes of the nucleus of the amphibian **oocyte** (Fig. 1).

Figure 1. A phase contrast image of portions of lampbrush chromosomes isolated from an oocyte nucleus of the North American newt, *Notophthalmus viridescens*. The chromosomes were centrifuged onto a microscope slide and fixed with formaldehyde. Lateral loops of transcriptionally active DNA display nascent ribonucleoprotein matrices (arrow heads). Multiple nucleoli (arrows) within the oocyte nucleus produce enormous numbers of ribosomes. These particular nucleoli have partially fragmented during preparation. Many other small ribonucleoprotein particles are clearly evident (see text). Photomicrograph was kindly provided by Dr. Joe Gall, Carnegie Institution of Washington, Department of Embryology.



Ultrastructural examination of glutaraldehyde-fixed interphase cells reveals patches of condensed chromatin within their nuclei, usually just beneath the nuclear envelope or near the nucleolus. The term **'heterochromatin'** was defined by E. Heitz in 1928 to describe chromatin that remains condensed when the chromosomes normally decondense in the late **telophase** and early **interphase** of the cell cycle. Because of its condensed state during the interphase, this heterochromatin is generally believed to be transcriptionally silent. Different cell types contain different amounts of heterochromatin. Metabolically active cancer cells, for example, display very little condensed chromatin, whereas orthochromatic erythroblasts (red blood cells that will soon lose their nuclei) contain large amounts of condensed chromatin(7). There are actually two types of heterochromatin. Constitutive heterochromatin remains condensed throughout the cell cycle and development. This chromatin contains highly repetitive sequences that play a structural role in chromosomal structure and mechanics (ie, centromeric DNA functioning in chromosomal movement during **mitosis**) rather than actual **gene expression**. Facultative heterochromatin has the potential for gene expression at some point in development, and it can be either condensed or decondensed, depending on the cell type. The mammalian Barr body is a excellent example of facultative heterochromatin. The Barr body is one of the two **X-chromosomes** in mammalian female cells. It remains condensed during the interphase and is almost completely silent in transcription(8), whereas the other X-chromosome in the cell is decondensed and transcriptionally very active. Euchromatin is the term used to describe decondensed interphase chromatin that is either transcriptionally active or has the potential for transcription.

Replication of eukaryotic chromosomes requires elaborate DNA polymerase complexes that replicate the entire genome within the physical confines of the nucleus (see **DNA replication)**. To replicate the enormous lengths of eukaryotic chromosomes, several autonomously replicating sequences (ARS), situated along the length of each chromosome, initiate replication in both directions along the DNA, thus leading to rapid replication of the entire chromosome. Eukaryotic genomic replication occurs during the interphase of the cell cycle, specifically during the **S-phase** between growth phases 1 and 2 (G_1 and G_2). The precisely timed onset of DNA replication is controlled by elaborate signal transduction cascades that work in conjunction with cyclin-dependent

kinases (see Cell Cycle). Enhanced production of new histone proteins is concomitant with genomic DNA replication to ensure the timely packaging of the nascent DNA. **Telomeres** are unique structures at the very ends of chromosomes that provide for completion of their replication(9) and also interact with the nuclear envelope during **meiosis** (10, 11), perhaps to help align the chromosomes for recombination.

Fully replicated chromosomes condense during mitosis in preparation for orderly segregation into progeny cells. Each mitotic chromosome consists of two sister **chromatids** held together by their centromeres. Centromeres play a structural/mechanical function in chromatid segregation during mitosis and meiosis. They are sites for peripheral **kinetochoric** assembly during the **prophase**, one kinetochore for each chromatid. A set of microtubules from the mitotic spindle attaches to the kinetochores to align the chromosomes on the **metaphase** plate. At **anaphase**, the centromeric connection between the chromatids splits, and the kinetochoric microtubules depolymerize to "pull" the separated chromatids (now called chromosomes) toward opposite poles of the spindle.

2. Genomic Expression

Transcription is the initial step in **gene expression** in the nucleus. Transcription units (TU) are defined as thin-to-thick ribonucleoprotein (RNP) fibrils that remain attached to active **RNA polymerase** complexes on genes as viewed by electron microscopy of spread chromatin preparations (13) or of the transcriptionally active loops of lampbrush chromosomes (14; Fig. 1). The nascent RNP fibrils are shortest near transcription start sites, and they are longest near transcription stop sites (the so-called "Christmas tree"). The pre-messenger RNA resulting from transcription of genes that encode proteins is also known as heterogeneous nuclear RNA (**hnRNA**). Almost immediately after its synthesis by RNA polymerase II, the 5′ ends of the nascent hnRNA are capped with a 7-methyl guanine nucleotide (see **5′-Cap**). The cap is important for transporting the mature mRNA from the nucleus, for protecting of the 5′ end from exonucleases, and for recognizing the mRNA by translational initiation factors within the cytoplasm. Polyadenylation of pre-mRNA also occurs in the nucleus before mRNA export, and is generally believed to stabilize the transcripts in the cytoplasm.

The ribosomal RNA (rRNA) genes are transcribed within the nucleolus. The precursor rRNA is processed to yield the mature 18S, 5.8S, and 28S rRNA found in cytoplasmic ribosomes.

2.1. Spliceosomes and Heterogeneous Nuclear RNA Processing

One of the most important aspects of eukaryotic gene expression, other than the transcription of the gene itself, is the precise splicing of premessenger RNA (pre-mRNA) transcripts, first to remove nonprotein coding **introns** and then to join (ligate) the protein-coding **exons** (see RNA Splicing). Both events must occur precisely to maintain the proper protein translational reading frame. Sequences within the nascent transcript direct the assembly of the nuclear splicing machinery. Nuclear ribonucleoprotein (RNP) particles that mediate the transesterification and ligation reactions of splicing are called **spliceosomes**. They consist of five different small nuclear RNP particles (snRNP). Each snRNP consists of a unique **small nuclear RNA** (snRNA), either U1, U2, U4, U5, or U6. The snRNP particle is referred to by its constituent snRNA (eg, the U1 snRNP). In addition to the snRNA, each snRNP consists of proteins that are either unique to the specific snRNP particle (eg, the 70-kDa U1-specific protein) or common to the different snRNP (ie, the snRNP core proteins). The common proteins initiate snRNP complex formation upon recognizing a single-stranded region of the snRNA at the Sm site.

Spliceosome assembly is a complex process involving the various snRNPs and the pre-mRNA. Auxiliary proteins are also involved in either spliceosome assembly or pre-mRNA splice site selection where alternative donor and acceptor splice site choices are possible. Upon excising the intron and ligating of the two exons, the spliceosome disassembles, and the ligated, processed mRNA is released. Individual snRNPs are conserved and reutilized for other splicing reactions.

The genes for transfer RNA in yeast, wheat germ, and vertebrates also contain small introns (6 to 80 nucleotides) just downstream of the central anticodon region. These introns are removed by endonuclease activities, and the two halves of the tRNA are ligated(15).

3. Subnuclear Organelles, Compartments, Particles, and their Functions

3.1. The Nuclear Envelope

The nucleus is bordered by two membrane bilayers—the nuclear envelope. Metabolically active cells (eg, the *Xenopus* oocyte) may display folds or blebs in the nuclear envelope as a mechanism to increase its surface area. The outer membrane is continuous with that of the endoplasmic reticulum. In fact, some electron micrographs show ribosomes on the surface of the outer nuclear membrane. The space between the two nuclear membranes, the perinuclear space, is continuous with the lumen of the endoplasmic reticulum. The nuclear side of the inner membrane is lined with a laminar matrix (the nuclear lamina) that consists of nuclear **lamins** A, B, and C, each an intermediate filament-type protein. The lamina lends support and shape to the nucleus and is considered part of the nuclear matrix.

The inner and outer membranes fuse at the nuclear pore complexes that traverse both bilayers. Nuclear pore complexes mediate bidirectional transport of macromolecules between the nucleus and the cytoplasm (see Nuclear Import, Export). An individual pore complex displays eightfold symmetry and is a huge macromolecular assembly with a combined mass of approximately 124 megadaltons.

3.2. Nuclear Matrix

The nuclear matrix is a three-dimensional fibrogranular latticework that permeates the nucleus but has been elusive to define completely. Components include the nuclear envelope with its pores, interchromatin RNP granules, perichromatin RNP fibrils, the nucleolus, tightly bound chromatin (matrix attachment regions, MARS), and associated pre-mRNA. Chromatin does not simply occupy random placement within the interphase nucleus (16, 17). Instead, specific regions of euchromatin and heterochromatin associate with the nuclear envelope(18). Observations such as these suggest that specific three-dimensional positioning of genetic loci occurs within the nucleus. This is an important aspect of the gene gating hypothesis of Blobel(19), which originally proposed that nuclear pore complexes, the nuclear lamina, and components of the nuclear core (the matrix) topologically position (eg, gate) transcribable chromatin near the envelope pores for efficient export of the mRNA.

3.3. The Nucleolus and Ribosomal Subunit Production

The nucleolus is the most conspicuous organelle within the interphase nucleus. Our traditional understanding of the nucleolus is that it is responsible for (1) synthesizing a large nascent precursor ribosomal RNA (pre-rRNA) that is 47S in mammals and approximately 13,000 nucleotides long in humans; (2) the processing (cleavage and base modification) of this RNA to yield mature ribosomal RNA of 18S (2,000 nucleotides), 5.8S (160 nucleotides), and 28S (5,000 nucleotides); and (3) the concomitant assembly of these RNAs with incoming ribosomal proteins to generate small and large ribosomal subunits that then pass into the cytoplasm (see Nucleolus).

Three distinct ultrastructural regions constitute the prototypical interphase nucleolus: the fibrillar center (FC), the surrounding dense fibrillar region (DFR), and the peripheral granular region (GR). Particles of preribosomal subunits are visible within the GR and are 15 to 20 nm in size. Vacuoles are sometimes found within nucleoli, but their significance is unknown. The relative sizes and distributions of the three principal nucleolar compartments vary among different cell types and among different metabolic states and cell cycle phases within the same cell type (21, 22).

The number of nucleoli per nucleus also differ. The yeast cell contains one relatively large nucleolus with respect to its nuclear volume, and most metazoan cells display one or a few nucleoli. At the other extreme, *Xenopus* oocytes contain over 1000 nucleoli per nucleus (germinal vesicle) because of selective ribosomal DNA **amplification** in the very early stages of meiosis I (pachytene). These

multiple nucleoli are independent of the lampbrush chromosomes within these oocytes (see Fig. 1), a unique feature that allows exclusive study of nucleoli without interference from nonnucleolar chromatin. These nucleoli produce an incredible 300,000 ribosomes per second during mid-oogenesis in *Xenopus* .The number of nucleoli per nucleus also varies during the cell cycle. For example, cells in the early interphase may show several small nucleoli that reflect the number of NOR unique to the species. As the interphase progresses, the small nucleoli may fuse to reduce the number of nucleoli.

Nucleoli originate from and are intimately associated with the nucleolar organizer regions (NOR) that appear as secondary constrictions within certain ("nucleolar") mitotic chromosomes(20). The NOR are genetic loci that contain repeated 47S ribosomal RNA genes in tandem array. Each gene within the array is separated by intergenic spacer regions. The repeated ribosomal RNA genes each encode (in order) an external transcribed spacer, the 18S region, the first internal transcribed spacer, the 5.8S region, the second internal transcribed spacer, and finally the 28S region. Processing of the nascent transcript yields mature 18S, 5.8S, and 28S rRNA found in cytoplasmic ribosomes. The precise site of transcription has been controversial, although fibrillar centers (FC) of interphase nucleoli clearly contain ribosomal DNA. Good arguments place transcription within the FC, within the DFR, or on the borders between the two compartments . Nascent transcript processing (cleavage, folding, and base modification) and early ribosomal subunit assembly clearly take place within the DFR. Processing events include cleavage of the nascent transcript into smaller intermediates and then into the individual mature rRNA molecules, site-specific methylation of the pre-rRNA, and conversion of specific uridine residues to pseudouridine (see Ribosomes). Processing of the 47S transcript into the 18S rRNA (for the small ribosomal subunit) and the 5.8S and 28S rRNA (for the large subunit) occurs concomitantly with the association of ribosomal proteins that enter the nucleolus from their site of synthesis in the cytoplasm (there are approximately 85 different ribosomal proteins).

The 5S rRNA is transcribed by RNA polymerase III from multiple tandem genes that exist in genomic clusters outside the nucleolus. How the 5S transcripts make their way to the nucleolus and associate with the large ribosomal subunit remains uncertain. Assembly of large and small ribosomal subunits is a vectoral process beginning at the site of 47S RNA synthesis. By the time the particles reach the GR, the ribosomal subunits are nearly complete. Their assembly is completed once the subunits translocate to the cytoplasm, where a few more ribosomal proteins join the complexes. The large and small subunits finally associate as a complete ribosome in the recognition and translation of mRNA in the cytoplasm (see Translation).

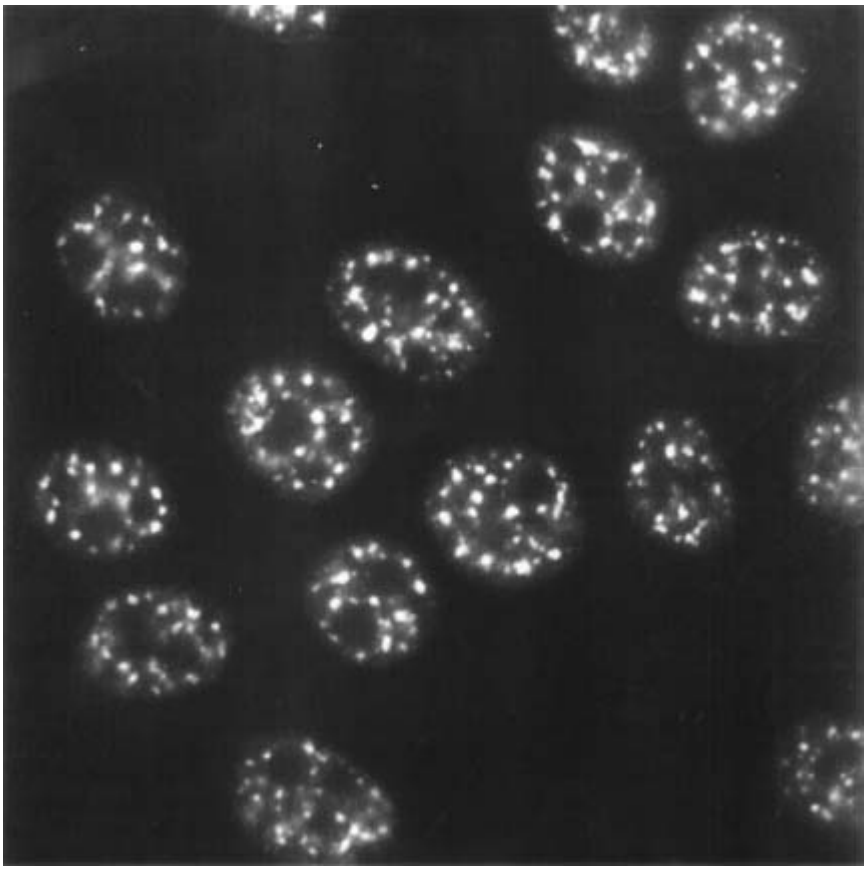
3.4. Nuclear Distributions of Splicing Components

Antibodies against spliceosome components have been used in **immunofluorescence microscopy** to localize the sites of splicing and the nascent pre-mRNA within the nuclei of various cell types. The amphibian oocyte that has large lampbrush chromosomes has been particularly informative (25, 26). Antibodies directed against snRNPs or the splicing factor SC35 stain the lateral loops of giant lampbrush chromosomes within *Notophthalmus viridescens* (newt) oocytes (Fig. 1). The chromosomal loops are sites of active transcription, and their staining with antibodies directed against splicing components strongly argues that initial splicing events occur while the transcripts are still attached to RNA polymerase II. Beautiful electron micrographs of active *Drosophila* **chorion genes** clearly show the processing of nascent transcripts while still associated with RNA polymerase II(27).

Antibodies directed against splicing components brightly stain a limited number of discrete foci above a lightly and uniformly stained background in interphase nuclei. For example, anti-Sm antibodies stain 20 to 50 foci in the interphase nuclei of CHOC 400 cells (Fig. 2) (24, 28). These speckles, as they are called, contain interchromatin granule clusters (IGC) interconnected by perichromatin fibrils (PF) to form a nuclear latticework. Functionally, the ICG may be centers for snRNP assembly and distribution, whereas the PF are sites of pre-mRNA synthesis and splicing as the transcripts make their way to the nuclear envelope. This latticework of clusters and

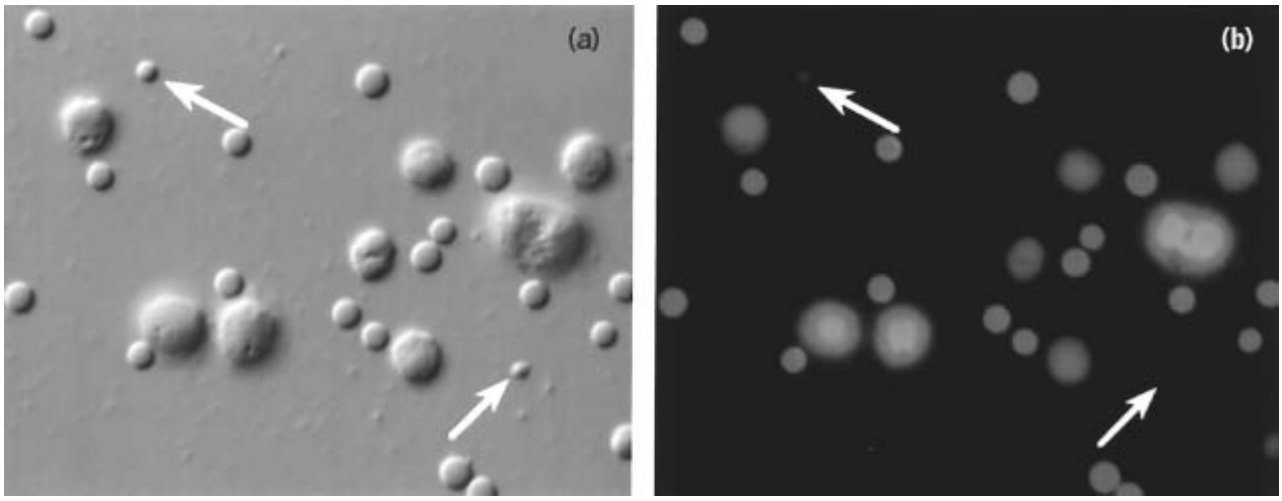
interconnecting fibrils is a dynamic structure that changes its morphology in response to changes in cell and nuclear physiology. In addition, the speckles themselves disassemble during mitosis and reassemble during the interphase. The existence and distinct distribution of the speckles within the interphase nucleoplasm clearly emphasizes the structural and functional compartmentalization of the interphase nucleus (Fig. 2).

Figure 2. Factors involved in pre-mRNA splicing are organized in a speckled distribution pattern in the interphase nuclei of mammalian cells. The speckles are composed of both interchromatin granule clusters (IGC) and perichromatin fibrils (PF). The PF represent sites of active transcription, and the IGC are thought to be storage and/or reassembly sites for splicing factors. Photomicrograph was kindly provided by Dr. David L. Spector, Cold Spring Harbor Laboratory.



Using antibodies directed against the Sm antigens and the unique trimethylguanosine cap of snRNA in conjunction with *in situ* hybridizations to detect snRNA, Wu et al. (26)described three types of snRNP-containing granules (A, B, and C types), which are called “snurposomes”(29). Although the antibodies also stain the lampbrush chromosomes, for the most part these granules are independent of the chromosomes. The A granules contain exclusively U1 snRNP, whereas the B granules (Fig. 3) contain all five snRNPs(26). The C granules are most interesting. They are the originally described sphere organelles(30) found near or at the histone gene clusters on the large lampbrush chromosomes of at least two amphibian species (31-33). The C granules contain the U7 snRNP(34) reserved for histone transcript processing(35). Interestingly, B particles often reside on the surface of C granules or within C granules as inclusion bodies, but the functional significance of this relationship remains unknown.

Figure 3. Contents from a *Xenopus laevis* oocyte nucleus spread for light microscopic examination. (**a**) DIC image. The multiple nucleoli were stained with propidium iodide. Arrows show micronucleoli. (**b**) Snurposomes were stained with monoclonal antibody Y12 which specifically binds the Sm epitope of several snRNP proteins. See the text for descriptions of the nucleoli, B snurposomes, snRNP proteins, and Sm epitopes. Photomicrographs were kindly provided by Dr. Joe Gall, Carnegie Institution of Washington, Department of Embryology.



3.5. Coiled Bodies

Coiled bodies were first discovered by Ramón y Cajal in 1903(36) as nucleolar accessory bodies in neuronal cell nuclei, but their function remains uncertain. They were described in detail as internal coiled fibers at the ultrastructural level by Monneron and Bernhard(37), who first used the name coiled bodies. The bodies are spherical, have diameters of 0.5 μm to 1 mm, and are found in both plant and animal cell nuclei. One to five coiled bodies exist per nucleus. The molecular constitution of coiled bodies has been examined only recently (24, 38-40). The protein p80-coilin is highly enriched in the coiled body and is considered a marker for the coiled body, although it has also been detected throughout the nucleus in relatively low concentrations (38, 41, 42). Its function is unknown.

Evidence suggests that the coiled body is related to the C snurposome (see previous): (1) Sph-1, a resident protein of the sphere organelle, is structurally homologous to p80-coilin(43); (2) antibodies directed against human p80-coilin stain the C granules intensely; (3) when mRNA-encoding, epitope-tagged, human p80-coilin was injected into *Xenopus* oocytes, the protein quickly localized to the C granules. Therefore coiled bodies and amphibian sphere organelles are likely to be similar in function. As in the case of amphibian C granule/sphere organelles, antibodies against Sm antigens and trimethylguanosine cap structures stain coiled bodies and, like the sphere organelles, coiled bodies in human and mouse culture cells contain high concentrations of U7 snRNA(44). Significant differences exist between coil bodies and the amphibian sphere organelles, however. First, unlike the sphere organelles, where only U7 snRNP has been detected, all five mRNA-splicing snRNAs (U1, U2, U4, U5, U6) have been detected within coiled bodies by ***in situ* hybridization**. Parenthetically, the coiled bodies are not the speckles described before because the splicing-dependent SC35 protein has not been observed within coiled bodies. Secondly, whereas no nucleolar components have been found in amphibian sphere organelles, fibrillarin and snRNA U3 (components intimately associated with nucleoli and preribosomal RNA processing, see Nucleolus) have been detected in coiled bodies of cultured cells (41, 45). As originally reported by Ramón y Cajal(36), coiled bodies closely associate with nucleoli(46) , but the physiological significance of this association remains uncertain.

Novel nuclear particles, referred to as Gemini of coiled bodies (Gems), were recently identified in HeLa cell nuclei using monoclonal antibodies against the spinal muscular atrophy (*SMN*) gene product(47). The SMN protein of 32 kDa binds several hnRNP proteins and the nucleolar protein,

fibrillarin, to form nuclear particles that closely resemble and associate with coiled bodies. Although closely related to coiled bodies in size and composition, Gems may be more closely related to the amphibian sphere organelles (C snurposomes). Their function remains unknown.

4. Mitotic Regulation of Nuclear Disassembly and Reassembly

For cells to divide, the nucleus must disassemble, and the genome must be divided exactly in two. Impressive intracellular reorganizations occur with the onset of **mitosis**. Cytoplasmic microtubules disassemble into tubulin dimers that then reassemble to form the **mitotic spindle**. The endoplasmic reticulum and the Golgi apparatus vesiculate. The nuclear envelope and nucleoli disassemble, and chromatin supercondenses. The onset of mitosis is driven by the activity of maturation promoting factor (MPF), a complex between cyclin B and $p34^{cdc2}$ kinase(48). MPF in turn is regulated by several factors and signal transduction events, one of which is the completion of genomic DNA synthesis and any requisite DNA repair. The driving mechanism behind these morphological changes is **phosphorylation** of cellular constituent proteins directly or indirectly by MPF (see **Mitosis**).

Nude Mice

Nude mice were first described in 1963 as hairless animals. The defect is the consequence of a recessive mutation of the "nu" **gene**, located on chromosome 11. It was subsequently found that these mice were also athymic, which rendered them highly susceptible to infectious diseases and necessitated that they be maintained in a strictly controlled microbiological environment. Because of the absence of a thymus, they are unable to mount **T-cell**-dependent immune responses and are especially lacking cell-mediated immunity. It is thus possible to transplant to these mice not only **allogenic** tissues, but also tissues of **xenogenic** origin.

T cells classically develop in the thymus, because the thymus provides the necessary epitheliostromal environment. In nude mice, there is no thymus, but T cells develop very slowly and may reach more than 10% of the amount found in normal mice. These T cells may express either the TCPab or the TCRgd T-cell receptors, although at a much lower density. The CD3 signaling module is also present, so the TCR is potentially functional.

B cells are present in normal amounts; but, as would be anticipated, **isotypes** that require T-cell help for class switching are absent or extremely reduced. Circulating IgM is present in normal amounts, but **IgG1**, IgG2a, IgG2b, and IgAare present only at very low levels. IgG3, which may be produced in response to T-independent **immunogens**, such as polysaccharides, is present in normal amounts. One role of the immune system that is frequently put forward is that of "immune surveillance"—that is, the elimination of potentially occurring tumors. In nude mice, however, there is apparently no impact on a possible increase in the emergence of spontaneous tumors, an observation probably explained by the presence of natural killer (NK) cells in increased numbers over normal mice. Because of the virtual absence of cell-mediated immunity, nude mice have been extensively used as recipients for tumor transplantation or for serial transfer of hybridomas as a source of monoclonal antibodies.

Null Mutation

A null mutation is a mutation that causes complete loss of gene function. The mutation that causes a null mutant can be of any class, for example, point mutations, deletions, or insertions.

O-Linked Oligosaccharides

There are three major types of O-glycosylation:(*1*) Mucin-type O-glycosylation;(*2*) Glycosylation leading to the formation of proteoglycans; and(*3*) O-mGlcNAc glycosylation of cytoplasmic and nuclear proteins.O-GlcNAc glycosylation involves only the addition of a single hexosamine, but the other two types of glycosylation, although using only a limited number of sugars, lead to the formation of O-glycans with a wide variety of structures.

1. O-glycans Added to Mucin Core Proteins

The sugars commonly found in the O-glycans added to mucins in higher **eukaryotes** are the hexosamines N-acetylgalactosamine (GalNAc) and N-acetylglucosamine (GlcNAc), the monosaccharides galactose (Gal) and fucose (Fuc), and sialic acid (SA), some of these sugars, as well as tyrosine residues in the core protein, may be **sulfated**. Sugars are added individually and sequentially in the Golgi apparatus, and the structure of the final O-glycan is generally thought of as being made up of three elements; (*1*) a core structure built on the linkage sugar, GalNAc; (*2*) a chain extending from the core, generally made up of repeating lactosamine units; and (*3*) a terminal region often containing **epitopes** recognized by naturally occurring **antibodies**:

GalNAc core—lactosamine chains—terminal epitopes (1)

O-glycans may be released from **glycoproteins** by hydrazine or by b-elimination in alkaline borohydride solution of the reduced form containing terminal GalNAcol residues. After purification, analysis of the released O-glycans has been carried out using **mass spectrometric** methods, methylation chemical analysis, and nuclear magnetic resonance (NMR) techniques (1). When only a few O-glycans are added to a core protein, their structure is usually simpler than that of the O-glycans found on the mucins, which carry multiple side chains. Analysis of the O-glycans from mucins shows a high degree of structural heterogeneity, but whether the heterogeneity is between or within individual mucin molecules is not clear. These preparations have been derived from tissues that contain different cell phenotypes, which could exhibit different profiles of expression of the glycosyltransferases involved in the synthesis of the O-glycans, resulting in a population of different glycoforms where an individual molecule carries only one kind of structure. On the other hand, the addition of multiple O-glycans during transit through the Golgi apparatus may necessarily result in heterogeneity of both chain initiation and extension. The core proteins are extremely large and, after the addition of the first sugar, must be quite extended. It is easy to imagine how all the sites on the protein and on the extending chain might not be found by the relevant transferase(s).

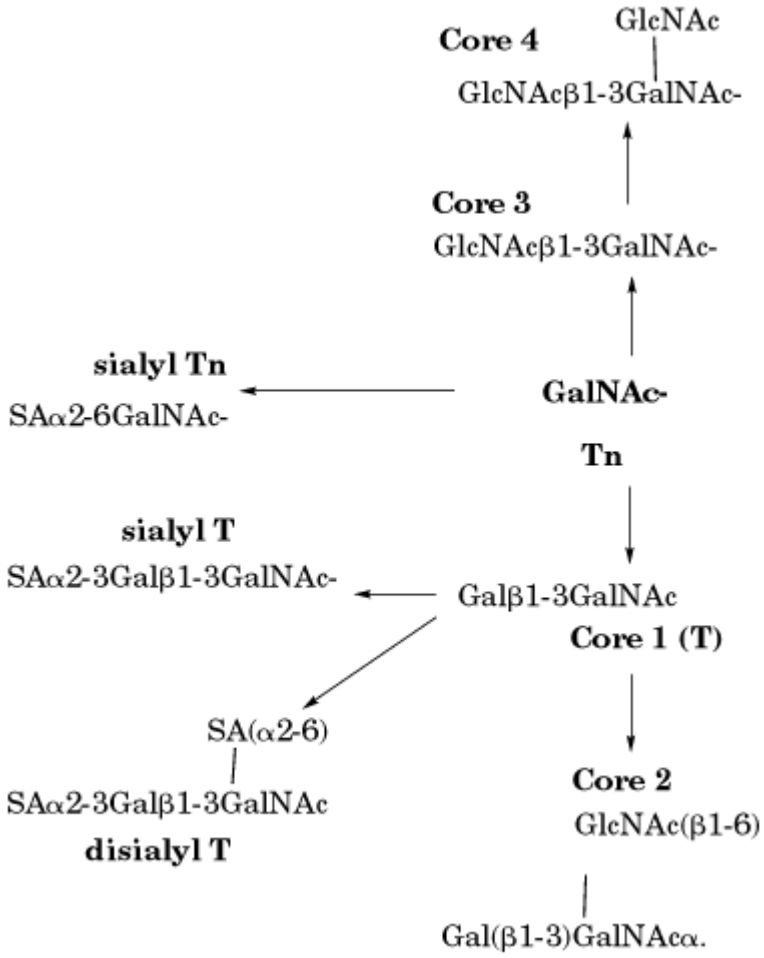
In addition to a complete analysis of the O-glycan structure, components may be detected with specific antibodies, such as those reacting with the common blood group antigens, which recognize terminal sugars, or those reacting with the branched and unbranched polylactosamine chains (I and i

antigens, respectively).

1.1. Core Structures

It is possible for an O-glycan to consist only of the initial sugar GalNAc, and this has been referred to as the Tn antigen. More often, core structures are formed by the addition of GlcNAc and/or Gal units, or the chain is terminated by the addition of sialic acid, forming the sialyl Tn epitope that is specifically expressed in carcinomas. Figure 1 shows the main core structures that have been identified to date as being present on mucins. Core 1 and core 2 are by far the most common structures.

Figure 1. Main core structures found on mucins.



Core 1, also referred to as the T antigen, may be found as such, particularly on mucins produced by carcinomas, but it is often sialylated in normal cells to give the mono- or disialylated T antigen. The reaction catalyzed by the core1 b3-Gal-T (UDP-Gal:GalNAc-R b 1,3-Gal-transferase) is:

$$\text{GalNAc}\alpha\text{R} + \text{UDP Gal} \rightarrow \text{Gal}(\beta 1-3)\text{GalNAc}\alpha\text{R}. \quad (2)$$

A **gene** coding for the mouse enzyme has only recently been cloned, and it remains to be seen how many enzymes catalyze this reaction, and whether the peptide sequence flanking the glycosylation site affects the specificity.

An important point is that core 1 can be a substrate not only for sialyltransferases that add sialic acid

in a-linkages and thus terminate the chain, but also for the core 2 enzyme, which is crucial for chain extension to proceed. Studies with cells transfected with these enzymes indicate that the two enzymes can compete for the core 1 substrate and therefore overlap in the Golgi apparatus. Differences in the activities of these enzymes, operating at an early stage of O-glycan synthesis, can therefore dramatically affect the final structure of the O-glycan and can explain the differences in the structure of the O-glycans added to MUC1 in breast cancer (1) or to leukosialin in T cell activation (ref 17 of O-glycosylation.)

Core 2 is generated from core 1 by enzymes catalyzing the reaction:

$$UDPGlcNAc + \mathrm{Gal}(\beta 1-3)\mathrm{GalNAc}\alpha\mathrm{R} \rightarrow \mathrm{GlcNAc}(\beta 1-6)[\mathrm{Gal}(\beta 1-3)]\mathrm{GalNAc}\alpha\mathrm{R} \quad (3)$$

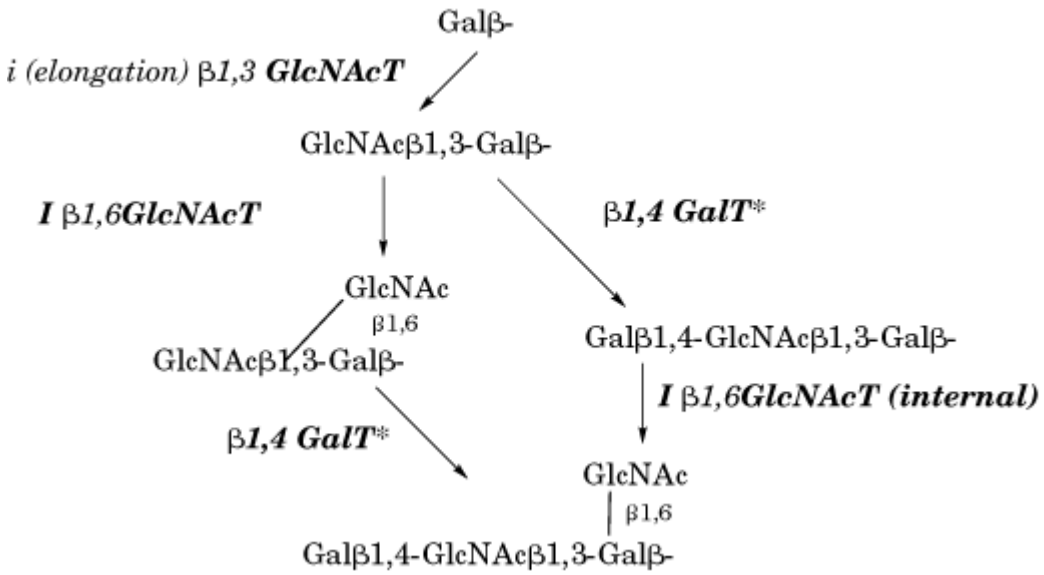
Two enzymes have been shown to catalyze the formation of core 2: the L enzyme, which catalyses only this reaction and for which the gene has been cloned (2), and the M enzyme, which has a wider substrate specificity and can also catalyze the formation of core 4 and internal chain branching. Changes in the level of activity of the enzyme(s) catalyzing the synthesis of core 2 have a profound effect on O-glycan structure in a wide variety of cell types.

Core 3 synthesis precedes Core 4 (see Fig. 1), and the enzymes catalyzing the synthesis of these structures have only been found in mucin-secreting tissues, such as those of the respiratory tract and the colon. Core 4 structures are more predominant than core 3, and because the transfer of GlcNAc to core 4 proceeds at a much faster rate than the b3-GlcNAc transferase making core 3, the activity and tissue distribution of the core 3 b3-GlcNAcT are the limiting factors in the synthesis of core 4. The enzyme catalyzing the synthesis of core 4 shows limited distribution, but it can also catalyze the synthesis of core 2 from core 1.

1.2. Backbone of O-Glycans

The elongation of O-glycans involves the addition of GlcNAc residues to Gal in b-1,3 or b-1,6 linkage and of Gal to GlcNAc in b-1,3 or b-1,4 linkage, to form linear and branched poly-N-lactosamine structures, as illustrated in Figure 2. Extension of the O-glycans based on core 2 can occur by the addition of sugars to either the Gal or the GlcNAc moieties. When extension is from core 4, galactose can be added to either glucosamine.

Figure 2. Elongation pathways forming the backbone of O-glycans.



(*1*) The elongation b3-GlcNAc transferase catalyses the addition of GlcNAc in b-1,3 linkage to Gal on core 1 and core 2. (See Fig. 1 for the structures of core 1 and core 2.) The enzyme shows limited distribution and may be reduced in cancers of the colon and breast. Elongation from core 1 prevents the formation of core 2, but it seems likely that core 2 is usually formed before elongation from Gal occurs.

(*2*) The i b3GlcNAc transferase enzyme adds GlcNAc to Gal in chains that have already been extended from cores. This enzyme is found ubiquitously and catalyzes the addition of GlcNAc alternately with Gal, producing a linear chain that is the blood group i antigen.

(*3*) The I b6-GlcNAc transferases are responsible for the formation of the blood group I antigen found on adult human erythrocytes, where it replaces the i antigen found in the fetal cells. The I antigen represents the branch initiated by these enzymes either immediately after the action of the b3 GlcNAc transferase or after the addition of lactosamines (see Fig. 2), and such branched O-glycans are found on many mucin-type molecules.

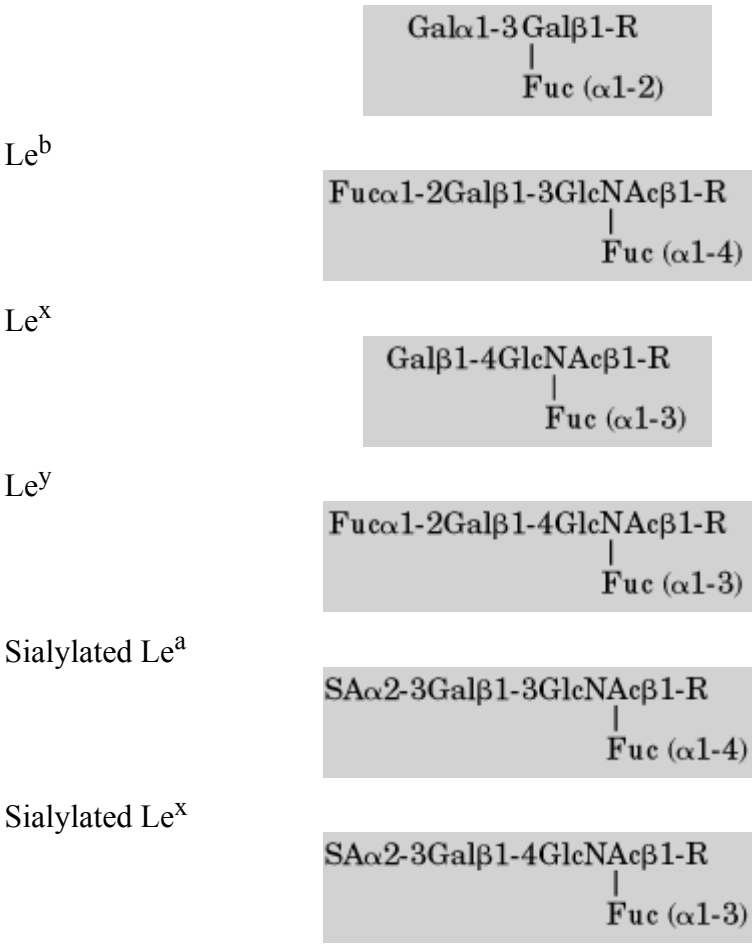
(*4*) The b-1,4 and b-1,3 galactosyltransferases add galactose from a UDP-Gal donor to GlcNAc in the growing polylactosamine chain in either b-1,4 or b-1,3 linkage. When the linkage is b-1,4, the chain is referred to as type 2, whereas the b-1,3 linkage is type 1. Both types of chain may be linear or branched.

1.3. Terminal Glycosylation

The terminal epitopes of the O-glycans on mucins are probably the most important in determining whether the molecule plays a role in cell adhesion phenomena. The epitopes recognized by antibodies related to the ABO and the Lewis blood group antigens are also found in this terminal region. Terminal sugars added in alpha linkage include sialic acid, Fuc, Gal, GalNAc and GlcNAc; Table 1lists some of the more important structures. Some sulfation of the sugars in terminal structures may also occur.

Table 1. Terminal Epitopes in Mucin O-glycans

Antigen	Structure
Blood group A	GalNAcα1-3Galβ-R | Fuc (α1-2)
Blood group B	Galα1-3Galβ1-R | Fuc (α1-2)
H (masked by A and B)	Fucα1-2Galβ1-R
Le[a]	



Sialyltransferases that are clearly specific for O-glycans are those that add sialic acid in a2-6 linkage to GalNAc(Tn) or in a2-3 linkage to core 1 (Galb1-3 GalNAc). O-glycans with an SA in a2-6 link to GalNAc(Tn) cannot be acted on by any known transferase. This link can be formed however, after the addition of SA in a2-3 linkage to Gal. The shorter O-glycans (ie, Tn, T, and their sialylated derivatives), are found on mucins expressed by some carcinomas, and the change from the normal glycosylation pathway has been analyzed in greatest detail in breast cancer (1). Several genes coding for sialyltransferases responsible for terminating the short O-glycans have been cloned (3) and show differing substrate specificities: some can synthesize the same linkage in glycolipids. Because of the multiplicity of glycosyltransferases, it is only by cloning the individual genes, thereby allowing work with the recombinant enzymes, that the biosynthetic pathways will be unambiguously clarified.

The position of glycosyltransferases in the Golgi apparatus also plays a significant role in whether the enzymes can act on a particular substrate. One of the sialyltransferases that add SA in a2-3 linkage to Gal in core 1 has been localized to the medial/*trans* Golgi stacks, with some found in the *trans* Golgi network (TGN). This is a relatively early position and allows competition with the core 2 enzyme and possibly the elongating enzymes (see ref. 12 of O-Glycosylation). It is assumed that the sialyltransferase that adds SA to Gal at the end of the extended chains may be located further down the Golgi pathway in the *trans* Golgi or TGN, but this has not been clarified. The location probably also relates to whether the same enzyme can add SA to lactosamine chains in both N and O-glycans. The sialylated derivatives of the Le^a and Le^x antigens terminating lactosamine chains are proving to be of great interest, as they appear with the change to malignancy in some tissues (4) and constitute the epitopes on the selectin ligands expressed by normal cells.

Fucosyltransferases form a large group of enzymes, and genes for several of these transferases have been isolated (5). They are involved in chain termination and are of particular interest in the synthesis of blood group antigens and in the sialylated derivatives of Le^x and Le^a that form the epitopes on selectin ligands. At least four a3-fucosyltransferases exist (a3 Fuc-T-III to-VI) that add fucose in a1–3 linkage to form the Le^x epitope illustrated in Table 1. Of these, Fuc-T-III has the broadest substrate specificity, because it can act on type 1 or type 2 structures and also add fucose in a1–4 linkage, thus synthesizing several human blood group epitopes (Le^a, Le^b, Le^x, and Le^y as well as sialyl Le^a and sialyl Le^x). When added in this position, fucose terminates the chain and needs to be added after sialic acid to create the sialylated Lewis epitopes.

1.4. Functions of O-Glycans

Extracellular mucins such as MUC2 form large oligomers, and although dimerization and some oliogomerization occur within the cell, the interactions that continue after secretion into the mucous layer depend to a large extent on the presence of the O-glycans. Although the detailed structure of the O-glycans may not be so important for this function, it is relevant that the structures found on the mucins produced in the gastrointestinal and respiratory tracts carry large, complex O-glycans, which probably relate to the protective function that is crucial in these tissues (6). In glandular epithelia such as that in the breast, the O-glycans are shorter and simpler but still extended (7, 8). The carbohydrate side chains also serve to bind invading micro-organisms, and heterogeneity in their structure would serve to allow interactions with a variety of **receptors**. Specific interactions of defined structures present in the O-glycans involved in cell-cell adhesion, however, are now becoming clarified and are of great interest.

Selectin ligands are mucin-like glycoproteins that interact with the selectins expressed on endothelial cells, leukocytes, and platelets (ref. 15 of O-glycosylation). The interaction mediates rolling of leukocytes on blood vessels during inflammation, and, at the molecular level, the O-glycans expressed on the selectin ligand play a major role in determining the specificity of the interaction. The selectins show weak binding of sialylated fucosylated oligosaccharides, such as sialyl Le^x, but bind much more strongly to glycoproteins carrying these O-glycans, which may be sulfated.

P-selectin glycoprotein ligand-1 (PSGL-1) is expressed on leukocytes and interacts with both E-selectin found on endothelial cells and P-selectin on platelets. The specificity of the ligand interaction has been studied by transfecting complementary DNAs coding for glycosyltransferases and PSGL-1 into CHO cells, which lack both the core 2 and the a1–3 fucosyltransferases required for chain extension and for the formation of the Le^x epitope. Only CHO cells expressing both transferases were able to bind to P- and E-selectins (9). Because sialidase treatment also eliminates the binding of PSGL-1, sialyl Le^x has been identified as the specific epitope required for interaction with the selectins. Binding to P- but not E-selectin also requires sulfation of **tyrosine residues** in the core protein. Clearly, the core protein plays a role in the presentation of the O-glycan, possibly by specifying the clustering and conformation, as well as by providing amino acid residues for sulfation.

The appearance of sialylated Le^a in mucins expressed in colon cancer cells suggests that the interaction of the carbohydrate may influence the metastatic process by enhancing binding of the cancer cells to endothelial cells (10).

Sialoadhesin is a molecule expressed at high levels by macrophages (11) that interacts specifically with monosialylated core 1 (sialyl T). Its normal function is thought to relate to interactions with leukocytes. Because this structure is overexpressed on mucins expressed by cancer cells, however, the possibility exists of some interaction between the tumor cells in carcinomas and the infiltrating macrophages.

Membrane mucin MUC1 is unusual among the epithelial mucins in that it is a **transmembrane** molecule and, as such, resembles the selectin ligands. Being widely expressed on glandular epithelial

cells from which carcinomas develop, it is highly expressed by these cancers and aberrantly glycosylated, with the O-glycans being based mainly on core 1 rather than on core 2. This makes the molecule antigenically distinct, and both humoral and cellular responses to the cancer-associated mucin have been seen in breast and ovarian cancer patients. In addition to responses being generated by the whole molecule, it is becoming clear that glycopeptides can be presented by major histocompatibility complex (MHC) molecules. Moreover, peptides carrying larger core 2-based structures are not presented as well as glycopeptides carrying Tn or T (12). The role of O-glycosylation in the immune response is of interest in the wider context, as many **antigens** from infectious agents are glycoproteins carrying O-glycans, including HIV, in which the *env* protein carries a sialyl Tn epitope (13).

2. The O-glycans of Proteoglycans

Proteoglycans are proteins that carry glycosaminoglycan side chains (GAGs), which can range from a simple linear chain of sugars to highly charged, sulfated polysaccharides. Proteoglycans can carry one to more than 100 GAGs, which consist of alternating hexosamines and hexuronic acid or galactose units and carrying sulfated substitutions at various positions.

2.1. Linkage Regions

The GAGs are linked to the protein core via a four-sugar bridge: glucuronic acid b1-3galactoseb1-3galactoseb1-4xylose-O-serine. The attachment of xylose to the serine residue of the protein core is catalyzed by xylosyltransferase (see O-Glycosylation). The linkage region is basically the same for most proteoglycans, and in both chondroitin sulfate and heparin sulfate (see text below), a proportion of the xylose has been shown to be phosphorylated (14). In chondroitin proteoglycans, the galactose residues have also been shown to be sulfated. Skeletal keratan sulfate is unlike the other GAG, as it is O-linked to serine or threonine residues via a GalNAc residue (15), as in mucin-type O-glycans.

2.2. The Glycosaminoglycan Chains

The hexosamines in the GAGs can be either D-glucosamine (GlcN) or D-galactosamine (GalN) and the hexuronic acid either D-glucuronic acid (GlcA) or L-iduronic acid (IdoA). These sugars and galactose are arranged in an alternating unbranched sequence and can carry sulfate substitutions at various positions. Table 2shows the compositions of the common GAGs.

Table 2. Composition of the Common GAG[a] Chains of Proteoglycans

Name	Hexosamine	Hexuronic acid	Galactose
Chondroitin sulfate	Galactosamine	Glucuronic acid	—
Dermatan sulfate	Galactosamine	Glucuronic acid and iduronic acid	—
Keratan sulfate	Glucosamine	—	Galactose
Heparan sulfate	Glucosamine	Glucuronic acid and iduronic acid	—

[a] Key: GAG, glycosaminoglycan.

The inherent structure of the alternation of two types of monosaccharides would be expected to give simple polysaccharide units. Considerable heterogeneity exists within and among the individual

chains, however, due to modification of the repeating units that is often incomplete. This includes sulfate substitutions at differing positions and **epimerization** of carbon 5 of GlcA to form IdoA. For example the biosynthesis of heparan sulfate and heparin is initiated by the formation of [GlcAb1-4GlcNAca1-4]$_n$, which is then N-deacetylated, N-sulfated, and undergoes C5 epimerization of GlcA to yield IdoA. The IdoA units and GlcN can then be O-sulfated. The final product is therefore very diverse, and four distinct HexA and six GlcN units have been identified, allowing 17 different HexA-GlcN and 10 different GlcN-HexA.

Which GAG is attached to which protein depends on the protein core and the cell type. For example, CD44, which can mediate cell adhesion, trafficking, and motility, can be expressed as a chondroitin sulfate or heparan sulfate proteoglycan in a cell-type specific manner (16).

2.3. Function of the GAGs

The biological roles of proteoglycans are many and diverse, ranging from simple mechanical support to playing an important part in cellular recognition, adhesion, motility, and proliferation. Most of these effects depend on the binding of macromolecules to the GAGs; in fact, the anticoagulant and antiproliferative activities of heparin and heparan sulfate are mediated by the free GAG. Most biological activities, however, depend on the GAG in association with the protein core of the proteoglycan. Binding of GAGs to proteins can be highly specific, as in the binding of heparin to antithrombin, or, as is often the case, the interaction can be less specific and usually electrostatic in nature. The biological activities expressed by a single GAG can often be attributed to specific carbohydrate structures. For example, the interaction between heparin and the proteinase inhibitor antithrombin is based on the occurrence in the GAG of a sequence of five specific oligosaccharides. This sequence is composed of three GlcN units, one GlcA unit, and one IdoA unit, with O-sulfate groups at various positions. The key feature of this structure is an O-sulfate group on the internal GlcN, which is essential for the high-affinity binding of the proteinase inhibitor. Another specific sequence that has been defined on GAGs is that involved in the interaction between dermatan sulfate and heparin cofactor II. As many of the genes encoding the core proteins carrying GAGs have been or are being cloned, and as the methodology improves for the sequence analysis of the GAGs, it is likely that many interactions involving highly specific recognition/binding sequences in the GAGs will be found.

3. Concluding Remarks

The structure of O-glycans, synthesized from relatively few building blocks, is made extremely diverse by both the order of the addition of the sugars and the large number of covalent linkages that are possible. Thus the conformation of the O-glycan differs markedly when the same sugar is added to the same substrate in a different linkage (eg, Le^a vs Le^x). These differences in shape can be recognized both by B cells producing specific antibodies and by cell surface receptors such as the selectins. The demonstration of such specificity has generated interest in the role of these interactions in differentiation and in cell-cell adhesion. Moreover, the very large number of genes identified that catalyze the reactions leading to the synthesis of O-glycans emphasizes the importance of their fine structure to the organism. The development of **knockout** mice defective in these genes will go some way toward identifying the crucial functions they control.

Ochre Mutation

An ochre mutation is a nonsense mutation that changes a sense **codon** (one specifying an amino acid) into the stop codon UAA, causing premature termination of the polypeptide chain during translation. The mutation, the codon, and the mutant are all called ochre. Ochre mutations arise by single base changes in the codons for seven amino acids (and in the UGA and UAG stop codons, although these would not be nonsense mutations). In principle, mutations in the anticodons of the transfer RNAs that read those seven codons could give rise to ochre suppressors, but suppressors are recovered only if a second tRNA exists that reads the codon. In *Escherichia coli*, five ochre suppressors that arise by a single base change have been identified. Unlike amber mutations, ochre mutations are suppressed only by ochre suppressors. Ochre suppressors have effects that are much more deleterious than amber suppressors, reflecting the fact that ochre codons are the most frequent stop codon in *E. coli* and related bacteria. Consequently, most ochre suppressors are weak (inefficient at reading ochre codons) and allow most polypeptide chains to be properly terminated. The term ochre first appears in the literature in 1965 (1), apparently coined by Sydney Brenner to

complement amber.

Ochre Suppressor

Ochre suppressors are mutant tRNAs that translate the UAA (ochre) termination codon as a sense codon. Ochre suppressors allow for protein synthesis beyond the translational block resulting in active protein. Due to wobble decoding, most ochre suppressors also decode the UAG (amber) stop codon. Ochre mutations cause protein synthesis to terminate prematurely, resulting in inactive, truncated polypeptides. Hence the term "suppressor;" these mutant tRNAs "suppress" the phenotypes of ochre mutations. These suppressors have been extensively used in prokaryotic genetic studies, and in studies of the translational apparatus and mechanisms. For complete discussions of these and other suppressors, see Nonsense Suppression, Suppressor tRNA, and Genetic Suppression.

Okazaki Fragments

The short stretches of **DNA** attached to RNA **primers** on the *lagging* strand during DNA replication are called *Okazaki fragments*, after their discoverer (see Primer and Leading and Lagging Strands). In other words, the Okazaki fragment is a unit of discontinuous DNA replication on the lagging strand.

Okazaki fragments were first identified during a course of study on the most recently synthesized, or nascent, DNA molecules in the replication of **bacteriophage** T4 DNA (1). Those molecules **sediment** with sedimentation coefficients of about 8 S to 10 S in alkaline sucrose gradients, corresponding to chain lengths of 1000 to 2000 residues. To make such an analysis possible, Okazaki and colleagues developed a **pulse-chase labeling** technique, by which much of the nucleotide precursor label could be captured as the nascent DNA. After the chase, with subsequent exposure to high concentrations of unlabeled precursors, the radioactive precursor was found exclusively in high-molecular-weight DNA. This means that the Okazaki fragments have a very short life-time and are connected to a long stretch of DNA in cells. RNA linked to Okazaki fragments can also be identified, although the RNA primers are removed quickly *in vivo* (2).

In a wide variety of bacteriophages and **prokaryote** cells, the size of the nascent DNA is between 1000 and 2000 nucleotides. In eukaryotic cells, however, the Okazaki fragments are between 100 and 200 nucleotides (3). This difference seems to reflect a difference between prokaryotes and eukaryotes in the rate of chain elongation on the leading-strand template. The velocity of the replication fork movement, which represents the rate of leading-strand DNA synthesis, has been estimated from the size of a replicon and the length of its replication period. In *E. coli*, the replication fork proceeds at 1000 residues per second, and one Okazaki fragment is synthesized every 1 to 2 sec. In eukaryotic cells, the rate of fork movement is slow, 10 to 100 residues per second, but the time required for completion of one Okazaki fragment is the same as in the

prokaryotic cells. The distinction between prokaryotic and eukaryotic replication may be due to a difference in the replication machinery or in the structure of the chromosomes.

At least six proteins are involved in the initiation, elongation, and completion of Okazaki fragments in *E. coli*. Those are primase, single-strand DNA binding protein (SSB), DNA polymerase III, DNA polymerase I, ribonuclease H (RNaseH), and DNA Ligase (see Discontinuous DNA Replication). Primase synthesizes RNA primer in a manner dependent on DnaB protein, which acts as a major replicative DNA helicase at the replication fork (4). *In vitro* experiments suggest that the primase is recruited anew from solution for each cycle of Okazaki fragment synthesis and that association of primase with the replication fork occurs via a protein–protein interaction with the helicase, DnaB (5). Thus, the interaction between primase and DnaB at the replication fork is the primary regulator of the cycle of Okazaki fragment synthesis. SSB is required for the initiation of Okazaki fragment synthesis, as well as for chain elongation by DNA polymerase III holoenzyme. DNA polymerase I, assisted by RNaseH, removes the primers and then fills the resulting gaps, to enable the short fragments to be joined by DNA ligase (6). *E. coli* DNA ligase cannot connect RNA to DNA. This process is very important for cells to maintain a high fidelity of DNA replication, since the primase has no proofreading capacity and the mismatch repair system is not effective on errors in the primer synthesis.

E. coli mutant cells deficient in DNA polymerase I or DNA ligase accumulate large amounts of Okazaki fragments. If Okazaki fragments are not connected efficiently, a daughter DNA molecule synthesized on the lagging strand will suffer from double-strand DNA breaks upon the next round of DNA replication. Thus, null mutants of the genes encoding DNA polymerase I (*polA*) or DNA ligase (*lig*) cannot be isolated. Repair of the double-strand DNA breaks involves functions of **RecA** protein in *E. coli*. Temperature-sensitive *polA* or *lig* mutant cells show a lethal **phenotype** when a *recA*$^-$ mutation is introduced into the strain.

Oligo (dT) Cellulose

Oligo (dT) cellulose is routinely used to enrich from a total **RNA** population for RNAs that have

poly A tails, specifically, messenger RNA (1). The oligo (dT), which can be of various lengths, is attached covalently to the insoluble matrix, cellulose. This is then incubated with RNA under conditions where the poly A tail of the mRNA will hybridize to the oligo (dT). The unbound material can then be removed from the oligo (dT) cellulose by repeated rounds of washing, and the bound polyadenylated RNA eluted for further analysis, such as hybridization to a specific DNA probe in a **Northern blot**.

An alternative use of oligo (dT) is to enrich for cellular proteins that show a preference for binding to this homopolymer. A similar approach has been used with homoribopolymers in characterizing the binding characteristics of the heterogeneous **ribonucleoproteins** (2).

Oligomer

An oligomer is the general term for a short polymer, consisting of a small number of linked, repeating monomer units. The cutoff between an oligomer and a polymer is indistinct, but an oligomer generally has between 2 and 50 repeating units. An oligomer of two repeating units may be more specifically referred to as a *dimer*, three repeating units as a *trimer*, four repeating units as a *tetramer*, and so on. Like polymers, oligomers can be synthetic or naturally occurring. For example, synthetic oligomers formed from a small number of **nucleotide** repeating units—**oligonucleotides**—are used for the polymerase chain reaction (**PCR**) in molecular biology. Many hormones and toxins are **oligopeptides**—that is, naturally occurring oligomers of amino acids.

Oligomeric Proteins

Proteins that contain more than one polypeptide chain are said to be *oligomeric* or *multimeric*, as opposed to *monomeric* proteins with a single chain. The Greek “oligoi” means “few” and the Latin “multi” means “many,” yet oligomeric and multimeric have become essentially equivalent. The first

term, which was introduced by J. Monod and collaborators in the context of allostery (1), will be used here for proteins with two to a few tens of polypeptide chains, as opposed to large assemblies such as muscle fibers, which have hundreds or thousands. The individual polypeptide chains in an oligomer are also called *subunits* . The terms *homo-oligomer* and *homo-multimer* apply to oligomeric proteins built from only one type of polypeptide chain, the product of the same gene. Other oligomeric proteins are *hetero-oligomers* or *hetero-multimers* .

Whereas most proteins have a primary structure (amino acid sequence), **secondary structure** (alpha-helices and beta-sheets), or a **tertiary** structure (three-dimensional), oligomers have an additional level called the *quaternary structure* . The quaternary structure of a homo-oligomer may be coded by the formula a_n, where *n* is the number of copies of the polypeptide chain. Many proteins are oligomers, and quaternary structures of all sorts are found in nature. Beyond formulae such as a_n that describe the number and nature of polypeptide chains, the quaternary structure is part of the three-dimensional structure and is determined along with it in X-ray crystallography or NMR studies.

1. Symmetry

The presence of multiple copies of the same chemical unit leads to the possibility that the three-dimensional structure has internal molecular symmetry. Molecular symmetry is easily established in crystal studies, where it can be either included in the symmetry of the crystal lattice or simply local. In electron microscopy, molecular symmetry is the basis for powerful image reconstruction methods (see Single Particle Reconstruction), and it can also be used to refine X-ray crystallography data (see Molecular Averaging). X-ray data indicate that symmetry is the rule in homo-oligomeric proteins, the lack of symmetry being the exception (2). An object with internal symmetry can always be divided into smaller identical units, the smallest of which is called the asymmetric unit by crystallographers. Monod and collaborators coined the word *protomer* to designate the same entity in an oligomeric protein, and it shall be used here to distinguish the asymmetric unit of the protein from that of the crystal, which may contain more than one protomer. The protomer itself may be more than one polypeptide chain. In hetero-oligomers, it must contain each type of chains; for instance, an immunoglobulin G molecule has one heavy and one light chain in its protomer. In the discussion below, we assume for simplicity that the protein is a homo-oligomer and the protomer a single polypeptide chain, but the same conclusions are readily extended to hetero-oligomers.

Proteins are **chiral** objects that may not have inversion centers or mirror symmetry, both of which would invert the chirality. Protomers must be related to another by a rotation, translation, or screw rotation, which is a combination of a rotation and translation. When repeatedly applied to the protomer, these operations reconstitute the whole object. Their combination constitutes a group in the mathematical sense of the word. Groups of symmetry operations that generate objects of finite size are known as *point groups*. The number of asymmetric units is a characteristic of the group called its *multiplicity*. Chiral point groups belong to one of three families:

1. *Cyclic* C_n symmetry (also noted as *n*). Protomers are related by rotations of 360/ *n* degrees about a single axis *c*. The oligomer must therefore contain *n* protomers and the multiplicity is $m = n$.
2. *Dihedral* D_n symmetry (also noted as *n*2). Protomers are related either by rotations of 360/*n* degrees about axis *c*, or by a 180° rotation about one of *n* two-fold axes in the plane orthogonal to *c*. The oligomer then contains $m = 2n$ protomers.
3. The *cubic symmetries* of a tetrahedron, an octahedron, or an icosahedron. All have multiplicities of 12 or a multiple of 12. Tetrahedral symmetry has nonorthogonal two-fold and three-fold axes; in addition, octahedral symmetry has four-fold axes, icosahedral symmetry five-fold axes.

The symmetry of an oligomeric protein is closely related to the number of protomers and, therefore, polypeptide chains (Table 1). The only possible point group symmetry for a homo-dimer is C_2,

which has a single two-fold axis and $m = 2$. A homo-trimer must have a three-fold axis (120° rotation) and cyclic C_3 symmetry ($m = 3$), if it is symmetric at all. On the other hand, a homo-tetramer can have two symmetries: either a four-fold axis in the cyclic point group C_4, or three orthogonal two-fold axes in the dihedral point group D_2 (also noted as 222). Both point groups have $m = 4$, yet they yield very different quaternary structures, and D_2 is much more frequently observed than C_4. Dihedral symmetry, which requires the number of subunits to be even ($m = 2n$), is very common in globular soluble proteins. Homo-hexamers generally have D_3 symmetry. An example is *Escherichia coli* aspartate transcarbamoylase, in which each of the six protomers comprises one catalytic and one regulatory chain. Octamers have D_4 symmetry, illustrated by *hemerythrin* in Figure 1. In contrast, membrane proteins often have cyclic symmetry and odd numbers of subunits. **Porins** of the bacterial outer membrane and the bacteriorhodopsin of *Halobacterium halobium* are homo-trimers with C_3 symmetry, whereas the a-*hemolysin* of *Staphylococcus* is a heptamer with C_7 symmetry. Cubic symmetry is less common, but it is found in ferritin and large assemblies, such as the *pyruvate decarboxylase* complex or icosahedral **viruses**. The latter have capsids made of an assembly of one or several different polypeptide chains, all present in multiples of 60, the multiplicity of the **icosahedral symmetry** group.

Figure 1. Octameric hemerythrin. Hemerythrin is a nonheme iron protein that transports oxygen in sipunculid worms. Sketch of the crystal structure (11) with subunits in different shades of gray and a-helices as cylinders. The assembly of eight identical chains has exact dihedral D_4 symmetry (also called 42 symmetry). Here it is viewed along the four-fold axis (diamond); two-fold axes (arrows) run horizontal and vertical along the diagonals of the square-shaped tetramers.

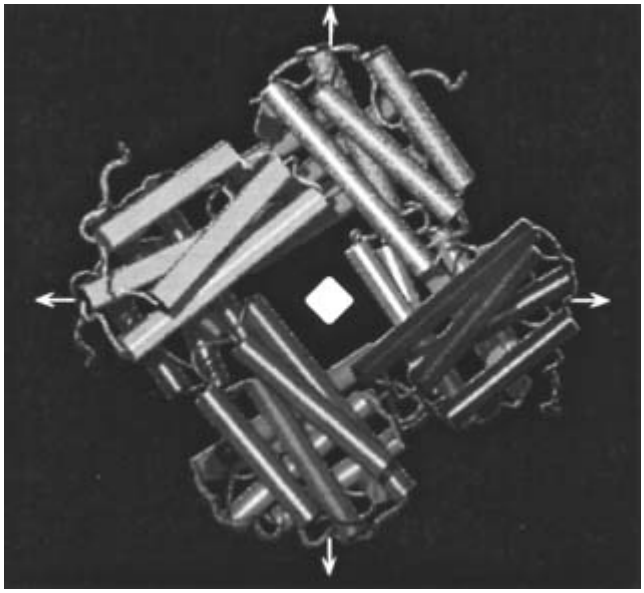

Table 1. Symmetry of Oligomeric Proteins[a]

Protein	Quaternary Structure Point Group
Cyclic	

HIV proteinase	a_2	C_2
Hemoglobin[b]	a_2b_2	C_2
Porin	a_3	C_3
Neuraminidase (flu virus)	a_4	C_4
Pentraxins	a_5	C_5
a–Hemolysin	a_7	C_7
Light harvesting complex II	a_9b_9	C_9
Dihedral		
Phosphofructokinase	a_4	D_2
Aspartate transcarbamoylase	a_6b_6	D_3
Hemerythrin	a_8	D_4
GTP cyclohydroase	a_{10}	D_5
GroEL chaperonin	a_{14}	D_7
Cubic		
Phaseolin	a_{12}	Tetrahedral
Apoferritin	a_{24}	Octahedral
Virus coats	a_{60}, a_{180}	Icosahedral

[a] Adapted from ref. 2, where references to X-ray structures can be found.
[b] Hemoglobin also has approximate D_2 symmetry.

2. Approximate Symmetry and Asymmetry

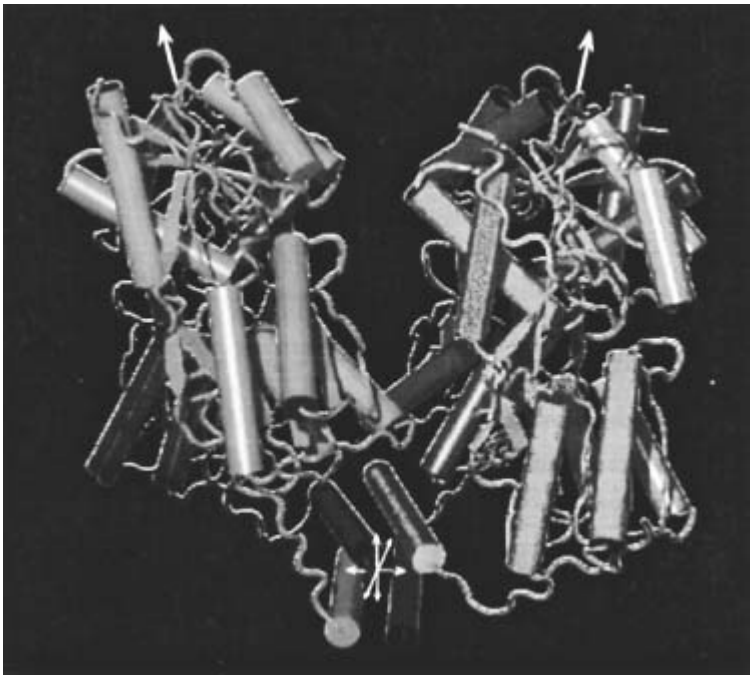
Symmetry requires the exact geometric repetition of chemically identical units, but approximate symmetry can nevertheless be observed in assemblies that do not satisfy this condition exactly. In mammalian **hemoglobins**, the a_2b_2 oligomer displays the exact symmetry of point group C_2 with the two-fold axis relating the two ab units; in addition, there is an approximate D_2 symmetry equivalencing the very similar tertiary structures of the **homologous** a and b chains. Approximate symmetry between structural **domains** of a single-chain protein is also well documented, and it is usually interpreted as an indication that the protein derived from a symmetrical homodimer by gene duplication and gene fusion.

Because symmetry is so frequent, asymmetry is remarkable when it occurs, and it is usually reflected in the function. The F1 fragment of the ATP synthase of mitochondria and **chloroplasts** has the formula a_3b_3g. The three-fold symmetry of the assembly of a and b chains is broken by the presence of a single g chain in the middle. Contacts with g make the three active sites carried by the three b chains nonequivalent, an essential feature of the catalytic mechanism. Simpler examples are two dimeric proteins from the human immunodeficiency virus (HIV), the HIV proteinase and HIV **reverse transcriptase**. In both, X-ray crystallography studies have demonstrated departure from two-fold symmetry. Alone, the HIV proteinase dimer does display exact C_2 symmetry, but this is incompatible with the binding of a peptide substrate and with the catalytic mechanism. A peptide cannot have internal symmetry, and the mechanism of hydrolysis requires one of two intrinsically

equivalent active site aspartate residues to be protonated, the other deprotonated (see Carboxyl Proteinase). In crystalline complexes of the enzyme with substrate analogues, the symmetry is broken. Minor structural changes occur in the protein to fit the asymmetric ligand, and the complex retains approximate symmetry. In contrast, HIV reverse transcriptase displays a major asymmetry. Its two chains are the product of the same gene, but one has undergone **proteolytic** processing. They adopt grossly different folds in the dimer and play very different roles in DNA synthesis. In this case, asymmetry exists in the chemical as well as the three-dimensional structure. It is not known whether or not the asymmetry preexists the proteolytic cleavage that yields the active dimer.

Less often, oligomeric proteins display symmetries that do not belong to one of the point groups mentioned above and cannot be exact. The tetrameric *E. coli* lactose repressor is a case in point (Fig. 2). It is assembled from two dimers, each of which has C_2 symmetry. The dimers are related by an approximate two-fold axis that is not orthogonal to those of the dimers as D_2 symmetry would require. The result is that all four subunits have their DNA-binding headpieces on the same face of the tetramer, which they could not do in a D_2 tetramer. On the opposite face, the C-terminal a-helices of each subunit form most of the dimer-dimer contacts. Remarkably, the four C-terminal a-helices assemble with D_2 symmetry, whereas the rest of the protein does not, which a long connecting peptide makes possible by adopting different conformations in two of the subunits (3).

Figure 2. The lactose repressor of *E. coli*. The homo-tetramer is made of two dimers, each with two-fold symmetry. However, their two-fold axes (arrows) are not orthogonal, and only the four-helix bundle made by C-terminal a-helices at the bottom of the molecule shows the usual D_2 (or 222) symmetry of tetramers. Residues 1 to 61 of each 360-residue monomer form N-terminal DNA-binding domains located at the top of the molecule. In the absence of DNA, they are so mobile that they cannot be observed in the crystal structure of the protein alone (3).



3. Subunit Interactions

The stabilities of quaternary structures result from the contacts between subunits. Subunits form pairwise interfaces of two different characters, depending on whether or not they are related by a two-fold axis. Two-fold symmetry implies that the same surface and same amino acid residues of

both subunits are in contact. Interfaces having other cyclic symmetries, or no symmetry at all, usually involve different sets of residues on the two partners. Following the nomenclature of Monod et al. (1) once again, *isologous* interfaces refer to those with two-fold symmetry, *heterologous* the others. All interfaces are isologous in C_2 dimers and D_2 tetramers; in other systems, at least one set of interfaces must be heterologous.

When the three-dimensional structure is known from X-ray or NMR studies, the extent and nature of the interactions between polypeptide chains can be analyzed in atomic detail. A convenient estimate of the extent of the contact is the *interface area*, the area *B* of the protein surface that is buried (made inaccessible to the solvent) as a result of the interaction. In a dimer, *B* is derived from the atomic coordinates of the structure by calculating the area of the solvent-accessible surface for the dimer and for the two isolated subunits, and subtracting the first value from the sum of the other two. Table 2 quotes interface areas observed in some oligomeric proteins. B_{tot} is the total area of the surface buried in the quaternary structure. In all cases, it is at least 1400 Å^2, similar to the surface area buried in contacts between an antibody and a protein antigen, or proteinase and a proteinase inhibitor (see Protein–Protein Interactions), and this may be the minimum required for stable association. However, most oligomeric proteins have much larger subunit interfaces than this minimum. In bovine catalase, the quaternary structure buries as much as 70% of the protein accessible surface, in six large interfaces. All are isologous, and the D_2 symmetry of the tetramer makes them two by two equivalent. Thus, only three pairwise interface areas are listed in Table 2.

Table 2. Area of Interfaces between Subunits of Oligomeric Proteins[a]

Protein	Molecular Weight (Da)	Accessible Surface Area (Å^2)	Interface Area (Å^4)			
			B_{tot}	B_{pair}		
Dimers						
Avian pancreatic peptide	8500	5300	1400			
Uteroglobin	15,800	7500	3000			
Superoxide dismutase	31,400	13,800	1350			
Triosephosphate isomerase	53,000	20,300	3180			
Alcohol dehydrogenase (ADH)	79,800	29,000	3260			
Citrate synthase	96,000	28,500	9800			
Tetramers						
Mellitin	11,400	6300	4160	880	820	520
Glutathione peroxidase	83,600	28,600	6280	1520	1520	180
Phosphofructokinase	141,200	40,600	14,400	4500	2520	180
Catalase	231,700	60,900	42,300	9260	9140	4120
Hexamer						
Insulin	34,600	13,100	8600	1280	1400	*180

Octomer						
Hemerythrin	107,500	35,900	13,600	1780	260	*1420

[a] Adapted from ref. 4, where references to X-ray structures can be found. The molecular weight, accessible surface area, and total interface area are quoted for the whole molecule. Tetramers and larger oligomers contain several interfaces, with areas given per pair of subunits. Dimers in this table have C_2 symmetry, tetramers, D_2 symmetry, with isologous interfaces only. Larger oligomers also contain heterologous interfaces marked with an asterisk. (1 Å $= 10^{-10}$ m.)

In general, the buried surface area B_{tot} is distributed among several pairwise interfaces, up to $n_{pair} = n(n-1)/2$ for an assembly of n subunits when each one is in contact with all others. In a dimer, $n_{pair} = 1$, in a tetramer, $n_{pair} = 6$. Indeed, most D_2 tetramers have six pairwise interfaces like catalase. In phosphofructokinase, let us label the four subunits *A, B, C*, and *D*. Symmetry-equivalent *AB* and *CD* pairs make extensive contacts burying 4500 Å^2 (Å = 10^{-10}m) each. As *AC* and *BD* pairs bury significantly less, and *AD* and *BC* pairs very little, phosphofructokinase appears, based on the size of the pairwise interfaces, to be a dimer of *AB*-like dimers. It might be expected that *AB*-like dimers are actual intermediates in tetramer assembly, but this is not known. Dividing large oligomers into smaller assemblies on the basis of their three-dimensional structure is often an arbitrary decision. Hemerythrin, illustrated in Figure 1, is an octamer with D_4 symmetry. Is it a dimer of cyclic tetramers, or a cyclic tetramer of dimers? Either description fits. Within a tetramer, each hemerythrin subunit makes two symmetry-equivalent heterologous interfaces with neighbors, eg, the green subunit of the top tetramer with the red and purple subunits, and two isologous interfaces with subunits of the other tetramer, eg, the green subunit with the yellow and brown bottom subunits. Both the green–yellow interface forming a dimer and the green–red or green–purple interfaces forming the tetramer are relatively large, making both types of substructures plausible.

The chemical composition of the protein surface involved in subunit contacts is generally richer in aliphatic or aromatic groups than is the surface accessible to solvent, and it therefore is less polar. On average, nonpolar groups contribute 65% of the interface areas and only 57% of the accessible surface (4). From this point of view, subunit interfaces in oligomeric proteins tend to resemble protein interiors, whereas the interfaces of protein–protein complexes are more like the rest of the protein surface (see Protein–Protein Interactions). **Hydrophobic** (aliphatic or aromatic) amino acid residues are correspondingly overrepresented, and the most abundant residue at subunit interfaces is leucine. The well-known leucine zipper is an example of a coiled-coil dimerization motif formed by the surfaces of two leucine-rich a-helices, but there are many other situations where leucine residues contribute to interfaces. Remarkably, the second most abundant residue is arginine. Its very polar guanidinium group, which is almost always a surface group in monomeric proteins, is frequently involved in the quaternary structure of oligomers. This and other polar groups buried in subunit contacts contribute to the stability of the assembly by forming intersubunit hydrogen bonds. Such bonds occur at the rate of about one per 250 Å^2 of interface area (5), and the partner groups are favorite targets for site-directed mutagenesis aiming to perturb the quaternary structure.

4. Quaternary Structure Changes

The quaternary structure of oligomeric proteins is often as stable as the tertiary structure itself, with the subunits dissociating only under conditions that **denature** the polypeptide chains. There are nevertheless cases where a dissociation equilibrium is observed under nondenaturing conditions. In the case of human hemoglobin, the a_2b_2 oligomer is normally stable when the protein is in the deoxy-form, but when oxygen binds, it dissociates into ab units with an equilibrium **dissociation**

constant of the order of 1 μM. This is much too low for dissociation to play a physiological role in red blood cells, where the hemoglobin concentration is greater than millimolar, yet the coupling between oxygen binding and tetramer dissociation provides a powerful biochemical tool for the study of the allosteric transition (6).

While remaining tetramers, mammalian hemoglobins can still adopt more than one quaternary structure. This has a major functional significance, for the different structures have different affinities for oxygen and other ligands. The **allosteric** model of Monod et al. (1) makes quantitative predictions of how a quaternary structure change can lead to **cooperative** ligand binding in an oligomeric protein. The X-ray structures of deoxy- and oxy- or carbonmonoxy-hemoglobin give a structural basis for this model. Both forms of the protein are symmetrical a_2b_2 tetramers, yet the relative orientations of the ab units differ, and many contacts at the interface are disrupted or rearranged. Changes within ab units (tertiary structure changes) are of much lesser amplitude, but connect the heme sites to the interface. At least one other quaternary structure, called Y or R2, has been identified in mammalian hemoglobins, confirming the plasticity of the interface between the ab units. In contrast, the interface between a and b within each unit is essentially invariant.

Quaternary structure changes generally appear in X-ray structures as rotation or translation movements of the constituent subunits relative to each other, which perturb the contacts that hold together the assembly, without abolishing them. Such movements have been characterized in several allosteric proteins, for instance, in *E. coli* aspartate transcarbamoylase, but they also exist in oligomeric proteins that are not usually considered allosteric and display no cooperativity in ligand binding. In immunoglobulins, the interface between the variable domains of the heavy and light chains shows significant plasticity, and this may be important for antigen recognition, since the combining site spans that interface.

5. Folding and Evolution

The oligomeric proteins listed in Table 2 are fairly globular, and their overall accessible surface area is correlated with their molecular weight (4). In many cases, the individual subunits are also reasonably globular and can remain folded in isolation, so these proteins assemble by the individual subunits folding, then associating. In other cases, however, the subunits themselves are often far from globular, and some parts of individual polypeptide chains may make more interactions with other subunits than with their own. In such cases, the subunit fold found in the oligomer is unlikely to preexist the assembly, and folding must therefore be tightly coupled with association. The **protein folding** of oligomeric proteins is less easily studied than that of small monomeric ones. **Denaturation** with urea or guanidinium salts is often irreversible, as the correct reassembly of the monomers competes with their aggregation, leading to insolubility. However, it has been achieved in a number of cases, showing that complete self-assembly can be reproduced *in vitro* (7). In some cases, a folded monomer or smaller oligomer can be characterized as an intermediate. For instance, *E. coli* aspartate transcarbamoylase catalytic chains form active trimers in the absence of regulatory chains. But, intermediates are often too short-lived for detection during reassembly. This is illustrated by the possibly extreme case of the Arc repressor of bacteriophage P22, a small dimer that can refold very rapidly. No folded monomer is detected, and refolding and association appear simultaneously as a second-order reaction, even on a millisecond time scale (8).

The evolution of oligomeric proteins offers a number of similarly remarkable features. Closely related proteins usually have the same quaternary structure, and residues forming the ab interface in mammalian hemoglobins are invariant like the internal residues. Nevertheless, the quaternary structure is much less well-conserved than the subunit fold. Globins can be monomeric (myoglobin, plant and insect hemoglobins), dimeric (lamprey hemoglobin), tetrameric (mammalian hemoglobins), or larger oligomers, while preserving the same fold and the same capacity of binding heme and oxygen. Other protein families are like the globins and, in general, the quaternary structure need not be the same in homologous proteins when the amino acid sequence identity is below 50%, a

level at which tertiary structures hardly change. In globins, oligomerization is accompanied by a gain of function: Oxygen binding becomes cooperative. As mentioned above, the cooperativity results from an allosteric mechanism whereby ligation at the heme site is coupled to a change in quaternary structure. There is therefore a natural selection pressure on the quaternary structure distinct from that which maintains the tertiary structure of the subunits. It is focused on amino acid residues forming interfaces between ab units, and specific disorders in humans are associated with mutations that change these residues.

The gain of function is even more evident in many enzymes where the active site is made of residues from more than one subunit. An example is the dimeric HIV proteinase mentioned above. Its catalytic mechanism is the same as in monomeric carboxyl proteinases, such as **pepsin**, and involves two aspartate residues. In HIV proteinase, they are the same residue from each of the two subunits; in pepsin, they are different. The longer polypeptide chain of pepsin is a two-domain structure that displays approximate internal symmetry, each domain resembling the viral proteinase monomer. Thus, the single-chain enzyme reproduces the structure of the dimer, giving strong support to the hypothesis that single-chain carboxyl proteinases evolved by gene duplication and fusion from a shorter dimeric precursor. This hypothesis had been made on the basis of the sequence and structure of aspartate proteinases many years before the viral enzyme was known (9).

Dimerization is often assumed to be an acquired feature in evolution. However, in the carboxyl proteinase family, the HIV-type of dimer is the ancestral form relative to the pepsin-type of monomer and, moreover, a monomeric ancestor could not have been a proteinase, for this function requires both aspartate residues. This shows that evolution can undo quaternary structure, as well as create it. In the globin family, the more complex dimeric or tetrameric hemoglobins are considered to have evolved from single-chain globins found in lower organisms, but in many other families there is no evidence for a monomeric precursor. Nevertheless, an evolutionary scenario for dimerization can be proposed. As pointed out by Monod et al. (1), isologous association should be easier to achieve, because two-fold symmetry duplicates any favorable (or unfavorable) interaction. Thus, a small number of mutations at the protein surface might yield a C_2 dimer. An alternative model for dimerization is domain swapping (10), which does not even require mutations to form novel interactions. In domain swapping, domains *A* and *B* interact either within a monomer, or with domains *A′*-*B′* of a second monomer, yielding a (*AB′*) (*A′B*) dimer where noncovalent *A*-to-*B′* and *A′*-to- *B* interactions are essentially identical to *A*-to-*B* interactions in the monomeric form. Domain swapping was named for the phenomenon in diphtheria toxin, where it can be induced by temperature changes. There are some obvious cases in families of homologous proteins, such as the *crystallin* family of eye lens proteins in mammals (12). It includes monomeric g-crystallins and dimeric b-crystallins, all made of two domains that have very similar folds and related sequences, but swap their positions in the dimeric proteins, relative to the monomeric proteins.

Domain swapping is a plausible evolutionary source of oligomers in which large parts of the polypeptide chain wander away from their subunit to interact with others, yielding some of the largest interfaces in Table 2. It could, in principle, yield more complex assemblies with cyclic symmetry, eg, a (*AB″*) (*A″B′*) (*A′B*) trimer where each subunit donates a domain to its neighbor. However, assemblies such as hemoglobin or hemerythrin in Figure 1 show no indication of domain swapping, and many evolutionary mechanisms must coexist. Cells are very dense and complex mixtures of macromolecules. Any change on a protein surface must affect its capacity not only to form legitimate interactions with its siblings in an oligomer, but also illegitimate ones with other components of the cytoplasm, membrane, or organelle, and all these interactions compete in evolution.

Oligomycin

The oligomycins are a family of macrolide antibiotics composed of three major members: oligomycins A, B, and C that are produced by *Streptomyces diastatochromogenes* (1). The family now includes rutamycin (oligomycin D), rutamycin B, and oligomycins E, F, and G (1-5). This antibiotic has antifungal activity, but it is not clinically useful because of its toxicity to mice and HeLa Cells (1, 3). However, Lardy et al (6) reported that oligomycins inhibit oxidative phosphorylation of mitochondria, a finding that attracted the attention of biochemists. Since then the oligomycin family has been shown to be a specific and reversible inhibitor of two ATPases: H^+-ATPase that is present in mitochondrial inner membranes and the Na^+, K^+-ATPase that is present in animal plasma membranes. In addition, it has been reported that oligomycins inhibit some drug-translocating ATPases that confer drug-resistance to mammalian and yeast cells, although the inhibition mechanism is unknown (7, 8), and that oligomycins are suppressive agents for human B cell activation (4).

1. Physicochemical Properties

Oligomycins A, B, and C are commercially available, separately and in mixtures, from a few companies, including Sigma Chemical Company (USA) and Merck KGaA (Germany). Because the

three compounds are used extensively in the fields of biochemistry and molecular biology, their physicochemical properties are described.

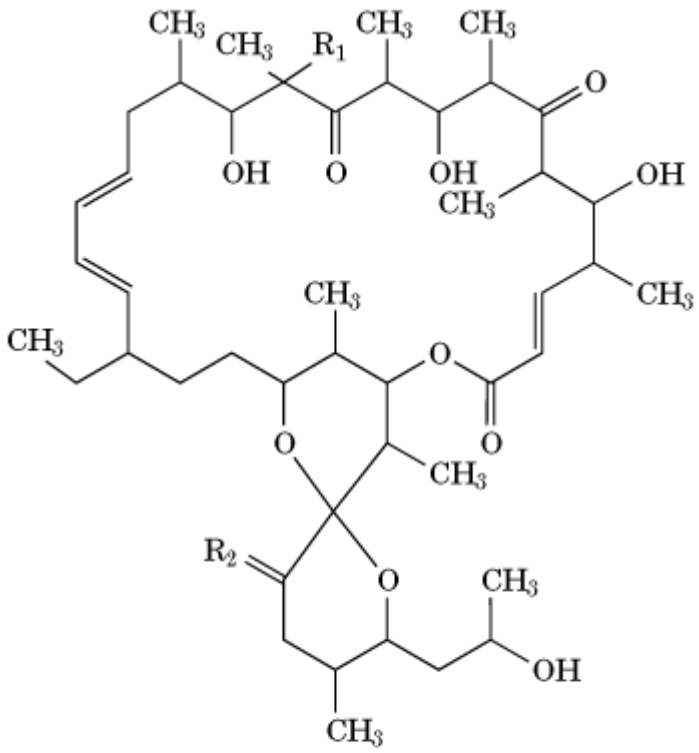
1.1. Molecular Formulas and Formula Weights

The molecular formulas and formula weights of oligomycins are $C_{45}H_{74}O_{11}$ and 791.1 for oligomycin A, $C_{45}H_{72}O_{12}$ and 805.1 for oligomycin B, and $C_{45}H_{74}O_{10}$ and 775.1 for oligomycin C (2, 10).

1.2. Structures

Structures of the oligomycins are shown in Figure 1. The three-dimensional structure of oligomycin B was determined by von Glehn et al (9).

Figure 1. Structures of the oligomycins (2, 3, 10).



Oligomycin	R_1	R_2
A	OH	H_2
B	OH	O
C	H	H_2

1.3. Molecular Absorption Coefficient (e)

The maximal molecular absorbance coefficients of the oligomycins in methanol are 37,400 at 225 nm for oligomycin A, 32,200 at 224 nm for oligomycin B, and 33,500 at 224 nm for oligomycin C (2).

1.4. Solubilities

The oligomycins are stable compounds. Their inhibitory potency is little changed on storage at pH 3 to 10 at 37°C for 54 h (10). They are almost insoluble in water but are soluble in water-miscible solvents such as ethanol, methanol, dimethyl sulfoxide, dimethylformamide (10) acetone, glacial

acetic acid, and in ether (1). Oligomycins are usually dissolved in ethanol and stored in a refrigerator. Their maximum solubility in ethanol seems to be not more than 10 mM (about 8 mg/ml). Their solubility in water including 1% ethanol seems, from examination using [^{3}H]-labeled oligomycin made in our laboratory and not commercially available, to be up to 10 mM (about 8 mg/ml).

1.5. Toxicities

The LD_{50s} of oligomycins A, B, and C in mice injected intraperitoneally are 1.5, 2.9, and 8.3 mg/kg of body weight, respectively (1). The corresponding inhibitory concentrations (IC_{50s}) toward HeLa cells are 0.008, 0.015, and 0.106 mg/ml, respectively (3).

1.6. Other Properties

The melting points, infrared absorption spectra, and optical rotations of the oligomycins, including oligomycins D, E, G, and rutamycin B are available in the literatures (1-3, 5, 11).

2. Biochemical Properties

Various ion (proton)-translocating ATPases are present in prokaryotic and eukaryotic organisms. These ATPase are classified into three groups: F-type, V-type, and P-type (12) (see ATPase). Mitochondrial H^+-ATPase belongs to the F-type group and is called F_1F_0-ATPase or ATP synthase in some cases. Other F-type H^+-ATPases, present in thylakoid membranes of chloroplasts and inner membranes of bacteria, other than some photosynthetic bacteria, are oligomycin-insensitive (10).

Na^+, K^+-ATPase belongs to the P-type group. In some cases, this ATPase is called the **sodium pump**. Other P-type ATPases, including Ca^{2+}-ATPase and H^+, K^+-ATPase, localized in the sarcoplasmic reticulum and gastric cell membranes, respectively, are oligomycin-insensitive (13, 14). V-type H^+-ATPase, which is localized in membranes of subcellular particles in eukaryotic organisms, such as vacuoles and lysosomes, is also oligomycin-insensitive (15).

The mechanisms by which oligomycin inhibits mitochondria H^+-ATPase and Na^+, K^+-ATPase are explained below.

2.1. Inhibition of Mitochondrial H^+-ATPase by Oligomycin

Mitochondrial H^+-ATPase functions as an ATP synthase coupled to the respiratory electron flow in intact mitochondria. The yeast mitochondrial ATPase is less sensitive to oligomycin than the animal mitochondrial ATPase (16). The inhibitory potency of oligomycin is often expressed as an amount of oligomycin per milligram of ATPase: 95% inhibition is achieved by 0.4-µg oligomycin/mg of bovine heart mitochondrial ATPase; 85% inhibition is achieved by 4-µg oligomycin/mg of *Neurospora crassa* ATPase; and 90% inhibition is achieved by 10-µg oligomycin/mg *Saccharomyces cerevisiae* ATPase (17). F-type H^+-ATPase is composed of two components: the F_1 and F_0 portions. The F_1 portion is an oligomer composed of five different kinds of hydrophilic subunits named a, b, g, d, and e, and it includes the catalytic center for the synthesis or hydrolysis of ATP. The F_0 portion is an integral membrane protein composed of three (bacteria) or more (eukaryotic organisms) different kinds of **hydrophobic** subunits (Table 1), and it functions as a proton channel. The ATPase activity of the isolated F_1 region is not inhibited by oligomycin (18).

The component that controls the oligomycin sensitivity of H^+-ATPase has been purified from bovine heart mitochondrial ATPase and named oligomycin sensitivity-conferring protein (OSCP) (19). However, OSCP does not contained a binding site for oligomycin; instead, it is one of the components required for correct binding between the F_1 and F_0 portions (18, 20). The amino acid sequence of OSCP has homology with that of the d subunit in the F_1 portion of bacterial H^+-ATPase,

which is insensitive to oligomycin (21). Oligomycin-resistant mutants have been isolated from yeast and Chinese hamster ovary cell lines and analyzed genetically. The majority of the mutations were mapped at loci *oli 1* to *oli 4* (16). The *oli 2* and *oli 4* loci were found in the gene for subunit 6 of F_0, whereas the *oli 1* and *oli 3* were found in the gene for subunit 9 of F_0 (Table 1) (16, 22). Some of the amino acids substituted in the mutants have been identified (23, 24). In addition, the binding of dicyclohexylcarbodiimide (DCCD), another inhibitor of H^+-ATPase, to subunit 9 is reduced by oligomycin (16). In *Esherichia coli* H^+-ATPase, which is insensitive to oligomycin, the region around *oli 4* in the gene for subunit a, which corresponds to subunit 6 (Table 1), is deleted? suggesting that the binding site for oligomycin is absent in the *E. coli* protein (22). These results suggest that subunits 6 and 9 of the F_0 portion determine the oligomycin sensitivity of F-type H^+-ATPase (16, 22). OSCP apparently affects the oligomycin sensitivity indirectly.

Table 1. Correspondence between Subunits of F_0 Portions of F-Type H^+-ATPases from Various Sources (26)

Bacteria	Yeast Mitochondria	Anmal Mitochondria
a[a]	6[b]	a[b]
b[a]	P25	PVP
—	P18	F_6
—	F_1I	F_1I
c[a]	9[c]	c[c]
—	8	A_6L
—	—	d
—	—	F_B

[a] Other nomenclatures of subunit a, b and c are, respectively, *unc*B (or c), *unc*F (or y), and *unc*E (or w) (25).

[b] Another name for subunit 6 and a is ATPase 6 (22, 24, 26).

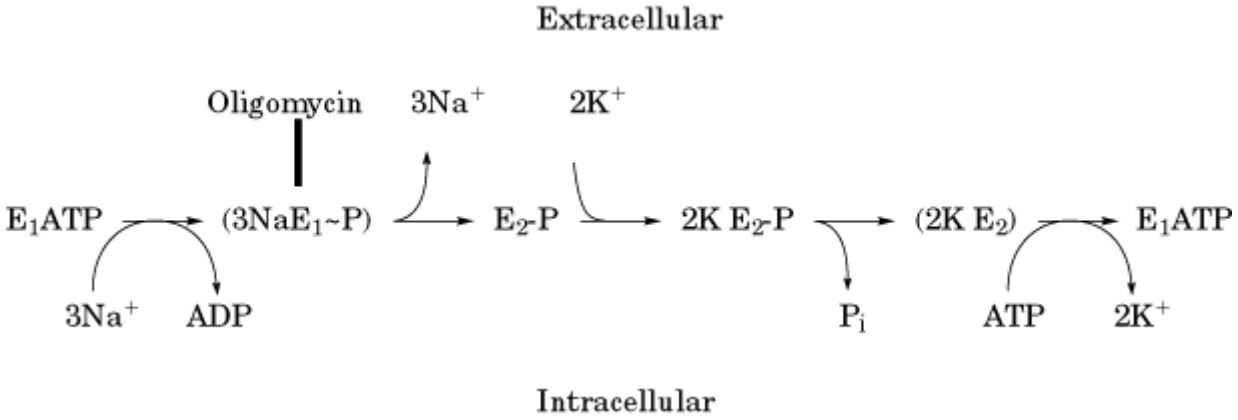
[c] Another name for subunit 9 and c is ATPase 9, or Proteolipid, or DCCD-binding protein (24, 27, 28).

2.2. Inhibition of Na^+, K^+-ATPase by Oligomycin

Na^+, K^+-ATPase is an **antiporter**, which actively translocates Na^+ from the inside to the outside of animal cells and translocates K^+ in the reverse direction, using the hydrolysis of ATP as the driving force. The resultant Na^+ gradient is essential for excitation of nerve tissues and for absorption in the intestine of amino acids and glucose (29). Oligomycin inhibits ATPase activity by about 80% at 10 mg/ml (30-32), and the inhibition is incomplete (32, 33). Na^+, K^+-ATPase is composed of a and b subunits (29): the a subunit possesses the catalytic center. In the ATPase reaction sequence, known as the Post-Albers scheme (Fig. 2), oligomycin inhibits neither the formation of the Na^+-dependent phosphorylated intermediate (3NaE1~P) nor the K^+-dependent $E_2$2-P hydrolysis activity (34, 35). The point of inhibition by oligomycin is the 3NaE1~P to $E_2$2-P + $3Na^+$ step, which is coupled to

Na^+ translocation (Fig. 2) (34, 35). These findings are consistent with the inhibition of only Na^+ translocation by oligomycin *in vivo* (32, 36). The sodium ions in the 3NaE1~P intermediate are called the occluded sodium because these sodium ions seem to be embedded transiently in the ATPase molecule (37). Homareda et al (31, 32, 38) showed that oligomycin increases the affinity of Na^+, K^+-ATPase for Na^+, but not for K^+, under nonphosphorylative conditions. This finding is in agreement with the observation that oligomycin accelerates the rate of the transition from E2K to E1Na but not in the reverse direction (39-41). These results suggest that oligomycin leads to the occlusion of sodium ions by interacting specifically with the Na-bound Na^+, K^+-ATPase, irrespective of whether the Na^+, K^+-ATPase is phosphorylated or not. Therefore, oligomycin has been used to block the reaction from 3NaE1~P to $E_2$2-P + $3Na^+$ and as a stabilizer of the occluded Na form.

Figure 2. Reaction sequence of Na^+,K^+-ATPase according to the Post-Albers scheme (34, 35). E_1 and E_2 denote the conformation showing high affinity for Na^+ and K^+, respectively. E_1~P and E_2-P denote the phosphorylated intermediate with high and low energies, respectively. $3NaE_1$~P and $2K{\cdot}E_2$ denote the confirmation with occluded Na and K, respectively. Pi is inorganic phosphate.



Various Na^+, K^+-ATPase **isoforms** have either low or high sensitivities to ouabain, a classical Na^+, K^+-ATPase inhibitor; both are inhibited by oligomycin (32). Oligomycin seems to act from the extracellular side of Na^+, K^+-ATPase molecule (42). It is suggested that the 200 N-terminal amino acids of the Na^+, K^+-ATPase a subunit include a binding domain of oligomycin (43).

Oligopeptide

An alternative term for a peptide, an oligopeptide is an oligomer or short polymer consisting of a

small number (usually between 2 and 50) of linked amino acids. Oligopeptides have a well-defined sequence of amino acids but may or may not have a well-defined three-dimensional structure (see Protein Structure). Many oligopeptides, such as hormones and neuropeptides, have important biological functions.

[See also Peptide.]

Omega Loop

The W-loop describes a common type of nonregular **secondary structure** observed in protein structures that is characterized by a loop-shaped backbone conformation resembling the Greek letter omega (W). The W-loop consists of six or more amino acid **residues** that cause a reversal in the direction of the polypeptide chain of the protein, so that the two ends of the loop are close in space (Fig. 1). Unlike the regular secondary structure types—**a-helix** and **b-strand**—the omega loop does not have repeating backbone dihedral angles. Also, there are no regular repeating patterns of hydrogen bonds like those of the a-helix, although omega loops do form hydrogen bonds. Furthermore, their structures are compact and globular, with the side chains often packing into the center of the loop. In some cases, omega loops have specific functions, including substrate binding, catalysis, or molecular recognition. Examples of omega loops having specific functions are (a) the phosphate-binding loop (P-loop) of **nucleotide-binding proteins** and (b) the **hypervariable regions** of **antibodies** that interact with **antigens**.

Figure 1. The structure of **interleukin**-1b (1) is depicted, with b-strands shown as arrows and connecting loops and turns as thin ribbons. An example of an W-loop, as defined by Leszczynski and Rose (2), from interleukin-1b is shown circled. (**Right**) The atomic structure of this omega loop is shown in detail. This figure was generated using Molscript (3) and Raster3D (4, 5).

OmpA

Gram-negative bacteria such as *Escherichia coli* are surrounded by two lipid bilayer membranes, which are separated by the murein-containing **periplasmic** space. About 50% of the mass of the outer membrane consists of protein (1). The most abundant proteins include OmpA, Braun's lipoprotein, and the **porins**. Transcription of the *ompA* **gene** leads to a very stable messenger RNA (mRNA), whose degradation pathway is beginning to be understood. The OmpA protein is synthesized as a precursor **pre-protein** that is secreted into the periplasmic space. After proteolytic processing of the signal peptide, the protein is assembled into the outer membrane. As one of the first proteins characterized with respect to secretion and outer membrane localization, OmpA has become a paradigm for the study of the underlying processes. The one-domain membrane moiety of this relatively small and monomeric protein represents a very useful model for the investigation of membrane assembly of b-structure membrane proteins *in vivo* as well as *in vitro*.

1. Discovery

The OmpA protein and *ompA* gene were discovered in the 1970s, independently by a number of different groups using different methods. Nomenclature became a problem. Although gene designations reflected different functions (see below) of the gene product [eg, *con* (2), *tolG* (3), *tut* (4)], the detection and biochemical characterization of several major proteins in outer membrane preparations led to arbitrary names in different laboratories: outer membrane protein B (5), II* (1), 7 (6), C (7), 3a (8), d (9), O-10 (10). It was finally agreed to refer to the genetic locus as the outer membrane protein A (ompA) since it represented the first locus of a structural gene for a major outer membrane protein to be established (11). The *ompA* gene was eventually mapped at 22 min (near *pyrD* and *fabA*) on the *E. coli* chromosome (12, 4); it was subsequently **cloned** (13, 14), and both the gene (14, 15) and the protein (16) were **sequenced**.

2. Expression

The *ompA* gene is constitutively expressed, leading to about 10^5 protein molecules per cell (1). This high expression level is reflected by the tendency to use codons that are recognized by major isoaccepting species of transfer RNA (14). Since the amount of OmpA protein in the outer membrane remains constant over a wide range of generation times, a mechanism for adjusting the rate of biosynthesis is required. In fact, there is a 2.5-fold decrease of OmpA synthesis at slow growth rates compared to the amount produced at rapid growth (17). This decrease is caused by a reduced stability of the *ompA* mRNA. In rapidly growing cells at 30°C, the *ompA* transcript has an unusually long half-life of about 15 min (18), which drops to only 4 min during slow growth (19). It

was found that a 134-nucleotide 5′-untranslated region (UTR) (20, 21) is the determinant responsible for stabilization of the mRNA (22, 23). The control exerted by this *ompA* element is under regulation by the growth rate (24, 25). The 5′-UTR serves as a target for a rate-limiting endonucleolytic cleavage event, which represents the initial step in *ompA* mRNA degradation (26, 27). Detailed studies of this element indicate that it forms a highly structured secondary structure essential for its activity as a stability determinant (28-30). Also, synonymous codon substitutions among 12 enterobacterial species do not occur at random along the *ompA* coding sequence (31), which may reflect selection for a conserved mRNA secondary structure. The *ompA* 5′-UTR can also act in *cis* to stabilize heterologous downstream RNA (23, 24, 32), suggesting that this element blocks a major mRNA degradation pathway in *E. coli*, which probably involves **ribonuclease** (RNase) E (24, 27, 33). However, the exact degradation pathway of *ompA* transcripts is still unknown. In a triple mutant that cannot synthesize polynucleotide phosphorylase, RNase E, and RNase II, the half-life of the *ompA* message was only barely changed (34). In contrast, a further deletion mutation in *pcnB*, encoding the poly(A) polymerase PAP I, dramatically increased the messenger half-life (2.5-fold) and influenced the decay pattern, but only in combination with the other three mutations. By itself, this *pcnB* mutation had no influence on the *ompA* transcript (34). This indicates that both termini of the transcript are important for its turnover and multiple degradation pathways exist that may or may not depend on RNase E and/or PAP I.

Cells can regulate the protein occupancy of the outer membrane. For example, **merodiploidy** for the *ompA* gene did not cause increased OmpA protein as a result of a gene dosage effect (11). Overproduction of the OmpA protein inhibited synthesis of the porins OmpC and OmpF, and its absence led to an increased concentration of these porins (and vice versa). This effect is specific for outer membrane proteins, ie, the level of periplasmic proteins remained unaffected. There are conflicting results concerning the mechanism of occupancy regulation. Initially, it was concluded that a feedback mechanism operated at the level of transcription. It was later found that overproduction of OmpC causes an almost immediate decrease (about six-fold) in the stability of *ompA* mRNA, indicating that feedback control influences mRNA decay rates. Interestingly, this cross regulation operates only for a subset of outer membrane proteins; many of those (unidentified) present at low concentration were not affected. Hence, there should be a property common to the relevant mRNA allowing them to be recognized as belonging to this subset [for more details, see ref. 35].

The *ompA* gene is adjacent to the *sulA* gene, which encodes an **SOS response**-inducible inhibitor of cell division. Both genes are arranged in tandem in the order *sulA* - *ompA*. Upon induction of the SOS response, a novel hybrid transcript encoding both the SulA and OmpA proteins is produced, resulting from transcription reading through the *sulA* terminator and the intergenic region (36). At the same time, a decrease in the abundance of the authentic *ompA* mRNA was observed as a result of **promoter** occlusion. However, the amount of the OmpA protein produced was almost the same. Finally, the turnover of the *ompA* mRNA displays a strong dependence on growth temperature; at 37°C the messenger exhibits a half-life of only 4.5 min (37).

3. Function

OmpA is involved in several processes, and mutations that interfere with some of them were isolated and reflected in their genetic nomenclature. It acts as a receptor for several **T-even**-type **bacteriophages** (*tut* mutants) (4), the best known of them being phages K3, M1, Ox2, and TuII* (38). Colicins K and L need OmpA for their entry into the susceptible cell (*tolG* mutants) (3). In these cases, OmpA is parasitized by toxic agents, and thus these interactions do not, of course, represent normal physiological functions. OmpA is also essential for the formation of mating aggregates in liquid media during **F**-mediated **conjugation** (*con* mutants) (2). Furthermore, OmpA has been reported to form pores *in vitro*, with an estimated pore diameter of ~1nm judged by liposome swelling assays (39), or ~0.6 to 0.7 nm by black lipid bilayer measurements (40). However, using different OmpA preparations, no ion conductivity could be measured in two other laboratories

(41, 42). Only a small fraction of the molecules (2 to 3%) were observed to contain an open channel (43), and the contribution of OmpA to the overall permeability of the outer membrane of *E. coli* is expected to be insignificant, as the major porins such as OmpF and OmpC would make overwhelmingly large contributions to permeability.

The strongest evidence concerning the physiological function of OmpA came from the observation that double mutants in *ompA* and *lpp* (encoding Braun's lipoprotein, another highly abundant outer membrane protein) lacking both proteins had lost their rod shape and required increased concentrations of electrolytes for optimal growth (44). Null mutations of *ompA* or *lpp* alone do not have any phenotype under normal laboratory conditions. Electron microscopy (EM) revealed that the murein layer was no longer associated with the outer membrane in the double mutant (44), and OmpA in wild-type cells could be **crosslinked** to the murein by the **bifunctional reagent** dithio-bis-succinimidyl-propionate (45, 46). Furthermore, regions in OmpA have been identified that are **homologous** to several other proteins known or proposed to interact specifically with the peptidoglycan, eg, the peptidoglycan-associated lipoprotein or MotB protein of **flagella** motors (47, 48). Hence, OmpA is an important structural component of the bacterial cell surface, providing a physical linkage between the outer membrane and murein sacculus.

An *ompA* mutant showed attenuated virulence in two different types of *E. coli* K-1 model infection (embryonic chicken, neonatal rat), implicating OmpA in the pathogenicity of virulent *E. coli* (and possibly other enterobacteria) (49). The mutant was also more sensitive to the bactericidal effect of human **serum** by the classical pathway of **complement** activation, suggesting that OmpA contributes to *E. coli* K-1 pathogenesis by a mechanism that may involve increased serum resistance (49). The invasive capability of the **wild-type** *E. coli* K-1 toward brain microvascular endothelial cells was 25- to 50-fold greater than that of an isogenic mutant lacking OmpA, and the invasion of the wild-type *E. coli* K-1 was inhibited by purified OmpA proteins and polyclonal anti-OmpA **antibodies**. Therefore, OmpA may also be involved in causing meningitis in newborns by helping in the traversal of *E. coli* K-1 across the blood-brain barrier (50).

4. Structure

The 325-residue OmpA of *E. coli* is assumed to exist as a monomer in the outer membrane; oligomers have thus far not been observed. Although microcrystalline preparations of OmpA have been available since 1984 (51), its three-dimensional structure has not yet been solved. Nevertheless, a detailed model of its membrane topology has been proposed by means of comparative sequence analysis (52), phage-mapping (53, 54), linker insertion mutagenesis in combination with proteinase digestion experiments (55, 56), spectroscopic analyses [circular dichroism (CD) and vibrational spectroscopy] (57, 58), and computer-based predictions (58). This model predicts a two-domain organization of OmpA, with the 170 N-terminal residues residing in the outer membrane, in the form of an eight-stranded antiparallel b-barrel, and the remaining 155 C-terminal residues extending into the periplasmic space. The eight antiparallel b-strands are connected by relatively large and hydrophilic surface-exposed loops (L1 to L4) and short periplasmic turns (T1 to T3). Such an up-and-down b-barrel topology appears to be a common architectural principle of integral outer membrane proteins, as observed by X-ray crystallography for the porin family (59-61). The following lines of evidence led to this model:

1. The transmembrane nature of the surface-exposed OmpA protein was first demonstrated by its chemical cross-linking to the periplasmic murein layer in intact cells (45).

2. Proteinases acting on isolated cell envelopes degraded the OmpA protein (35 kDa) to smaller proteinase-protected fragments with sizes of 19 kDa (pronase) or 24 kDa (**trypsin**) (1). These fragments were still active as phage receptors and in inhibiting F-mediated conjugation (which was not, however, tested for the 19-kDa fragment). They corresponded to the N-terminal region of OmpA (62), and the pronase cleavage site was mapped at amino acid residue 177 (16). Also, the *in vivo* membrane assembly of C-terminally truncated OmpA variants (up to 193 residues) was not

affected and led to functional polypeptides (receptor for phages and colicin, F-mediated conjugation). From these results, it was concluded that OmpA consists of two domains: an N-terminal transmembrane domain (residues 1 to about 180) and a C-terminal domain (residues 178–325) that is exposed in the periplasm (63).

3. Mutations that rendered cells resistant to phage mapped at four regions around residues 25, 70, 110, and 154. It was suggested that these regions are located at the cell surface where they interact with the phages (53, 54).

4. Comparative sequence analysis of five enterobacterial OmpA proteins revealed that regions with high sequence variability coincided with those regions where phage-resistance mutations had been mapped. This finding was interpreted as further evidence of their surface localization (52).

5. Spectroscopic analyses (infrared, CD, and Raman spectroscopy) indicated a high beta-pleated sheet content for the protein (55%) (57, 58). When the N-terminal domain was analyzed separately, a complete absence of alpha-helix and an even greater fraction of (mainly antiparallel) b-structure (68%) was observed (58). This domain is resistant to sodium dodecyl sulfate (SDS)-induced denaturation at room temperature (64), causing an aberrant migration behavior of the OmpA protein in **SDS–PAGE**; its apparent molecular mass depends on the temperature used during preparation of the sample. Prolonged heating in SDS results in a conversion from ~30 to ~35 kDa; this phenomenon has been called “heat modifiability” (65). Since OmpA adopts its heat-stable b-structure only during membrane assembly, demonstration of heat modifiabilty is sufficient to prove membrane assembly of mutant OmpA variants. However, mutants exist that assemble into the membrane but are not heat-modifiable.

6. With an antiparallel b-structure of the N-terminal domain, assumed, computer-based predictions suggest a detailed model of its membrane topology (58).

7. Linker insertion mutagenesis in combination with proteinase digestion experiments confirmed the location of two surface-exposed loops (55) and of all three periplasmic turns (56) of the N-terminal domain in the polypeptide chain.

8. In support of the two-domain structure of OmpA, a C-terminally truncated variant, consisting of only the N-terminal b-barrel domain (171 residues), was shown to assemble into the outer membrane as efficiently as the wild-type protein (56). This fragment, which was also heat-modifiable, was still active as a phage receptor (56) and in F-mediated conjugation (66).

9. Sequences homologous to the C-terminal 150 residues were found in numerous proteins, including various lipoproteins and the MotB protein of the flagella motor of both Gram-negative as well as Gram-positive bacteria, supporting its organization as a separate protein domain (47, 48).

10. Circularly permuted variants of the N-terminal domain were constructed at the DNA level and shown to assemble functionally into the outer membrane (67). This indicates the close proximity of both ends of the polypeptide chain in the folded structure and supports the b-barrel model.

11. Two short synthetic peptides corresponding to regions of the first two surface-exposed loops of OmpA (a hexamer, Asn27-Glu32, and a pentamer, Gly65-Asn69) significantly inhibited invasion of brain microvascular endothelial cells by *E. coli* (50), a result that could be easily explained by their surface location.

12. All four predicted surface-exposed loops (58) of the N-terminal domain could be shortened to three residues without interfering with membrane assembly (66). However, all four loops were necessary for efficient F-mediated conjugation in liquid media, and only the fourth loop was dispensable for functioning as a receptor for phage K3 (66).

Based on its transmembrane nature, OmpA was successfully used as a surface display vehicle (see Phage Display Libraries). Peptides of between 20 and 80 amino acids in length were inserted into all but the first surface-exposed loop and shown to be accessible from outside the cell (55, 68, 69). OmpA was also used for surface exposure of complete proteins, either as tripartite fusions consisting of parts of the Lpp lipoprotein, OmpA, and the target protein, eg, **b-lactamase** (70, 71), ScFv (single-chain antibody Fv fragment) (72), alkaline phosphatase (73), or as a sandwich fusion of influenza hemagglutinin into surface loop L3 (74). The target proteins could be detected at the cell surface. However, the exact arrangement of the polypeptide chain in the outer membrane was not analyzed, and it is possible that they adopted rather aberrant structures. This is most likely the case with the tripartite fusions, since they included only five (70, 72, 73) or fewer (71) of the proposed transmembrane strands of OmpA.

An alternative OmpA model predicts 16 transmembrane segments that are distributed throughout the polypeptide chain, forming a b-barrel-like structure (75). There are, among others, two main criticisms of this model. First, C-terminally truncated OmpA derivatives that would lack some of the predicted transmembrane segments can assemble into the membrane, which is incompatible with such an arrangement of the polypeptide chain. Second, speculations about an a-helical conformation of some transmembrane segments that were put forward to match the observed secondary structure composition contradict the prediction procedure, which was based on the detection of amphipathic b-strands.

5. Folding

The OmpA protein serves as a well-established model for the study of membrane assembly of b-structure proteins *in vivo* as well as *in vitro*. OmpA is synthesized as a precursor protein, pre-OmpA, which is then secreted across the cytoplasmic membrane with the assistance of its 21-residue signal peptide (76, 77) and the **Sec** machinery. An influence of the cytosolic SecB **molecular chaperone** in this process, as detected by a decreased processing rate of the signal sequence by the Lep leader peptidase during pulse-chase experiments, was observed with a *secB* null mutant (78) and when SecB was titrated with a secretion-defective mutant of **maltose-binding protein** (MBP) (79). Furthermore, binding of pre-OmpA to SecB has been demonstrated both *in vitro* (80) and *in vivo* (81, 82). As one of the first secretory proteins to be identified and cloned, OmpA became a well-established model for the study of protein secretion *in vitro* (83-88) as well as *in vivo* (89-91), and its signal sequence has often been used for the export of heterologous proteins. Several secretion vectors have been developed for this purpose (92).

After being translocated across the cytoplasmic membrane, a folding intermediate, imp-OmpA (immature processed OmpA), has been identified that was not yet assembled in the outer membrane and lacked heat modifiability (93). Sucrose gradient centrifugation located this species at the cytoplasmic membrane; when overproduced, it was found to be associated with the outer membrane. For such outer membrane association, whose nature has remained unknown, a region between residues 154 and 180 was found to be responsible (94, 95). This region includes the last transmembrane b-strand, with a conserved aromatic residue at its C-terminal position (96). There is, however, no sequence specificity for the last b-strand to function in assembly; it only needs to be amphipathic or **hydrophobic**, and it must not have a proline at the center (97). For incorporation into the outer membrane, OmpA does not depend on newly-synthesized lipopolysaccharides (LPS) (98). Instead, OmpA appears to associate with LPS preexisting in the outer membrane, and this association is required for phage receptor activity (98).

The b-barrel domain of OmpA is surprisingly tolerant toward changes of its amino acid sequence without preventing membrane insertion. Insertions of small peptides at all periplasmic turns (56), as well as the last three surface-exposed loops (the first loop was never tested), were well tolerated (55, 68, 69), as was drastic shortening of all surface-exposed loops to only three amino acid residues (66). Also, substitution by leucine of the turn-promoting proline residues that are present at all three periplasmic turns had no effect on membrane assembly (99). Apparently, neither turns nor loops

possess any topogenic information, which then must reside in the transmembrane b-strands. But even they exhibit a surprising tolerance toward mutagenic alterations. The last b-strand can be replaced by an arbitrary hydrophobic or amphiphilic sequence (97), and proline residues, which are generally avoided within transmembrane b-strands, can be introduced at several positions (100). Probably the information for membrane assembly is redundant and the b-barrel can accommodate some structural distortions without being affected in its general fold. The possibility of creating circularly permuted (67) and split (101) variants (by co-expressing pairs of complementary protein fragments) that assemble into the outer membrane *in vivo* underscores the robustness of the structure and of the folding process of the b-barrel domain of OmpA. In contrast, much less is known about the C-terminal periplasmic domain.

SDS-denatured OmpA could be refolded to its native conformation *in vitro* in the presence of LPS, but not synthetic dimyristoylphosphatidylcholine (DMPC) or total *E. coli* phospholipid (62). However, such denatured OmpA could readily assemble into DMPC **vesicles** when octylglucoside was first added to the protein. In this case, the protein was already refolded in the SDS-octylglucoside micelles and could be transferred into DMPC vesicles (102). In fact, the protein could also be assembled directly into such vesicles under conditions that tried to mimic what happens *in vivo* (103). In this case, the vesicles had to be very small, ie, highly curved, and the lipid had to be in the fluid state. When **urea**-denatured OmpA was added to such vesicles, it refolded and inserted in an oriented manner. This was also achieved with the tryptic fragment of OmpA that lacks most of its periplasmic domain. When the experiment was performed at a temperature below the lipid phase transition, the protein also folded and adsorbed to the vesicles but was not incorporated; raising the temperature also led in this case to incorporation. This polypeptide that is adsorbed possessed about the same content of b-structure (as judged by spectroscopic methods) as the protein incorporated into the vesicles (or present in the outer membrane) but lacked heat modifiability. Hence, this intermediate appears to correspond to the imp-OmpA observed *in vivo*. These results show that a lipid bilayer is not required for OmpA to assume its native conformation and it spontaneously refolds and inserts into a membrane, provided the latter possesses some defects (suboptimal packing of lipid in small vesicles or the presence of octylglucoside in large vesicles). From a study of the *in vitro* refolding kinetics, three transitions along OmpA's folding pathway could be distinguished (104). Their characteristic times are (1) less than a second, (2) in the range of minutes, and (3) in the range of an hour. These *in vitro* experiments appear to suggest that there are no helpers involved in the membrane assembly of OmpA. However, *in vitro* assembly is much less efficient than *in vivo* assembly; therefore, these experiments do not exclude the involvement of helper factors *in vivo*. The following proteins appear to participate in OmpA biogenesis: (1) The DsbA/DsbB system (see Protein Disulfide Isomerase PDI) is involved in the formation of the intramolecular disulfide bond that is located in the periplasmic domain (105, 106). (2) Peptidyl-prolyl cis-trans isomerases could be involved in potential peptide bond isomerizations, as OmpA contains several proline residues, although their isomeric state is unknown. A *rotA* mutant was not impaired in OmpA assembly (107), but SurA, another periplasmic isomerase, was shown to assist in the folding of OmpA (108). (3) The Skp protein, which was shown to bind selectively to OmpA and several other outer membrane proteins *in vitro*, is another candidate molecular chaperone along the route of OmpA to the outer membrane (109).

Note added in proof

The three-dimensional structure of the OmpA transmembrane domain has been solved by X-ray crystallography [A. Pautsch and G. E. Schulz (1998) *Nature Struct. Biol.* **5**, 1013–1017].

Oncogenes, Oncoproteins

In the past 25 years a major revolution has occurred in understanding the molecular basis of cancer. The long drive to understand how normal cells grow and contribute to the ordered development of an organism and the nature of genetic events that disrupt this ordered process and result in cancer has become a major focus of biological research. The explosion of knowledge from basic research on cancer has unified several disciplines of science and led to a clearer understanding of the mechanisms associated with normal cell growth, genetic events that produce defects in regulatory mechanisms that lead to aberrant growth and differentiation, and finally the molecular basis for disease processes, such as cancer.

The most important breakthrough that led to this scientific revolution was the discovery that a small set of **genes** (probably about 100) in mammalian and avian cells (which are estimated to contain approximately 200,000 genes) controls normal development of the organism. Aberrations introduced into these genes during the life span of an organism by **viral** infection or by exposure to chemical **carcinogens** leads to cancer. It is becoming very clear that a precise understanding of the structure of these genes and the mechanisms associated with their function will provide us with approaches to treat diseases, such as cancer, and also to correct genetically inherited forms of developmental defects. Therefore, we are at one of those exciting moments in science when many disciplines of scientific endeavor come together, and much that seemed impossibly obscure suddenly becomes clear.

It has been recognized for almost a century that cancer is a multistep process, which takes decades to develop. Because cancer cells grow at a much faster rate than normal cells and do not obey rules of ordered growth immediately suggested that cancer is an aberration of cell growth. This observation, combined with the fact that cancer is a multistep process, suggested the involvement of multiple genetic events of the growth deregulation seen in cancer cells. Research during the past decade has shown that these genetic events include activating a group of genes, termed “oncogenes,” and inactivating another group of genes named “growth suppressor genes.” By definition, oncogenes are genes that promote cell growth, and growth suppressor genes are those that block cell growth. A fine balance between the activities of these two groups of gene products dictates normal cell growth, and disrupting this balance provides a cell with a growth advantage that ultimately results in a neoplastic state.

1. Discovery of viral and cellular Oncogenes

Oncogenes were initially discovered by studying transforming retroviruses that produce tumors in animals. Several decades ago, it was observed that chickens die predominantly of cancer, suggesting that these animals have a genetic predisposition to this disease. This observation led to examining the tumors derived from these animals for a disease-transmitting agent, which led to the identification of retroviruses. In 1911 Peyton Rous at the Rockefeller Institute in New York first isolated a retrovirus from a spontaneous chicken sarcoma (1). He established the viral etiology of the tumor by demonstrating that extracts derived from the tumor could be filtered through membranes that retain bacteria and nevertheless induce cancer in animals injected with the filtered extracts. The virus

isolated by Rous has been named the Rous sarcoma virus in honor of its discoverer. Most interestingly, it was found that these viruses contain **RNA** as their genetic material and hence were called "RNA tumor viruses" or "retroviruses." Later studies revealed that extracts from animal tumors often contain two types of RNA tumor viruses, which were termed acute transforming viruses and leukemia viruses. These viruses differ from each other in a number of properties, which are listed in Table 1. The most important biological difference between these two classes of viruses is their ability to induce tumors *in vivo* as a function of time. Although acute transforming viruses induce tumors in susceptible hosts in a very short time (1 to 2 weeks), the leukemia viruses require several months to years. A second important difference between the two classes of viruses is their ability to transform cells in tissue culture. The acute transforming viruses readily transform cells in tissue culture, whereas the leukemia viruses fail to do so. Finally, several of the acute transforming viruses (with the exception of Rous sarcoma virus) are replication-incompetent, whereas leukemia viruses replicate readily *in vitro* and *in vivo*.

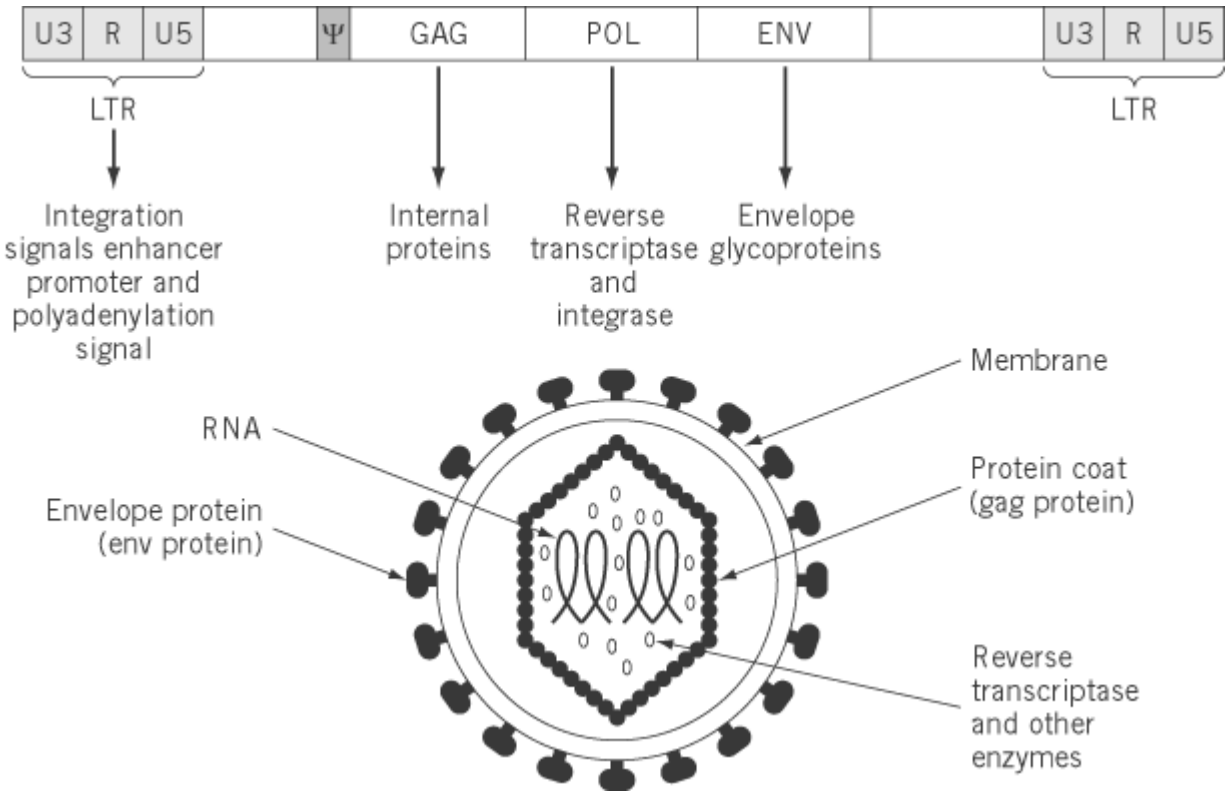
Table 1. Retroviruses or Type C RNA Tumor Viruses

Properties	Chronic Leukemia Viruses	Acute Transforming Viruses
Induce	Lymphomas	Sarcomas, carcinomas, and hematopoietictumors
Tumor latent period	Months to years	Weeks
Transformation of cells in culture	No	Fibroblasts and/orhematopoietic cells
Replication-competent	Yes	Generally not
Mechanism of transformation	Integration next to oncogene	Discrete cell-derived gene withinviral genome (oncogene)

The advent of recombinant DNA techniques in late 1970s allowed the molecular cloning and sequence analysis of the two types of viruses, which provided a molecular explanation of their biological differences. These studies showed that the leukemia viruses encodes three polypeptides, named gag, pol and env. Of these, the *gag* gene encodes a polypeptide chain that is cleaved **proteolytically** into smaller polypeptides that form the core proteins of the virion (Fig. 1). The *pol* gene encodes a polypeptide chain that is cleaved into two polypeptides, one of which is the **reverse transcriptase** that enables the virus to convert its RNA into DNA. The second polypeptide functions as an integrase that allows the proviral DNA to integrate into the host viral genome. The *env* gene encodes the viral envelope protein that plays an important role in virus–host cell membrane interactions. In addition to these three genes, the retroviral genome contains a stretch of sequences that are duplicated at the 5′ and 3′ ends of the provirus, termed Long Terminal Repeats (LTRs). The LTRs contain sequences that constitute some of the most potent eukaryotic **promoter**/enhancer elements in mediating high-level transcription of viral RNA.

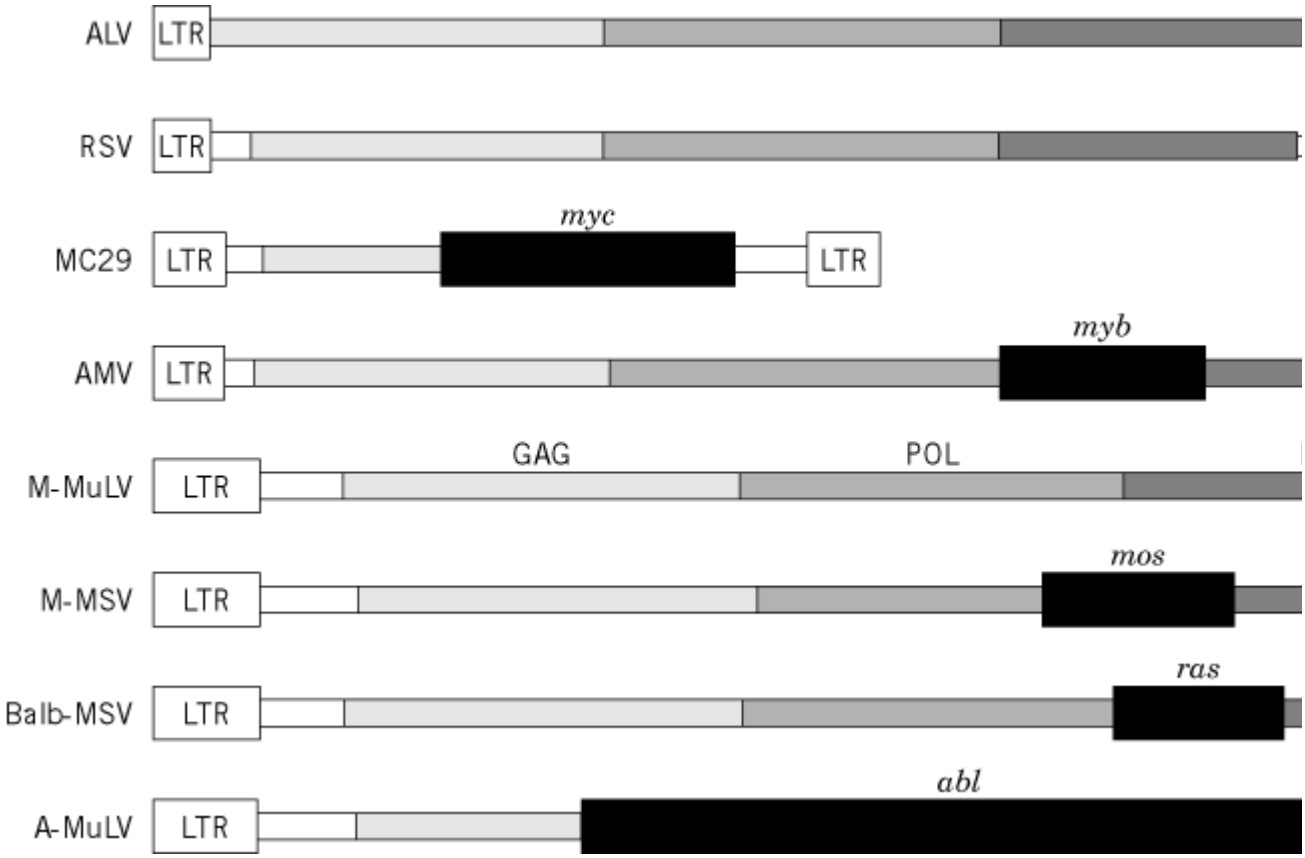
Figure 1. Genetic elements of retroviruses and their gene products. A typical retroviral provirus encodes three genetic elements, gag, pol, and env, that are translated into viral proteins. The gag sequences encode the viral core protein (an inner shell), the pol gene codes for reverse transcriptase (an enzyme that converts RNA into DNA) and the viral

integrase (an enzyme that facilitates the integration of viral sequences into the host genome), and the env gene product forms the viral envelope protein. The LTR sequences direct high levels of viral gene expression within the host cell. Y denotes the packaging signal that enables the viral proteins to recognize the viral RNA that is to be incorporated into the mature virion.



Comparison of the structures of the acute transforming and leukemia viral genomes revealed that the acute transforming viruses contain an additional segment of genomic RNA not present in leukemia viruses. Deletion of this sequence leads to loss of the transforming ability of these viruses. These observations suggested that a protein encoded by this unique piece of genetic material is responsible for inducing of tumors in animals. The first of these genes was originally found in the Rous sarcoma virus and was designated as the ***src* oncogene**. Structural analysis of several of the acute transforming viruses revealed that acute transforming viruses very often suffer deletions in their *env*, *pol*, and/or *gag* sequences, which explains their inability to replicate *in vitro* or *in vivo* (Fig. 2). The only exception to this rule is the Rous sarcoma virus, which contains all three structural genes of the avian leukosis virus, in addition to the *src* gene, and thus constitutes the only replication-competent acute transforming virus.

Figure 2. Comparison of the genomic structures of M-MuLV, ALV, and some of the acute transforming viruses. LTR: long terminal repeat.



An important breakthrough in cancer research came from the discovery that oncogenes of acute transforming viruses are in fact derived from normal cellular DNA and that this genetic information is transduced by acute transforming viruses via genetic recombination. An analysis of normal cellular DNA by Stehlin and his co-workers (2), using a probe derived from the *src* oncogene (derived from Rous sarcoma virus), revealed the presence of endogenous oncogene-related sequences in normal chicken DNA. Following the lead provided by the Rous sarcoma virus, retrovirologists have isolated more than 200 different tumor-producing, acute transforming viruses from animal tumors of different species. Table 2lists some of the acute transforming viruses and the oncogenes transduced by them. An examination of this table shows that several of the acute transforming viruses isolated from different animal species contain the same oncogene, suggesting that there are only a finite number of transforming genes in the avian and mammalian genomes and that these genes often undergo recombination with replicating retroviruses, leading to the formation of acute transforming viruses. Since the first identification of the v-*src* oncogene, a number of different approaches have been used to identify genes responsible for the altered growth properties of tumor cells. Now, the term “oncogene” is used more broadly to include any gene whose expression is associated with enhanced growth of tumor cells.

[a] Representative oncogenes, their transforming viruses, animal origin, molecular size, and function of the oncoproteins are presented here.

2. Mechanisms of Oncogene Activation by Retroviruses

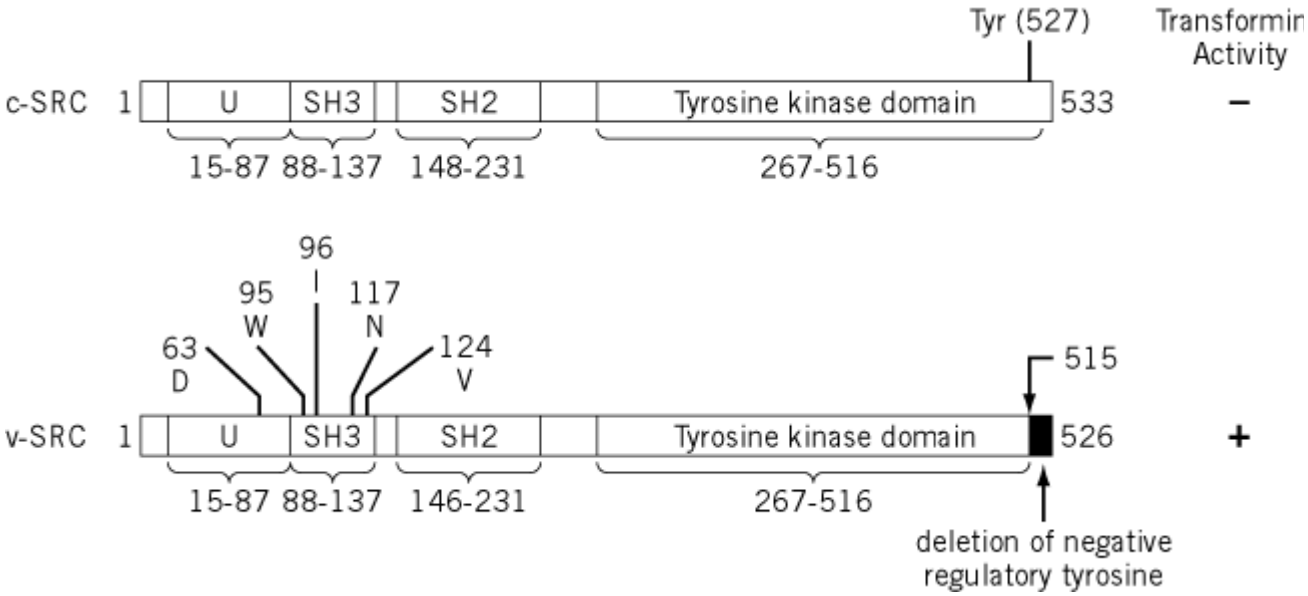
Since this discovery of the *src* oncogene, a number of investigators have demonstrated the presence of cellular homologues to retrovirally associated oncogenes, which today number approximately about 50. These studies demonstrated clearly that all retroviral oncogenes are derived form normal cellular DNA. A detailed comparison of the structure of the viral oncogenes with their cellular counterparts revealed that several of the viral genes often represent mutant versions of their cellular homologues. To distinguish the viral and cellular versions of these genes, the oncogenes present in normal cellular DNA were termed proto-oncogenes or c-oncogenes (c = cell), and those in RNA tumor viruses were termed v-oncogenes (v = virus). Several of the proto-oncogenes have been highly conserved through evolution because some of them are readily detected even in yeast by their homology to mammalian oncogenes, suggesting an important role for these genes in cell survival.

The observation that retroviral oncogenes are derived from normal cell DNA but readily transform cells in culture posed an important question how the same gene, expressed in the context of normal cell growth has no deleterious effect but readily induces transformation of cells when expressed as

an integral component of a retrovirus. A detailed structural analysis of v- and c-oncogenes revealed that retroviral oncogenes represent gain-of-function mutants of c-oncogenes. This is exemplified by the analysis of five retroviral oncogenes, v-*src*, v-*abl*, v- *ras*, v-*myb*, and v-*myc* and their normal cellular homologues, c-*src*, c-*abl*, c-*ras*, c-*myb* and c-*myc* (Fig. 2).

The c-*src* gene encodes a protein with four well-defined structural **domains**, termed the unique, **SH3**, SH2, and SH1 (or tyrosine kinase) domains (3). The kinase domain is located toward the C-terminus of the protein and contains a negative-regulatory **tyrosine** residue that is **phosphorylated** in a resting cell (3). This phosphorylated state adopts a local protein structure that renders the protein kinase inactive. Mitogenic stimulation of cells results in dephosphorylation of this tyrosine residue, which subsequently results in enhanced kinase activity of the protein. In the v-Src protein, this negative-regulatory region is deleted, resulting in constitutive activation of its kinase activity (3) (Fig. 3).

Figure 3. Activation of the *src* oncogene. The cellular *src* gene, designated as *c-src*, encodes a tyrosine kinase whose activity is regulated by tyrosine phosphorylation. In a normal resting cell, the Src protein is phosphorylated on a C-terminal, negative-regulatory tyrosine residue and has a low or undetectable level of enzymatic activity. Upon stimulation, the protein is dephosphorylated and active. As a consequence of transduction by RSV, the *v-src* oncogene contains a deletion at the 3′ end of the gene and does not encode a negative-regulatory tyrosine residue. As a result, its kinase activity cannot be regulated. This constitutive activation of the enzyme leads to cellular transformation. *v-src* also contains a number of other mutations that might enhance its oncogenic activity, but none of the mutations alone activate *c-src*.



Abelson murine leukemia virus (A-MuLV) is a replication-defective retrovirus (4) that induces B-cell lymphomas *in vivo* and transforms both lymphoid and fibroblast cells *in vitro*. The proviral genome of A-MuLV encodes a single protein that is a fusion product of the virus-derived *gag* and cell-derived *abl* sequences (5). Like the *src* gene, the ***abl*** *gene* codes for a tyrosine kinase that also contains unique, SH3, SH2, and tyrosine kinase domains (6). But it also contains an additional C-terminal domain, whose function is not entirely clear, and the gene product of c-*abl* does not contain the negative-regulatory tyrosine residue at its C-terminus. The kinase activity of the c-Abl protein is negatively regulated by its SH3 domain, which is deleted from the v- *abl* gene product. Interestingly, the v-*abl* gene product also contains a point mutation in its C-terminal sequence, which enhances its tyrosine kinase and transforming activities (7). Thus, both the v-*src* and v-*abl* genes have alterations in their regulatory sequences that result in the constitutive activation of their tyrosine kinase activities, and this correlates with their transforming function.

The ***ras* gene** is an important gene that has been studied extensively because of its role in **growth-factor**-associated **signal-transduction** pathways (8). The viral *ras* genes code for 21-kDa proteins, designated p21, that belong to the G-protein superfamily. G-proteins bind to GTP with high affinity and hydrolyze it to GDP (see GTP-Binding Proteins; Gtpases; Heterotrimeric G Proteins). The GTP-bound Ras protein is biochemically active, whereas the GDP bound form is inactive. More importantly, the proportion of GTP-bound p21 Ras is tightly regulated in normal cells by feedback mechanisms, and it normally represents less than 5% of the total Ras protein. Comparison of v- and c-*ras* revealed that the viral oncogenes contain two point mutations, one in **codon** 12 and a second in codon 59, both of which impair the intrinsic GTPase activity of the mutant proteins and render them resistant to negative regulation (8, 9). As a result, the v-Ras proteins remain in a constitutively activated (or GTP-bound) state, which contributes to their oncogenic activity.

The avian myeloblastosis virus, isolated in 1941 from a chicken tumor, is an acute transforming virus that causes myeloblastic leukemia in chickens and transforms myelomonocytic cells *in vitro* (10). Like most acute transforming viruses, AMV is replication-defective, having arisen by recombination between a nondefective leukemia virus and chicken cellular sequences. The normal cellular counterpart of this oncogene, c-*myb*, codes for a nuclear transcription factor that is essential for the proliferation of lymphoid, myeloid, and erythoblastoid cells. Sequence analysis of the c-***myb* gene** revealed that the encoded protein contains an amino-terminal **DNA-binding** domain, a central transactivation domain, and a C-terminal negative-regulatory domain (11, 12). Comparison of the v-*myb* and c- *myb* sequences showed that the viral oncogene arose as a result of deletions in the 5′ and 3′ portions of the coding sequences, which results in deleting of a portion of the DNA-binding domain and the entire negative-regulatory domain. Although the deletion in the DNA-binding domain does not affect the ability of the viral protein to bind to DNA, the deletion of the C-terminal negative-regulatory domain results in enhanced transcriptional transactivation by the v-Myb protein, which in turn enhances the proliferative activity of the virally infected myeloid cells (13).

The myc oncogene was originally identified as the transforming gene of an acute transforming virus, called MC29, which was isolated from a chicken that had spontaneous myelocytomatosis (14). *myc*-related sequences were subsequently identified in three other independently derived chicken retroviral isolates. Comparison of the MC29-derived v-*myc* and chicken c- *myc* sequences showed that the viral oncogene contains the entire coding sequence of the chicken c-*myc* gene fused to the viral gag sequences, thus producing a gag-*myc* fusion protein (15, 16). Although fusion of the *myc* sequences to the gag gene results in elevated levels of Myc protein expression, deletional analysis of the proviral genome suggests that elevated expression of *myc* sequences alone is adequate for the transforming activity of this oncogenic virus. Thus, unlike with other oncogenic viruses, structural alterations play a less important role in the oncogenic activity of this gene, and overexpression of the encoded protein product alone is adequate to induce transformation of appropriate target cells.

Studies with oncogenic viruses, like those illustrated previously, provided important clues regarding the relative contributions of different mechanisms to the activation of proto-oncogenes. These comparisons between the viral and cellular oncogenes revealed a high frequency of deletions and mutations in v-oncogenes. In a vast majority of cases, these changes result in a gain of function, which contributes to the oncogenic potential of the viral oncogenes. In addition, these studies also showed that the viral LTRs play a critical role in viral oncogenesis because they direct high-level expression of v-onc gene products.

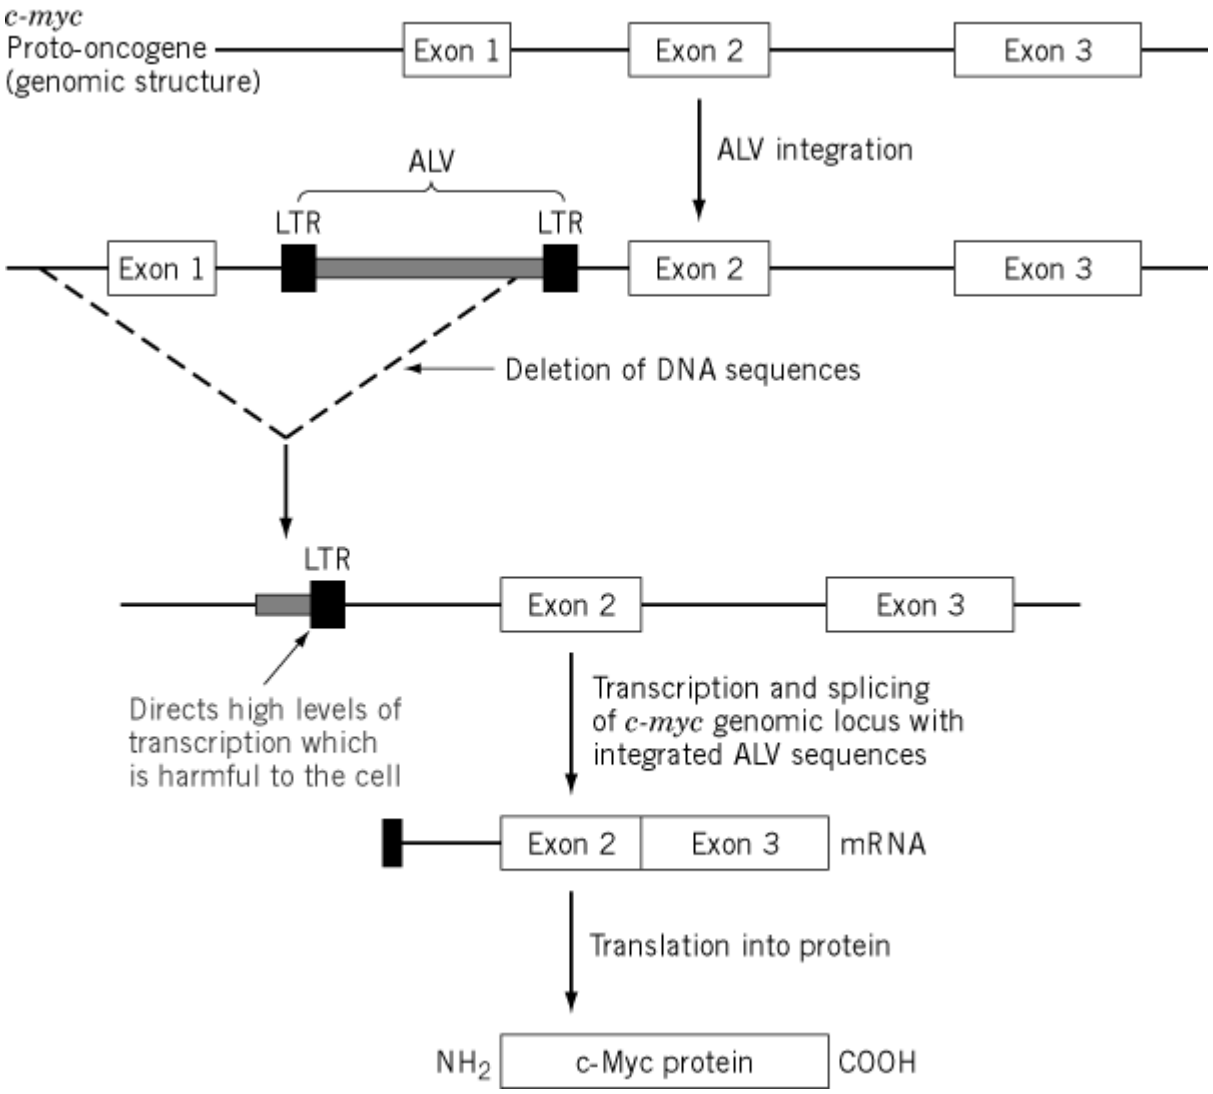
3. Oncogene Activation by Leukemia Viruses

The study of acute transforming viruses has provided us with a wealth of knowledge about the mechanisms of oncogene activation, but the mechanisms for the transformation by leukemia viruses, like ALV or Mo-MuLV, were not revealed by these studies. As noted in Table 1, leukemia viruses lack a cell-derived oncogene but nevertheless induce leukemias, albeit over prolonged periods of time. The long latency period for the development of leukemias suggested that genetic events in

addition to viral infection are required to induce transformation by this group of viruses. The first clues to the mechanisms for leukemia virus-induced transformation came from studies with ALV-induced bursal lymphomas in chickens (17) and Mo-MuLV-induced leukemias in mice (18).

Analysis of the chicken lymphomas induced by ALV demonstrated that these tumors contain integrated copies of the proviral genome and, most interestingly, these integration sites are often located within the c- *myc* proto-oncogene, the cellular homologue of the v- *myc* oncogene (17). Detailed analysis of the c-*myc* locus from these tumors indicated that the c-*myc* gene in normal cells contains three exons (see Introns, Exons), of which exon 1 contains the 5′ noncoding sequences, whereas exons 2 and 3 contain the entire coding region of the gene (Fig. 4). In ALV-induced bursal lymphomas, this locus is disrupted by insertion of the proviral genome within intron 1 of the c-*myc* gene (Fig. 4). Several of the tumors analyzed showed that, following the integration of the provirus, the viral genome itself often undergoes rearrangements that result in the deleting most of the structural genes and one of the LTR sequences. This results in positioning a viral LTR immediately upstream of exons 2 and 3 of the c-*myc* gene, placing c- *myc* under the transcriptional control of the viral LTR. Because the viral LTR is designed to express high levels of RNA, the lymphoid cells that contain the viral LTR integration express abnormally high levels of *myc* RNA and protein, which, in combination with other genetic alterations, leads to formation of the tumor.

Figure 4. Activation of the *c-myc* oncogene as a consequence of ALV integration. In a normal cell, the three exons of the c-myc gene (designated 1, 2, and 3) are normally spliced into an mRNA that can be translated into the c-myc protein (only exons 2 and 3 actually code for the protein). When ALV integrates into the c-myc locus (usually between exons 1 and 2), the presence of the LTR sequences in the transcript results in increased expression of the c-myc protein, which is harmful to the cell. The integration of ALV is often followed by deletion of portions of viral sequences, leaving one of the LTRs intact.



Mo-MuLV induces thymic lymphomas, when injected into newborn mice (18), and myeloid leukemias when injected into pristane-primed BALB/C mice (19). Analysis of the thymic lymphomas induced by this virus revealed that the integration of the provirus often occurs into two common loci. As with ALV-induced lymphomas, many of the Mo-MuLV-induced lymphomas exhibit integration of the proviral genome into the c-*myc* locus and deregulated expression of this gene (18). Several of the tumors did not have the provirus integrated into the c-*myc* locus, but into a new locus, which was named *pim-1* (proviral integration MuLV) (18). *pim-1* codes for a protein kinase that acts as a transforming gene when overexpressed in lymphoid cells. Interestingly, a number of tumors had the provirus integrated in both the c- *myc* and *pim-1* loci and therefore have elevated transcriptional rates of both of these genes.

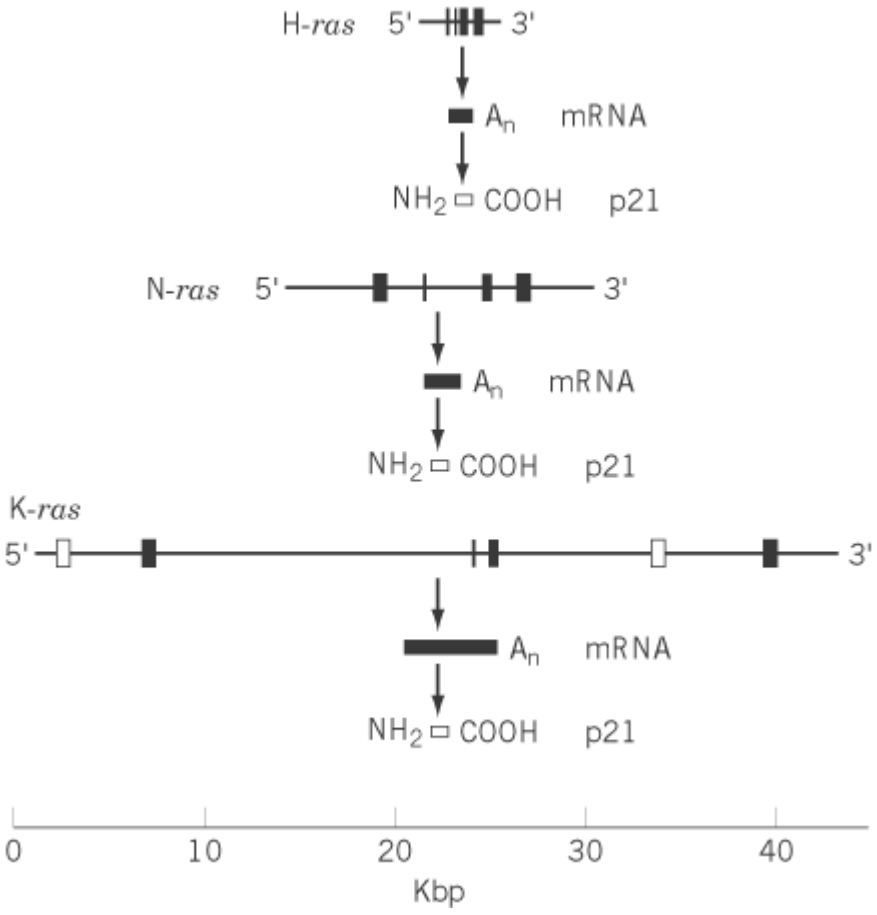
Analysis of myeloid tumors induced by Mo-MuLV revealed that the viral integrations in these tumors often occur in the c-*myb* locus, the oncogene originally identified in the avian myeloblastosis virus (AMV) (19). The mouse c-*myb* gene contains 15 exons, and viral integrations very often occur in either intron 3 or intron 9, resulting in either amino-terminal truncations or a C-terminal truncation of the protein after RNA splicing. This results in the synthesis of aberrant *myb* transcripts that lack either the 5′ or 3′ end. Interestingly, the aberrant messenger RNAs produced by these tumors exhibit deletions similar to those observed in the v-*myb* oncogene (20). Thus, activation of the *myb* gene is invariably accompanied by deletions in the coding regions of the gene. This finding lends support to the hypothesis that these structural alterations result in a gain of function for this oncoprotein, which in turn results in its oncogenicity.

3.1. Isolation of Dominant Transforming Genes from Human Tumor DNAs

Although the study of retrovirus-associated oncogenes led to the identification of a number of oncogenes, the link between these genes and human cancer was made by identiifying dominant transforming genes from human tumor DNAs. The development of the NIH/3T3 cell transformation assay system, which utilizes the NIH/3T3 mouse fibroblast cell line which efficiently in takes up and integrates exogenous DNA, has contributed immensely to identifying the transforming genes in human tumors. When the DNA from different human tumors is transfected and assayed for the induction of foci, about 20% of human tumors contain sequences that could transform NIH/3T3 cells (21). Molecular cloning and characterization of these sequences resulted in identifying several new oncogenes. One of the first human oncogenes identified from the T24 human bladder carcinoma cell line is related to the viral *ras* gene, previously found in the Harvey sarcoma virus that had been isolated from a rat tumor (22, 23). Detailed characterization of the genetic lesion associated with the transforming gene of the T24 bladder carcinoma cell line showed that a point mutation in codon 12 (similar to that seen in the v- *ras* oncogene), which leads to a single amino acid change in the coding sequence of this gene, results in its oncogenic activation (24, 25).

The human genome contains three closely related *ras* genes, all of which code for 21-kDa proteins and exhibit a high degree of homology (Fig. 5) (8). These three genes are called H-*ras*, K-*ras*, and N-*ras*. Of these, the H-*ras* gene is most similar to the v-*ras* genes derived from the Harvey sarcoma virus and BALB-MSV, whereas the K- *ras* gene is most similar to the oncogene encoded by the Kirsten sarcoma virus. The N-*ras* gene was originally isolated from a neuroblastoma after transfecting of the tumor DNA into NIH/3T3 cells and analyzing of the sequences responsible for inducing transformed foci. Detailed analysis of the tumor-derived oncogenic *ras* genes showed that almost all of these genes contain mutations in either the 12th or the 61st codon that result in constitutively activating of the protein products.

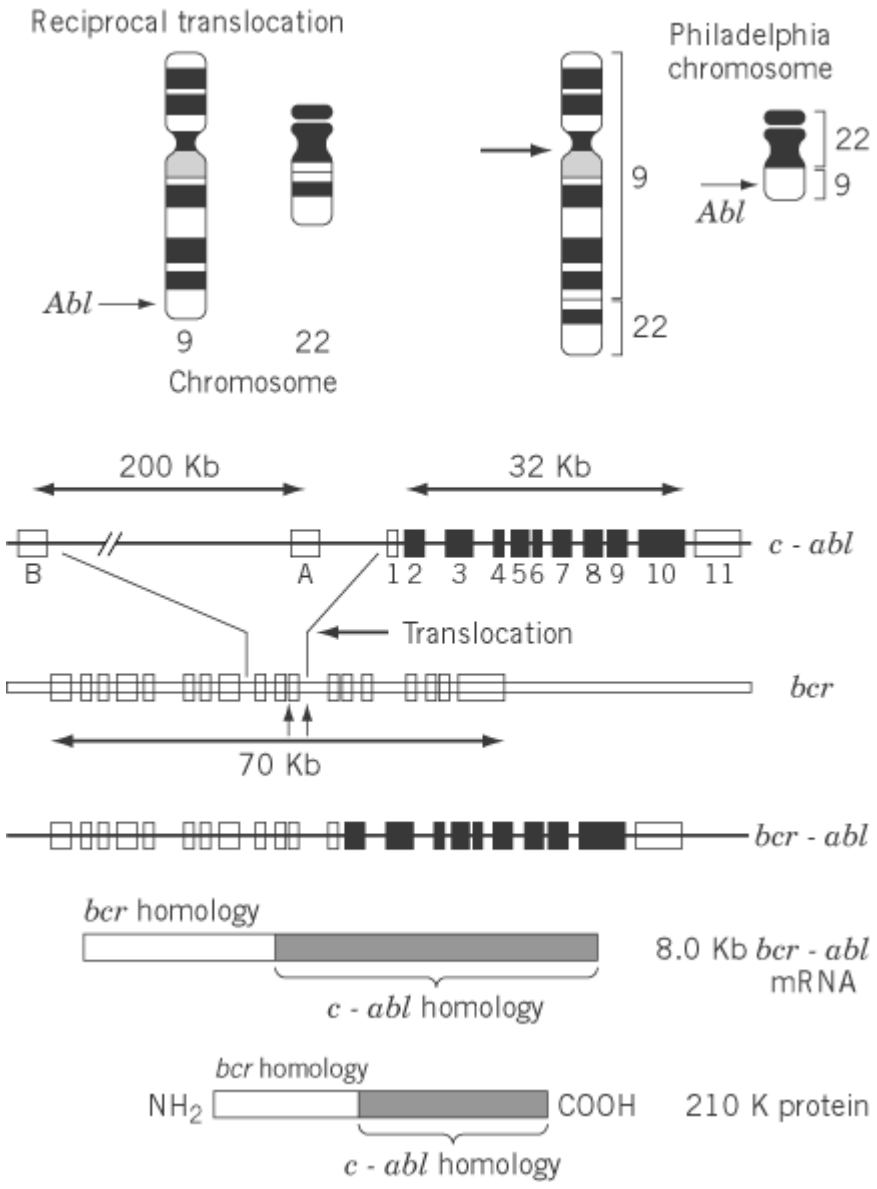
Figure 5. Comparison of the genomic structures of the *ras* proto-oncogenes. All of these genes encode four exons. K-*ras* encodes a fifth exon which is alternatively spliced during transcription. Although all of the encoded proteins are identical in size, the length of their transcripts and genetic loci differ considerably.



4. Oncogenes and Chromosomal Abnormalities

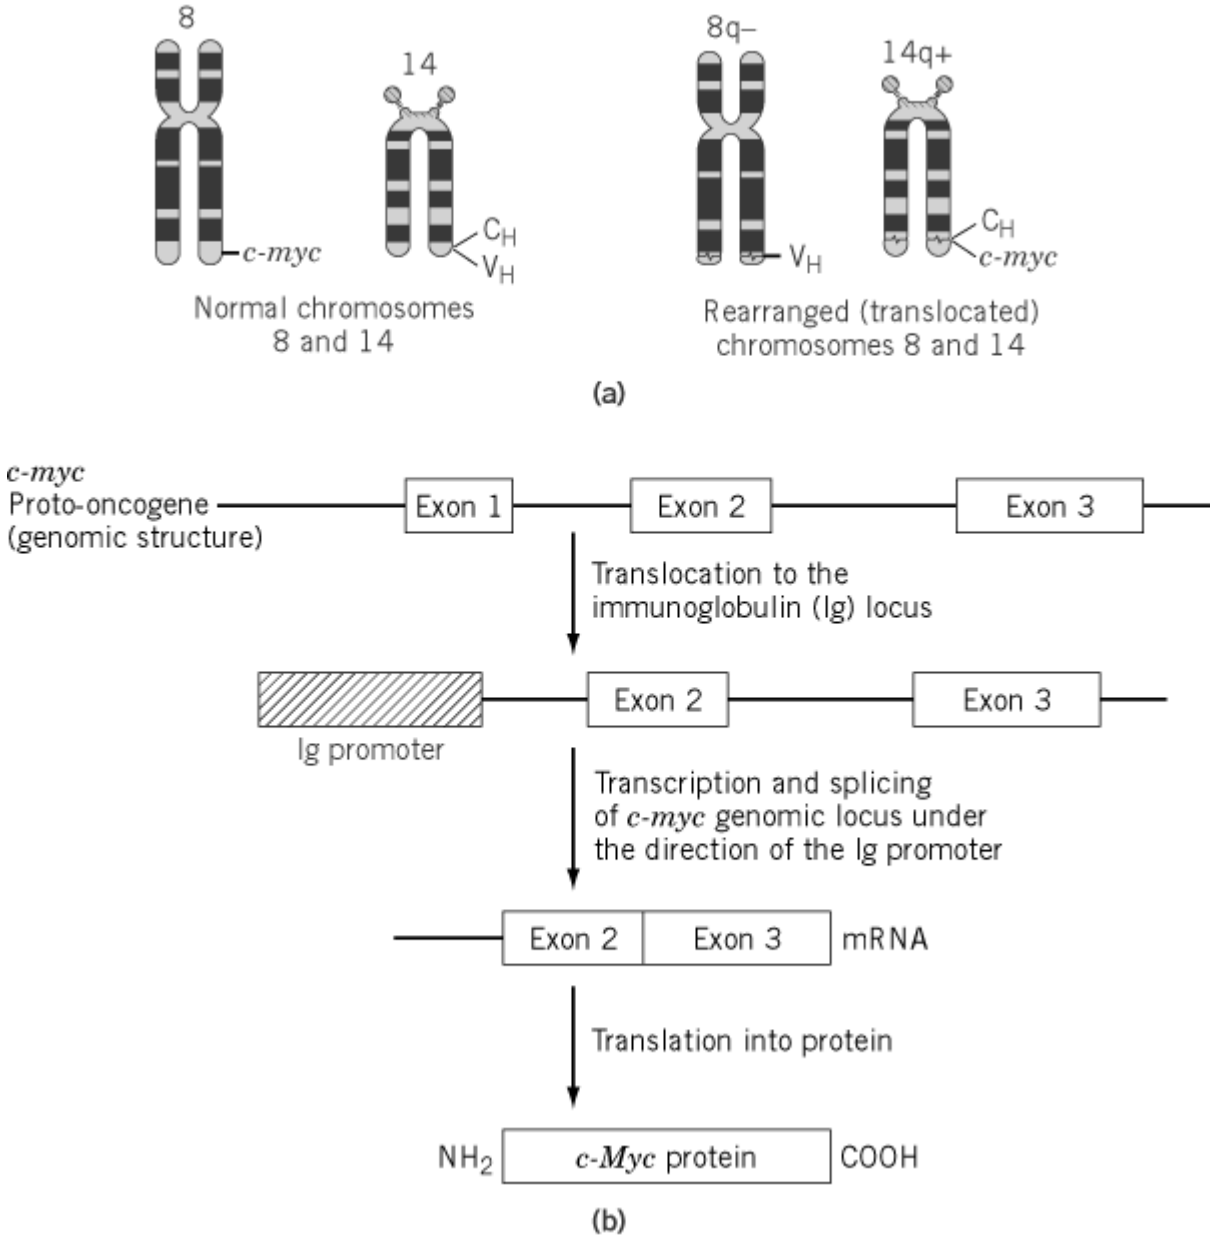
For many years, it has been known that tumor cells contain **chromosomal** abnormalities that are nonrandom. Although the hypothesis that such abnormalities might play a role in cancer was put forward in 1890 by Von Hansenmann (26), the first experimental evidence to support it was provided in 1960 by Nowell and Hungerford, who discovered the Philadelphia chromosome, a chromosomal abnormality consistently associated with human chronic myelogenous leukemia (CML) (27). This disease provides a paradigm of the genetic lesions associated with cancer because more than 90% of the cases involve a **translocation** in which a small portion of the long arm of chromosome 9 is transferred to the long arm of chromosome 22 (28) (Fig. 6). Even though later studies made it clear that a vast majority of human cancers contain one or more such chromosomal abnormalities, the actual molecular mechanisms associated with these abnormalities and their relationship to human cancer remained largely enigmatic until recently. During the past decade, a number of such chromosomal abnormalities have been studied in detail at the molecular level. All of the evidence accumulated thus far suggests that these chromosomal break points occur within or in the vicinity of an oncogene, which results in activating this gene. Thus, gene mapping studies have established that the c-*abl* oncogene is located on chromosome 9q34, the location where the break point occurs in the Philadelphia chromosome. During formation of the Philadelphia chromosome, a portion of the c-*abl* gene is translocated to chromosome 22 and is fused to a portion of the gene called *bcr*, which itself is disrupted during the translocation process (Fig. 6). This process generates a new gene, termed *bcr-abl*, that has enhanced oncogenic activity and whose expression leads the development of leukemia (29, 30). It is interesting to note that the BCR-ABL gene is structurally very similar to the GAG-ABL gene encoded by the Abelson murine leukemia virus. Both exhibit high levels of tyrosine kinase activity, which is essential for their transforming activity.

Figure 6. Generation of the bcr-abl oncoprotein by chromosomal translocation. The abl gene in a normal cell, is located on chromosome 9 and encodes a tyrosine kinase. During malignant transformation of myeloid cells, a portion of chromosome 9 that contains the abl locus translocates to chromosome 22 at the breakpoint cluster region (bcr) locus and generates the chimeric bcr-abl oncoprotein. Because the translocation results in deleting the sequences that negatively regulate abl tryosine kinase activity, the fusion protein has constitutive and increased levels of enzymatic activity.



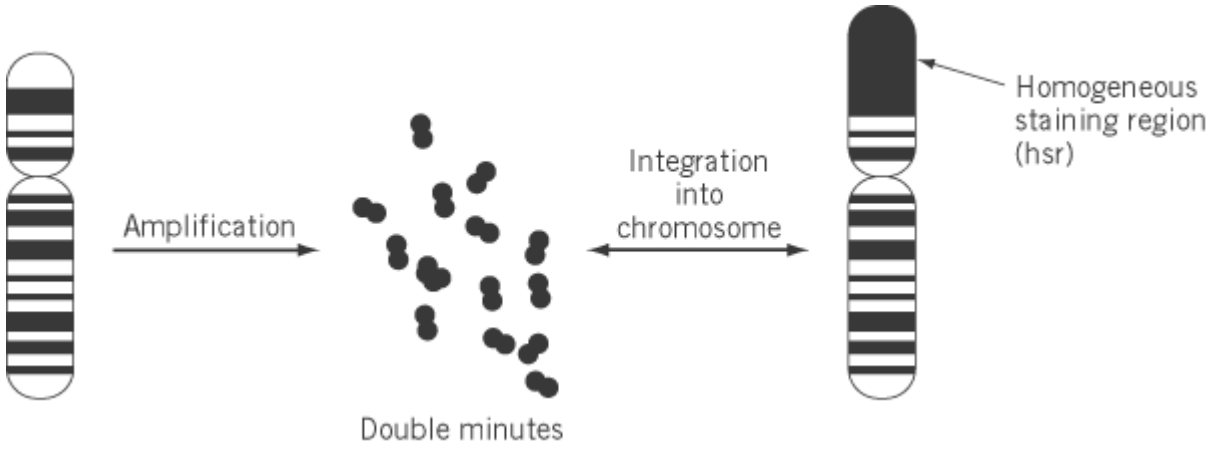
A second example of chromosomal abnormality is seen in Burkitt's lymphoma (a malignancy of the B-cell lineage), where a chromosomal exchange between chromosome 8 and 14 occurs (31, 32). This translocation results in juxtaposing the *c-myc* oncogene with the regulatory sequences of the immunoglobulin (Ig) genes (Fig. 7). Immunoglobulin loci code for **antibodies** produced solely by B lymphocytes. When these genes are expressed, the Ig regulatory sequences direct high levels of mRNA transcription of the Ig genes located next to them. When the *c-myc* oncogene is placed under the transcriptional control of the Ig regulatory elements, however, the B cell abnormally produces extremely high levels of *c-myc* mRNA and protein (instead of antibody), which induces a malignant phenotype.

Figure 7. Activation of the *c-myc* oncogene as a consequence of translocation in Burkitt's lymphoma. (**a**) During translocation, the c-myc gene (located on chromosome 8) translocates to chromosome 14 at a site next to the immunoglobulin heavy chain (C_H) locus. (**b**) This translocation results in juxtaposing the immunoglobulin regulatory sequences upstream of the *c-myc* gene. Because the immunoglobulin promoter positively regulates high levels of transcription in B lymphocytes, the *c-myc* gene (instead of the immunoglobulin gene) is constitutively transcribed and translated in the cell.



A third type of chromosomal abnormality is associated with the abnormal amplification of certain chromosomal regions that contain oncogenic sequences. The amplified DNA in these tumors can exist as a tandem copy of a set of genes on a given chromosome or as small chromosome-like structures, known as double minute chromosomes (Fig. 8). The double minute chromosomes present themselves as homogeneously staining regions (HSR) that are distributed over the entire field in a chromosome preparation. Thus, a variety of human neuroblastomas exhibit amplification of the N-*myc* gene (33), and several solid tumors are associated with the amplification of *erb*-B-2 gene (34). Interestingly, the prognosis for these tumors correlates with their level of oncogenic amplification. Poor prognosis is associated with greater amplification of a given oncogenic sequence.

Figure 8. Formation of homogeneous staining regions as a result of DNA amplification. Once a locus is amplified by several rounds of DNA amplification, tandem repeats can be excised to form double minute fragments. These fragments can integrate into the locus of another chromosome, forming a homogeneous staining region (HSR). Because this process is reversible, double minute fragments and HSRs are amplified regions of DNA that are interchangeable.



5. Chemical Carcinogens often target Oncogenes

Chemical **carcinogens** have a very broad range of structures that have little or no obvious structural or biochemical similarity to each other. This diversity of their structures clouded earlier studies of possible mechanisms for their mechanism of action. A more puzzling fact about the most commonly occurring carcinogens was their relative insolubility in water. Rapid progress in this field was made when it was discovered that most chemical carcinogens do not act directly but undergo modifications inside the cell, following their uptake, that generate a new group of chemicals which act as carcinogens. The enzymes that convert procarcinogens to carcinogens are called cytochrome P450s, and their major function in the cell is detoxification of foreign chemicals (35). Thus, there are two types of chemical carcinogens, one called direct-acting carcinogens that, as the name implies, act directly without any metabolic activation and the other, called indirect-acting carcinogens, which require metabolic activation for them to act as carcinogens. The terms procarcinogen and ultimate carcinogen describe the pre- and postprocessing states of indirect-acting carcinogens. Once inside the cell, both types of carcinogens interact with a wide variety of cellular components, including DNA, RNA, and proteins. It is now believed that the most important of these interactions is with DNA and results in introducing mutations. In fact, the finding that most carcinogens are mutagens allowed Bruce Ames to develop a number of assays using bacterial systems, the Ames test, that permit rapid analysis of various environmental agents for their possible oncogenic activity (36).

Although it was becoming clear that chemical carcinogens may exert their influence by acting as mutagens, the identity of their targets remained unknown for quite some time. The first clues about their targets came from DNA transfection experiments using NIH/3T3 cells, where it was shown that DNA from chemically transformed cell lines contain activated *ras* genes. These studies suggested that proto-oncogenes might be the crucial targets of the chemical carcinogens (37). This concept received much needed experimental support with the demonstration that a majority of rat mammary tumors induced with a single dose of *N*-nitroso-*N*-methylurea during sexual development have point mutation in the *ras* gene that coverts this proto-oncogene into a potent transforming gene (38). Following this discovery, it was shown that a number of chemical carcinogens act on proto-oncogenes and convert them into dominant transforming genes. Although the limitations of the NIH/3T3 assay system allowed detecting *ras* genes in a large number of chemically induced tumors, oncogenes other than members of the *ras* gene family have been identified in animal model systems. Thus, inducing neuroblastomas and gliomas by ethyl nitrourea or *N*-nitroso-*N*-methylurea activates the *neu* oncogene reproducibly (37). Therefore, it is increasingly evident that chemical carcinogens target cellular proto-oncogenes and bring about transformation through their action on these genes.

In summary, the evidence outlined shows that the mammalian organism contains a number of proto-oncogenes that have been highly conserved through evolution. These genes can be oncogenically activated through transduction by retroviruses, mutation by chemical carcinogens, or as a result of

chromosomal abnormalities that occur during the genesis of cancer. To develop rational approaches for treating cancer, it is essential that we understand the structure and biochemical function of the proteins encoded by proto-oncogenes and the nature of biochemical changes that accompany the structural changes in naturally occurring tumors. For this reason, during the past five years, a number of investigators turned their attention to the task of delineating the function of the proteins encoded by proto-oncogenes in normal cell growth and differentiation.

6. Function of Oncoproteins in the Normal Cell

The first clues about the normal function of oncogenes came from the observation that the *v-sis* oncogene product is highly related to the b-chain of the receptor for platelet derived growth factor (PDGF) (39). A second discovery that linked oncogenes with growth-factor signaling was the finding that the Erb-B2 oncogene, encoded by the avian erythroblastosis virus (Table 2), is an activated form of the epidermal growth factor (EGF) receptor (39). These two observations suggested for the first time that oncogenes might code for growth factors, their receptors, or signal-transducing proteins that relay the growth signal to the nucleus. Extensive biochemical analysis of these oncogenes has established that proto-oncogenes and their homologues are part of a stringently regulated cellular signaling network that controls cell proliferation and differentiation. In normal cells, the primary event leading to a cellular mitotic response is binding and activation of cellular receptors by growth factors (40, 41). Structural analysis of these receptors revealed that they contain a tripartite structure consisting of an external ligand-binding domain, a transmembrane domain, and an intracellular tyrosine kinase domain. Upon binding to growth factors, these receptors dimerize, which activates their intrinsic tyrosine kinase activity and leads to phosphorylation of multiple tyrosine residues in the intracellular portion of the molecule. These residues act as docking sites for a number of signal-transducing molecules that relay the signal to other proteins. An important feature of many signal-transducing molecules is the polypeptide sequences, called SH2 and SH3 domains, which were originally discovered in the v-Src protein (SH = Src–homology). It was subsequently discovered that peptides containing an SH2 domain recognize peptide segments containing phosphotyrosine residues in a sequence-specific manner (42). Similarly, peptides that contain an SH3 domain recognize sequence motifs that are **proline**-rich, usually containing the sequence motif Pro-X-X-Pro, where X is any amino acid residue (42). The molecules that contain these SH2 domains either have enzymatic activity or do not. The molecules that are enzymatically active include **phospholipase Cg**; (PLC), phosphatidyl inositol 3-kinase (PI3K), and the GTPase-activating protein for p21 Ras, p120 GAP. The proteins that lack enzymatic activity include proteins, such as SOS and Grb-2, both of which simply function as adaptor molecules that tether proteins in a larger, more elaborate signaling complex. Collectively, these signal-transducing molecules activate multiple pathways that bring about the pleiotropic responses to growth factors. For example, PLCg hydrolyzes phosphoinositols to generate **diacylglycerol** and **inositol-3-phosphate**. PI3K phosphorylates phosphoinositides and generates putative second messengers that mediate rearrangements of the cytoskeleton and cellular trafficking (43). Diacylglycerol activates protein kinase C, a **serine/threonine kinase** that activates transcription factors which constitute the components of a complex called AP1.

In contrast, proteins that act as adaptor molecules, such as Grb-2, simply contain SH3 and SH2 domains and bind to the receptor via their SH2 domain (Fig. 9) (39-42). Then, the SH3 domain of the protein binds to a second adaptor protein, called Sos, which contains a polyproline motif that recognizes the SH3 domain of Grb-2 and catalyzes exchange of GDP bound to Ras for GTP. Activated Ras plays a critical role in targeting Raf, another oncoprotein, to the plasma membrane. Ras contains a Cys-Ala-Ala-X box that is recognized by an enzyme called farnesyl transferase, which adds a **farnesyl** moiety to the cysteine residue, allowing Ras to bind to the plasma membrane. An adjacent polybasic domain of six lysine residues is a targeting signal for Raf. Once the Raf serine/threonine kinase has been activated by phosphorylation, it phosphorylates an enzyme called MEK. Phosphorylated MEK, in turn, initiates the activation/phosphorylation of mitogen-activated protein kinase (MAPK), which similarly activates Rsk (Fig. 10). Phosphorylation of transcription factors also results in their activation and participation in cellular proliferation pathways. The most

notable examples of the nuclear transcription factors activated by this pathway include Fos, Jun, Myc, and Myb, all of which were originally discovered as oncogenes of acute transforming viruses.

Figure 9. Interaction of SH2 domain signaling proteins with the PDGF receptor. The PDGF receptor contains several tryosine residues to which SH2 domain-containing, signal-transducing proteins bind, but only after these residues have undergone autophosphorylation. The open boxes in the intracellular portion of the receptor represent a single tyrosine kinase domain.

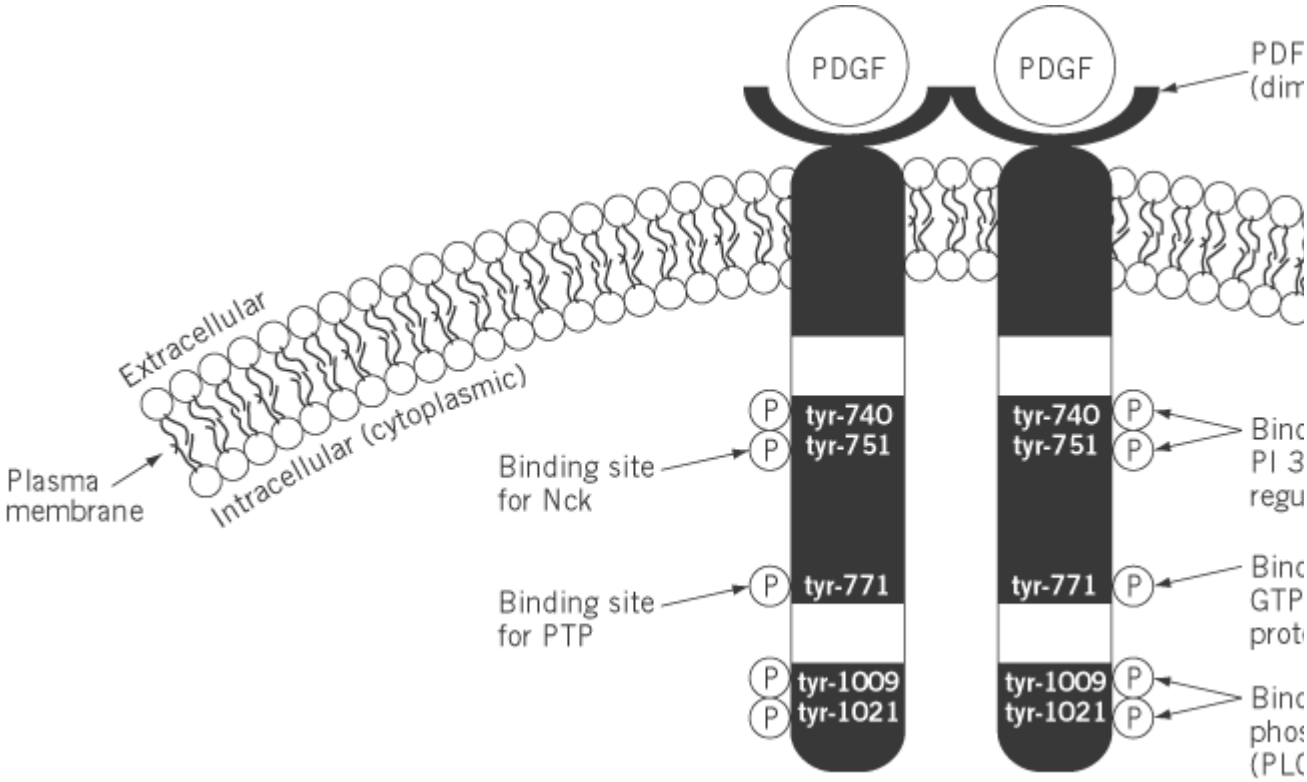


Figure 10. Schematic representation of receptor tyrosine kinase (RTK) signaling. (**a**) In a resting cell, RTKs exist as nondimerized, nonphosphorylated transmembrane proteins. The Grb-2 and Sos adaptor proteins are bound through the two Grb2 SH3 domains and the proline-rich regions of Sos. In addition, ras remains in an inactive, GDP-bound state. (**b**) Once the RTK has bound to its cognate ligand, it dimerizes and undergoes autophosphorylation on multiple tyrosine residues. Now, the phosphorylated receptor can bind to the Grb2:Sos adaptor complex. Because the function of adaptor proteins is to link multiple signal-transducing proteins within a single pathway, the Grb:Sos complex triggers the formation of GTP-bound, activated ras. Subsequently, activated ras initiates the ordered, sequential phosphorylation of RAF, MEK, ERK, and Rsk which is essential for cell growth and differentiation. The phosphorylation of several classes of transcription factors enables them to bind to DNA and induce gene transcription.

The activation of multiple signaling pathways by the PDGF receptor illustrates the complexity of the signaling networks involved in regulating cell proliferation. The constitutive activation of these receptors by truncation of the amino-terminal regulatory domain, by point mutations, or by overexpression activates all of these pathways and leads to oncogenesis.

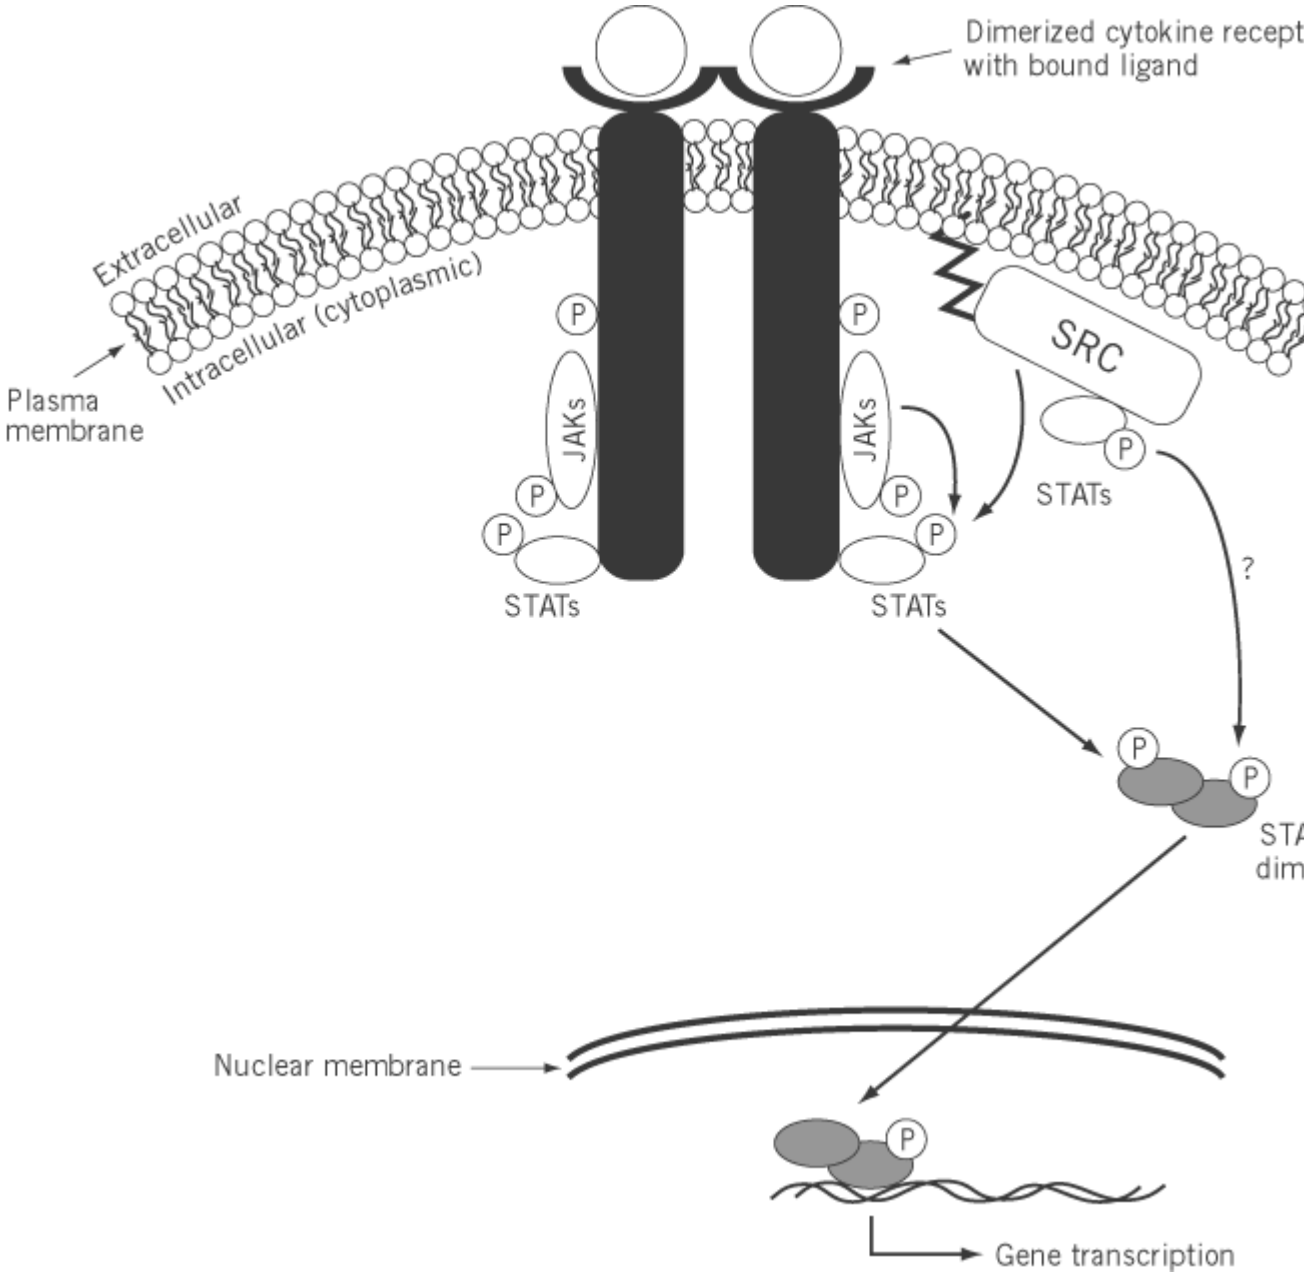
7. Subversion of Cytokine Signaling by Oncogenes

Cells of **hematopoietic** lineages transduce their growth signals predominantly via a group of receptors known as cytokine receptors. Molecular cloning of cytokine receptors and subsequent structure-function studies have revealed that, unlike growth-factor receptors, several of the cytokine receptors lack a cytoplasmic kinase domain. Nevertheless, interaction of a cytokine with its receptor rapidly induces tyrosine phosphorylation of the receptor and a variety of cellular proteins, suggesting that these receptors transmit their signals through cellular tyrosine kinases. Recently, new evidence has emerged to indicate that most cytokines transmit their signals via a new family of tyrosine kinases, termed JAKs, and via Src kinases (44, 45).

The JAK family of protein tyrosine kinases differs markedly from other classes of by the presence of an additional kinase domain. Currently, this family consists of four members, JAK1, JAK2, JAK3, and TYK2. Although JAK kinases do not contain the SH2 and SH3 domains that characterize Src family tyrosine kinases, they do possess highly conserved domains upstream of the kinase domains. These kinases, either alone or in conjunction with each other, are responsible for effects mediated by several cytokines and neurokines, including interleukins, interferons, erythropoietin, prolactin, growth hormone, oncostatin M, and ciliary neurotrophic factor.

Current models suggest that when cytokine receptors that contain single polypeptide chains (such as erythropoietin, growth hormone, prolactin, and GCSF) interact with cytokines, they undergo dimerization, which increases the affinity of the cytoplasmic domain of the receptor for JAK kinases and results in a ligand-dependent increase of a complex that contains the receptors and JAKs (Fig. 11) (44). This association requires the membrane-proximal cytoplasmic domain of the receptor and results in activating the JAKs through an event associated with tyrosine phosphorylation. Then, the activated kinases phosphorylate the receptors and cellular substrates that regulate a wide variety of responses in cells.

Figure 11. Activation of STAT proteins in response to cytokine stimulation. Cytokine binding induces receptor dimerization and the activation and phosphorylation of two classes of tyrosine kinases, termed JAKs and Src kinases. Once the Src kinases and the JAKs have been activated, they phosphorylate a second class of proteins, termed STATs. Once phosphorylated, these proteins dimerize and translocate to the nucleus where they bind to DNA and stimulate transcription of genes whose promoter sequences contain STAT-responsive elements.



A surge of recent studies has demonstrated that cytokine signaling is associated with the phosphorylation of a group of transcription factors, Signal Transducers and Activators of Transcription now known as STATs, or (46). In a resting cell, these STATs remain in the cytoplasm. Stimulation of cells with cytokines results in phosphorylation of STATs mediated by Src kinases and JAKs. This, in turn, results in migration of STATs to the nucleus, where they participate in binding to DNA sequences containing the STAT response elements. All of the STAT proteins are highly related and are characterized by a carboxy-terminal SH3 domain, followed by an SH2 domain. All of the proteins contain a conserved C-terminal tyrosine residue that is phosphorylated and is essential for their biochemical activity. Together, these studies suggest that, upon interaction with their receptors, cytokines activate JAKs and Src kinases, which in turn activate members of the STAT family of transcription factors.

Now, it is well established that several of the oncogenic tyrosine kinases that belong to the Src and Abl families have profound effects on the cytokine dependence of hematopoietic cell lines. Most notably, constitutive expression of the *v-src*, *v-abl*, and *bcr-abl* oncogenes in interleukin-dependent hematopoietic cell lines renders them cytokine-independent for growth. This alteration in growth-

factor dependence suggests that these oncogenes might interfere with signal-transduction pathways associated with cytokines. Recent studies have provided conclusive evidence that these oncogenes produce these transformations by constitutively activating STATs via tyrosine phosphorylation, often without activating JAK kinases (45, 47). For example, in BCR-ABL-positive CML cells, STAT 5 is phosphorylated constitutively, activating the proliferative pathways that are associated with this transcription factor in the absence of any cytokine-receptor interactions (48). These studies link chromosomal abnormalities that alter signal-transduction pathways to the onset of neoplasia.

8. Activation of Intracellular Phosphorylation Cascades Leads to Changes in Gene Expression

Activation of the intracellular phosphorylation cascades previously described invariably leads to two types of changes in gene expression. Early-response genes are induced with 15 minutes of growth-factor treatment, and their induction does not require **protein biosynthesis** because cycloheximide, a potent inhibitor of protein synthesis, has no effect on their induction (49). By contrast, delayed-response genes are not induced until at least 1 hour after growth-factor treatment, and their induction requires protein biosynthesis. Delayed-response genes are induced by the products of early-response genes, several of which are transcription factors (50). Examples of early-response genes are c-*fos* and c-*myc*, and c-*myb* is an example of a late-response gene.

Both classes of genes are silent and not transcribed in cells in the G_o phase of the cell cycle (see later), but they are induced at high levels when growth factors are added to cells. Prolonged exposure to growth factors results in a gradual decline of gene expression, for some genes apparently to zero, and for certain others to a steady-state level above that observed during G_o.

9. Growth Factors and Cancer

The importance of precisely regulating receptor activation and signal transduction is further exemplified by the fact that a large variety of structural changes found in receptors lead to their constitutive activation and, consequently, to subversion of molecular control mechanisms that contributes to the onset of neoplasia. Very often, human cancers have been found when the genes for growth factor receptors are amplified. This provides a great proliferative advantage to these cells. Additional changes that result in growth advantage are point mutations in the *ras* and raf genes that activate this pathway constitutively and overexpression of early-response or late-response genes, such as c-*myc* or c-*myb*, which activate transition from the G_1 to the S-phase of the cell cycle. Identification of aberrations in growth-factor-induced, signal-transduction pathways in tumor cells is currently an active area of research. Detailed understanding of these mutants will provide important insights into fundamental mechanisms of normal cell growth and will also enhance our understanding of oncogenesis and open new avenues for diagnosis and therapy.

10. Oncogenes and the Cell Cycle

The cell cycle is a regulatory “clock” that controls the proliferative rate of a dividing cell. More importantly, many of the controls that govern the progression and length of the cell cycle and the phases that comprise it are controlled by the products of oncogenes and a second class of proteins, termed tumor suppressor genes (50). The eukaryotic cell cycle has remained highly conserved throughout evolution and therefore has been studied in organisms ranging from yeast to man. Virtually all studies conducted thus far reveal that the cell cycle is divided into four phases (G_1, S, G_2, and M; see Fig. 12) and is heavily regulated at two checkpoints: (1) a point in the G_1 phase where the cell becomes committed to replicate its genetic material and; and (2) a point at the G_2/M border where the cell becomes committed to division.

Unless cells have received a stimulus to proliferate or differentiate, most remain in a resting state,

called G_o. When the organism requires additional cells, however, as is seen frequently in the hematopoietic system, extracellular stimuli induce the cells to enter the G_1 phase of the cell cycle and become committed to cell division. At a late point in the G_1 phase of the cell cycle a potentially dividing cell reaches the "restriction point," a time at which the cell must determine whether the conditions are suitable for continued proliferation. Provided that conditions are conducive to proliferation, the cell proceeds past this checkpoint. An absolute prerequisite for cell growth is the duplication of its genetic material, which occurs during the S-phase. Once the DNA is replicated, the cell "ascertains" whether this process has been correctly executed at the second checkpoint during G_2. Provided that it has, the cell divides during mitosis, the M-phase. Frequently, malignant cells effectively override one or both of the intrinsic checkpoints that are normally used by their normal counterparts. Although some of the oncogenes previously discussed, such as *ras*, force progression through G_1, other genes, called tumor suppressor genes, function as "gatekeepers" of these restriction points. Loss of these genes, therefore, enables a malignant cell to ignore all of the safeguards aimed at preventing unwanted cell division.

11. Conclusion

As summarized previously, we have come a long way during the past two decades in understanding the molecular mechanisms of cell growth, differentiation, and neoplastic transformation. It is becoming increasingly clear that aberrations in oncogenes, which act as positive regulators of growth, and aberrations in tumor suppressor genes, which act as negative regulators of growth, contribute to developing the neoplastic state. Although we have accumulated a great deal of information about the role of various oncoproteins in signal-transduction pathways, we have yet to define the precise pathways that lead to cell growth versus differentiation. It is becoming apparent that cell proliferation and differentiation are interrelated and that mechanisms that lead to a block in cell differentiation result in increased proliferation of cells and ultimately into neoplasia. It is reasonable to hope that a detailed understanding of the signal-transduction pathways for cell growth and differentiation will also provide us with clues that allow us to override the block in differentiation in tumor cells. The prospect of developing such therapeutic approaches for treating cancer is very promising in the immediate future. Identifying oncogenes and delineating their function clearly has had a major impact on the development of such approaches.

Opal Suppressor

Opal suppressors are mutant tRNAs that translate the UGA (opal) termination codon as a sense codon. Opal mutations cause protein synthesis to terminate prematurely, resulting in inactive, truncated polypeptides. Opal suppressors allow for protein synthesis beyond the translational block resulting in active protein. Hence the term "suppressor;" these mutant tRNAs "suppress" the phenotypes of opal mutations. These suppressors have been used in studies of the translational apparatus and mechanisms. For complete discussions of these and other suppressors, see Nonsense Suppression, Suppressor tRNA, and Genetic Suppression.

Operons

The term *operon* is occasionally used to mean any segment of DNA that is **transcribed** into a single **RNA** molecule, but in the more usual sense intended here, it denotes a set of contiguous **genes** that, though separately **translated** to yield distinct polypeptide chains, are transcribed together from a common transcription start point (**promoter**). This is a common mode of gene organization in **bacteria**, but it has not been described in eukaryotic organisms, except in nematode worms and **trypanosomes**, where it takes a rather different form.

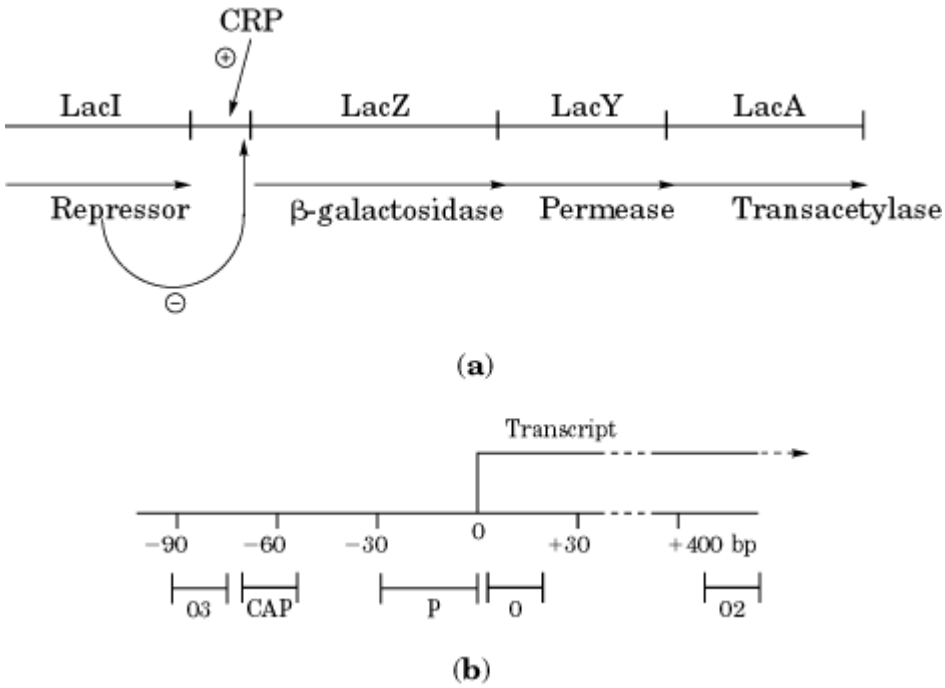
In bacteria, genes that contribute to a common function are frequently found united in an operon, an arrangement that makes it possible to regulate all their activities together by a single control of transcription. The operons of *Escherichia coli* and *Salmonella typhimurium*, by far the most thoroughly studied (1), may be considered as classified in three groups, involved, respectively, with utilizing occasionally available energy sources (eg, the sugars lactose, galactose, and arabinose; see Lac Operon, Gal Operon, ara Operon), with synthesis of amino acids (eg, tryptophan, histidine, phenylalanine—see leucine TRP Operon), and **protein biosynthesis** (operon organization of genes for **ribosomal** proteins). All operons are subject to some form of joint regulation of their constituent genetic activities to meet the current requirements of the cell. Thus, enzymes for utilizing sugar are produced only in the presence of the relevant sugars and the absence of glucose, the enzymes for synthesizing amino acids are not produced when the amino acids are already present in the growth medium, and ribosomal proteins are not allowed to accumulate in slowly growing cells. The joint regulation of the genes in an operon may operate through transcriptional or translational control or both.

1. The *lac* Operon - Transcriptional Regulation

The *lac* operon, the first to be described (2) and the one that provided the paradigm model for operon regulation, contains three genes. Two of them (*LacZ* and *LacY*) are essential for utilizing lactose as a carbon source, and code, respectively, for **beta-galactosidase**, which hydrolyses lactose to glucose plus galactose, and b-galactoside permease, a membrane protein needed to efficiently take up lactose into the cell. The third gene of the operon, *LacA*, encodes b-galactoside transacetylase, an enzyme that has defined chemistry but uncertain function and is lost by mutation without any obvious effect. The three genes are adjacent to each other in the order Z-Y-A, and are transcribed into a common messenger RNA. LacZ is at the upstream end ("upstream" with reference to the direction of transcription and translation). All three functions of the operon are **induced** in a constant ratio (coordinately) by lactose or some other inducing b-galactoside and are repressed by glucose. The synthetic b-galactoside thiomethyl-b-D-galactopyranoside (TMG) is often used as an artificial inducer but is not itself usable as a carbon source.

The keys to understanding of induction of the *Lac* operon were mutations that resulted in the production of b-galactosidase and the other operon products constitutively, that is, without the need for induction. These mutations, which did not affect repressibility by glucose, fell into two groups. One group mapped within a closely linked gene *LacI*, outside and upstream of the operon. The other group, called operator-constitutive (o^c), mapped within a very short segment called the **operator**, which mapped just upstream of the LacZ b-galactosidase-encoding sequence. A little further upstream another segment was identified through mutations that eliminate or reduce the level of expression of the operon under all conditions. This segment was called the **promoter**, the putative **RNA polymerase**-binding and transcription-initiation sequence (Fig. 1). Experiments with partial **diploids** that have duplicate *Lac* operon segments carried on plasmids, showed that the operator-constitutive (o^c) mutants are dominant over wild type, or, more precisely, cis-dominant because their mutant operators make b-galactosidase constitutive only when joined to a wild-type *LacZ*+ allele, not when o^c and *Lac*+ are on a separate piece of DNA. The *lacI* mutations, on the other hand, are recessive to *LacI*+, and the wild-type allele imposed the inducible state on *LacZ*+ whether joined to it on the same chromosome or not, that is, it acted both in *cis* and in *trans*.

Figure 1. The *Lac* operon that has a single mRNA for three protein-encoding genes. Its transcription is activated by CRP protein (see text) and repressed by the repressor protein encoded by the separately transcribed *LacI*. Arrows indicate the direction of transcription/translation. The action of the repressor is cancelled by allolactose or other inducers. (b) Protein-binding sites within the *Lac* control region (dotted circle in a). The repressor binds to the three operator sites, O, O2, O3. After Ref. 3 by permission.



Based on these observations, it was postulated that *LacI* encodes a repressor protein that binds to the operator segment to block the function of the promoter and that the *LacI* protein also binds to lactose and thereby undergoes a conformational (allosteric) shift that cancels its affinity for the operator (see Lac Repressor). Later molecular analysis has confirmed this hypothesis in every particular, except that it is a lactose derivative, allolactose, not lactose itself, that binds to the repressor.

The regulation of transcription of the *Lac* operon was initially thought to be entirely through repression and release from repression, and its paradigm status was such that this was assumed to apply to gene regulation generally. That this was not the case, even for *Lac*, became clear through investigating the mechanism of repression of the operon by glucose. First, it was found that the repression is partially relieved by adding to the culture medium 2′, 3′ cyclic adenosine monophosphate (cyclic AMP, cAMP), a metabolite that accumulates under conditions of sugar starvation. Then mutants were found that fail to respond to cAMP, and it was postulated that these fail to produce a protein with which cAMP combines to activate transcription. This protein, called CAP for catabolite activation protein (or CRP for **cAMP receptor protein**), was indeed identified. It binds to a sequence, which is a little way upstream of the promoter (Fig. 1), to activate transcription. The CRP–cAMP complex is required for transcription at all times, and when glucose is relatively abundant, cAMP levels fall to the point where activation is not effective.

Analysis of the DNA sequence of the whole *lac* operon control region combined with DNA-protein binding experiments and studies of the effects of various precisely-positioned mutations has resulted in more precise definition of the promoter, operator, and CRP-binding sequences, and also revealed further complexities (Fig. 1) (3). There are several partly overlapping sequences of 30 to 40 base pairs which conform more or less well to a consensus of *E. coli* promoters, but only one (P1) is important in the wild type. In addition to the main operator (O) there are two other short segments, quite widely spaced on either side, that are also bound by *LacI* repressor and are necessary for full repression. The highest affinity CRP-binding segment is 80 bp upstream of the transcription start point, but there is another that has lower affinity and uncertain significance, which more or less coincides with the operator.

Operon organization permits subjecting a group of functionally related genes to a common control mechanism that operates, in the case of *Lac*, at the stage of transcription. Another consequence of

common transcription was revealed by analyzing mutations that have polar effects that knock out the function of the gene in which they occur and reduce the expression of genes further downstream. Polar mutants are chain-terminating ("amber" or "ochre" stop codons, or **frameshift** mutations that lead to premature stops downstream). The earlier they terminate translation, the more drastic their effect on downstream genes (4). This can be explained in the following way. Translation of mRNA in bacteria follows closely on the heels of transcription. Ribosomes attach progressively to the growing mRNA from the 5′ end and begin to translate it even as it peels off the DNA template strand. There is evidence that the stability of the mRNA depends on promptly covering it with ribosomes, which become detached at termination codons. Premature polypeptide chain termination leaves mRNA unprotected by ribosomes and vulnerable to attack by **nucleases**. The severity of polar effects increases with the length of exposed mRNA, which is the distance from the premature termination point, where the ribosomes become detached, to the next initiation codon, where they reattach to the mRNA. Thus transcription and translation are interdependent. Translation obviously depends on prior transcription, and effective transcription depends on prompt translation of the transcript.

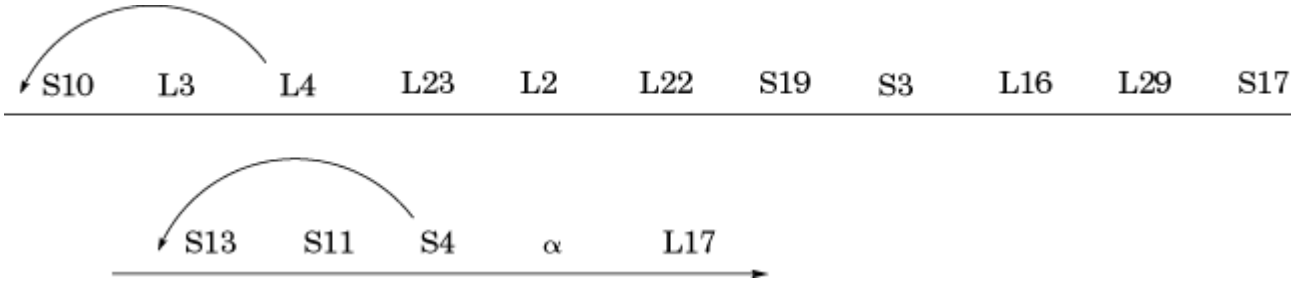
2. Other Bacterial Operons—Other Modes of Regulation

The combination of transcriptional activation and repression that governs the *lac* operon also applies to the gal operon, which is involved in utilizing galactose. Here the repressor protein, inactivated by galactose, is encoded by a distant gene *galR*, and again glucose repression is controlled by CRP and the level of cAMP. The arabinose ara operon has its own protein (the *araR* product), which acts as an activator or a repressor depending on the presence or absence of arabinose. It was the first operon to cast doubt on the repression-only model of gene regulation.

Whereas the sugar utilization operons are regulated solely at the transcriptional level, the operons of amino acid synthesis are subject either to transcriptional or translational regulation, or both. Transcription of the tryptophan operon (see TRP Operon) is repressed by the *trpR*-encoded repressor protein in the presence of tryptophan and is derepressed when the tryptophan level drops. But there is another, more rapid way of shutting down tryptophan synthesis called **attenuation**, which operates posttranscriptionally and is mediated by the short mRNA leader sequence. Within the leader is a short **open reading frame** (ORF) that contains two successive tryptophan **codons**, a striking coincidence considering the comparative scarcity of tryptophan in proteins. Ribosomes pass through this short ORF rapidly when there is an abundance of trytophanyl-tRNA, but they jam at the tryptophan codons when the tryptophan supply runs low. This prevents the assumption by the leader of a folding mode that would otherwise greatly reduce (**attenuate**) the translation of the rest of the operon. Similar attenuation mechanisms are found in other amino acid synthesizing operons that have runs of codons corresponding to the amino acid end product in the leader sequence in each case. Thus the **histidine operon** of *Salmonella typhimurium* (see His Operon) has eight consecutive histidine codons in its leader. Here attenuation is the sole means of regulation. There is no evidence for transcriptional repression or activation.

The six operons of *E. coli* that collectively encode all of the ribosomal proteins, together with several other components of the transcription/translation apparatus, exemplify another mode of regulation. These are regulated, at least in part, by repression of translation, and the control is exercised not by components of the growth medium (or, at least not directly) but rather by protein products of their own activity—negative feedback, the effect of which is to prevent ribosomal accumulation when growth is slowed for any reason. For each operon, one of its ribosomal protein products binds to the mRNA, generally but not always at the upstream end, to block the progress of the ribosomes (5) (Fig. 2). This stops translation of the next gene after the block and, to varying extents, that of the following genes also because translation of each gene is more or less coupled to that of the previous gene. Some of the genes, located at the downstream ends of their respective operons, escape inhibition, presumably because they recruit ribosomes independently.

Figure 2. The arrangements of genes within two of the *E. coli* operons that encode ribosomal proteins. L and S denote proteins of the large and small ribosomal subunit. a is the a-subunit of RNA polymerase. The arrowheads indicate the direction of translation of the mRNAs. The L4 and S4 proteins bind to the upstream ends of their respective mRNAs to b translation. L4 also has some effect as a transcriptional inhibitor (5).



The recently completed DNA sequence of the *Escherichia coli* genome (6), shows over 4000 genes that apparently encode polypeptide chains. About 1700 are organized into operons that have two or more genes—about 700 operons altogether. But not all sets of genes that one might think are good candidates for coregulation are linked in this way. The *E. coli* genes that encode the enzymes of arginine biosynthesis occur in scattered locations throughout the genome and, although they are all subject to a common transcriptional regulator, *argR*, they are not as tightly coupled in their activity as they would be in a common transcriptional unit. This looser type of functional grouping is sometimes called a *regulon*, and it may be appropriate in the case of the *arg* genes because the steps of arginine biosynthesis connect to a number of other metabolic pathways instead of being dedicated to a single common end product.

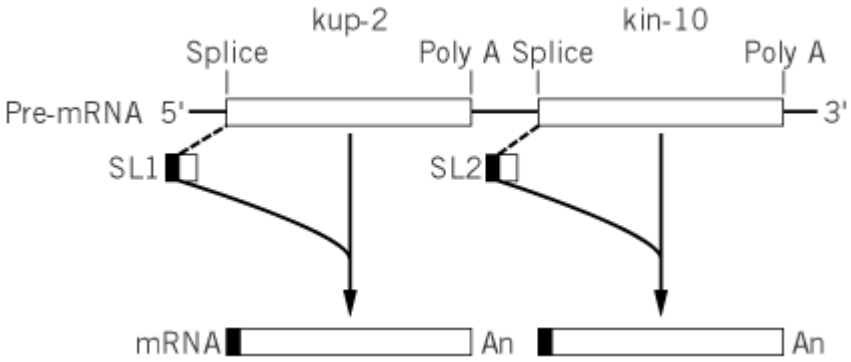
Coupling of gene activities need not be completely tight even within an operon. If the full-length multigene messenger RNA is always produced, translation is not necessarily initiated with the same efficiency at all initiation codons. The molecular yield of polypeptide chains decreases from *lacZ* to *lacY* and from *lacY* to *lacA* in the case of the *lac* operon. It seems that ribosome attachment is maximally efficient at the most upstream initiation codon and that on release from the first open reading frame the ribosomes reattach at the next initiation codon with something less than full efficiency.

3. Operons in *Caenorhabditis*

The generalization that operons are found only in bacteria was contradicted by the discovery that many genes in the nematode worm *Caenorhabditis elegans*, perhaps about 25% of the total, are organized in operons, in the sense of multigenic units of transcription. Another novel feature of *Caenorhabditis* gene expression, connected with the first, is that most gene messenger RNAs have leader sequences that are **spliced** after transcription (7, 8). These spliced leader sequences (SLs) are transcribed from separate genes present in multiple copies and are of several different kinds, of which SL1 is the most often used. The different gene sequences within an operon are separated by cleavage and individual splicing to yield separate mRNAs. The most upstream gene is generally spliced to SL1 but in some cases is not spliced, presumably because it has an its own adequate leader sequence. The genes further downstream are commonly spliced to SL2 or SL3, but sometimes to SL1 or one or other of at least seven less abundant SLs (8). One example is summarized in Fig. 3.

Figure 3. Common transcription and individual leader-sequence splicing of *Caenorhabditis elegans* genes. The individual mRNA segments are cleaved at their 5′ ends and spliced to 22-nucleotide leader sequences derived from SL RNA molecules, each approximately 100 bases in length and, transcribed from multicopy genes elsewhere in the

genome, and are cleaved and polyadenylated at their 3′ ends. Splicing to SL1 is characteristic of upstream gene transcripts. Those further downstream may be spliced to SL2 or some other SL. The splicing-out of any introns internal to the genes, which presumably occurs concurrently, is not depicted here.



The SL genes that occur in multicopy clusters on at least two different chromosomes have transcripts on the order of 100 nucleotides long, of which the 5′ 22 nucleotides are spliced on to the mRNA precursor to provide the 5′ cap site and probably essential elements of promoter sequences. The 3′ ends of the cleaved operon RNA become **polyadenylated**. The splicing reaction has much in common with the mechanism used in splicing-out introns. The SL transcript contains a typical 5′ splice sequence and a 3′ splice sequence, typically UUUCAG, is at the cleavage sites within the operon transcript (see RNA Splicing).

The functional significance of the different SL sequences, like that of bacterial operon organization, may be to do with regulating gene expression, but here linked to development rather than to metabolism. The abundance of SL4 in mRNA, which is low in the embryo, increases sixfold during postembryonic development, mostly in hypodermal cells.

A system of very similar gene organization operates in trypanosomes (9). Many and possibly most genes in this group of parasitic protozoa are grouped in multigene transcriptional units. The transcripts are cleaved into single gene units and each of these is spliced to a common leader sequence. It is a matter of convention within the respective groups that the term operon is used for the nematodes but apparently not for the trypanosomes.

4. Jointly Transcribed Nonmessenger mRNAs

Although operon-like organization of protein-encoding genes is rare in eukaryotes and is confined to nematode worms, trypanosomes, and perhaps more obscure groups yet to be investigated, it is common for several functionally distinct nonmessenger RNAs to be cut from the same primary transcript. The ribosomal RNA precursor, cleaved to yield 28S, 18S, and 5.8S molecules, is the most obvious example, but several short RNAs (snoRNAs) produced in the nucleolus and involved in processing the pre-rRNA transcripts, are themselves jointly transcribed in many eukaryotes (10). Though these multipurpose transcription units might be called operons, it is the convention to restrict the term to protein-encoding sequences.

Optical Density

Optical density, as well as extinction, are somewhat outdated synonyms for absorbance (see Absorption Spectroscopy). The term "optical density" (OD) is still widely used as a measure of the turbidity of liquid cultures of **microorganisms**, which is a measure of their density. The increase in light scattering that accompanies growth is usually measured at 600 nm and given as OD_{600}.

Organizer

One of the most important ideas in developmental biology over the last 75 years was put forth by Hans Spemann based on transplantation in amphibian **embryos**. This is the idea that certain regions of the embryo, called *organizers*, are responsible for instructing other tissues to follow particular developmental pathways (1). The particular region that Spemann identified, the dorsal lip of the blastopore, is usually referred to as the *Spemann organizer* in his honor.

Early in embryogenesis, when the amphibian embryo consists of a ball of cells called the **blastula**, the formation of an invagination called the *blastopore* leads to the formation of the three germ layers. These three germ layers—the endoderm, mesoderm, and ectoderm—are responsible for forming the various tissues and organs of the embryo. The ectoderm will form both the epidermis and most of the nervous system, but requires a signal from the cells of the dorsal lip of the blastopore in order to form the neural tube. In a series of classic experiments, Mangold and Spemann transplanted cells from the dorsal lip of the blastopore of a donor salamander embryo to a region on the opposite side of a host embryo of a different species of salamander (the two different species were used to allow the donor and host tissues to be distinguished after the transplantation). Not only did a neural tube develop in the normal position, but a second neural tube formed near the transplanted dorsal lip cells. This second neural tube was partially formed from cells in the host embryo that had been instructed, or induced, by the transplanted cells. Similar induction events have been shown to be important in the formation of other ectodermal structures, such as the lens of the vertebrate eye (2).

Since the Spemann organizer region was first described, many experiments have been done to identify the molecules involved. A large number of molecules have been shown to induce when misexpressed, but the nature of the real signal is still in debate. Several different signaling pathways have been implicated in the Spemann organizer, including the ***wingless*** Wnt signaling pathway (3-5),

the transforming growth factor b pathway (6, 7), and the fibroblast growth factor pathway (8, 9). The same signaling pathways have also been shown to be involved in developmental induction in *Drosophila* (10, 11). Although the induction events in the embryo, both in amphibians and in *Drosophila*, appear to involve signaling between a number of different tissues and several interrelated cascades of gene interactions, the combination of developmental and molecular experiments has come a long way in furthering our understanding of the nature and function of organizer regions in development.

Origin Recognition Complex

DNA replication in bacteria or **viruses** starts at a specific region of their chromosome, the replication origin, and is triggered by formation of a DNA–protein complex, called the *replicator*, at that distinct site. In general, the DNA-binding protein called *initiator* recognizes the specific DNA sequence at the replication origin and nucleates formation of the DNA–protein complex in an ATP-dependent manner. Although it has been difficult to identify such a specific DNA–protein interaction for DNA replication in most **eukaryotes**, studies with a simple eukaryote, *Saccharomyces cerevisiae* (**yeast**), revealed that eukaryotes will also have the same protein–DNA interaction during initiation of DNA replication. The replication origins in yeast chromosomes have been identified as autonomously

replicating sequences (ARS), which are defined within short regions by the essential ARS consensus sequence (ACS, the A element) and its accessory elements (the B elements). Many efforts to identify the potential yeast initiator protein as the ARS binding protein have been made, and a multisubunit protein complex called the *origin recognition complex* (ORC) was finally purified from yeast nuclear extracts (1).

The purified ORC binds to the typical yeast replication origin, ARS1, in the presence of ATP, covering the 11-bp A element **consensus sequence** and neighboring B1 element. In addition to this ARS-specific binding property, ORC satisfies several other criteria as the yeast initiator protein ((2, 3): (1) ORC binds to all functional ARS. (2) The relative binding of ORC to several mutant ACS parallels their replication activities. (3) **Temperature-sensitive** mutant forms of ORC subunits result in the temporary arrest of the cell cycle in G1 phase at a **nonpermissive** temperature and make ARS **plasmids** unstable even at the permissive temperature. This instability is suppressed by increasing numbers of ARS in the plasmid, suggesting that replication initiation functions are impaired in these mutants. (4) Direct measurement of origin initiation at ARS1 by two-dimensional gel electrophoresis indicated that only a small fraction of ARS1 are active in the temperature-sensitive ORC yeast cells at the permissive temperature; on the other hand, most of the ARS1 functioned in wild-type cells. (5) The ATP-dependence of the ARS1 binding activity is consistent with the requirement of many initiator proteins for ATP in their active form at the origin sequences.

ORC is composed of six different polypeptides, called ORC1 to ORC6, with respective molecular weights of 120, 72, 62, 56, 53, and 50 kDa. All the genes encoding these subunits are essential for the viability of yeast, meaning that none of them are dispensable. In addition to DNA replication, ORC 2 and 5 were identified as factors necessary for the **silencing** of **mating-type** gene expression (2, 4), indicating that ORC has dual functions in DNA replication and gene silencing. The primary structures of the ORC polypeptide chains have no similarity to each other, and no typical motifs have been identified, except for strong similarity of ORC1 with one yeast replication gene product, CDC6 (Cdc18 in *Saccharomyces pombe*) (5), and purine nucleotide-binding motifs in ORC1 and ORC5. Klemm et al. (6) actually showed ATP-binding and ATPase activities in ORC regulated by ARS DNA. Binding of ORC to ARS DNA requires the presence of ATP, but not its hydrolysis, and the ARS DNA inhibits the ORC ATPase activity, indicating that ATP will stabilize ORC on the origin DNA. Since the ATP-dependent ORC binding occurs at the prereplicative stage, a mechanism for inducing the ATP hydrolysis of ARS-bound ORC is suggested to activate the replication origin.

In parallel with studies of ORC function, a dynamic protein assembly at the replication origin of yeast was studied by *in vivo* DNase I footprinting (7). The analysis demonstrated the presence of a specific DNA-protein complex at the ARS1 *in vivo*. Since the protection pattern against the **nuclease** digestion *in vivo* was nearly consistent with that obtained with purified ORC, and functional ORC is required to form the complex, it is most likely that the ORC–ACS complex observed with purified components actually exists at the replication origins in yeast cells. One important observation is a periodic change in the protection pattern in which a protection wider than the simple ORC–ACS complex appears from the end of mitosis to G1 phase and is shifted back to the narrow protection pattern at the beginning of **S phase**. Since the ORC–ACS protection pattern always exists throughout the cell cycle, it was thought that ORC functions as a landing pad for additional factors, and the periodic change in the protection pattern represents the association of these factors with ORC. Since the wider protection appeared prior to initiation of replication at the replication origin and disappeared upon initiation, it represents formation of the so-called pre-replicative complex, which is defined as a protein assembly to make the replication origin competent for initiation. Several replication initiation-related gene products, CDC6, CDC7, and MCM, a potential licensing factor, are required to form the wider complex at the origin and are thought to be components of the pre-replication complex (8).

Accumulated knowledge about eukaryotic replication proteins inspired the idea that all eukaryotes have the same organization as replication proteins, with conserved primary structures. After the discovery of ORC in yeast, many efforts were made to identify ORC **homologues** in different

species, aiming to find their initiator proteins. Thus far, homologues have been identified in several organisms: *S. pombe*, Arabidopsis, Drosophila, Xenopus, and humans (9). The ORC2 homologue in Xenopus is necessary to initiate the DNA replication reaction in Xenopus egg extracts (10), and the homologue in Drosophila was genetically identified as a gene required for amplification of the **chorion** gene locus (11). In addition, ORC subunit homologues in these higher eukaryotes seem to form multisubunit complexes similar to the yeast ORC. Therefore, all eukaryotes may have a conserved mechanism to initiate DNA replication in chromosomes, in which interactions between the counterparts of ORC and ACS will be a central event.

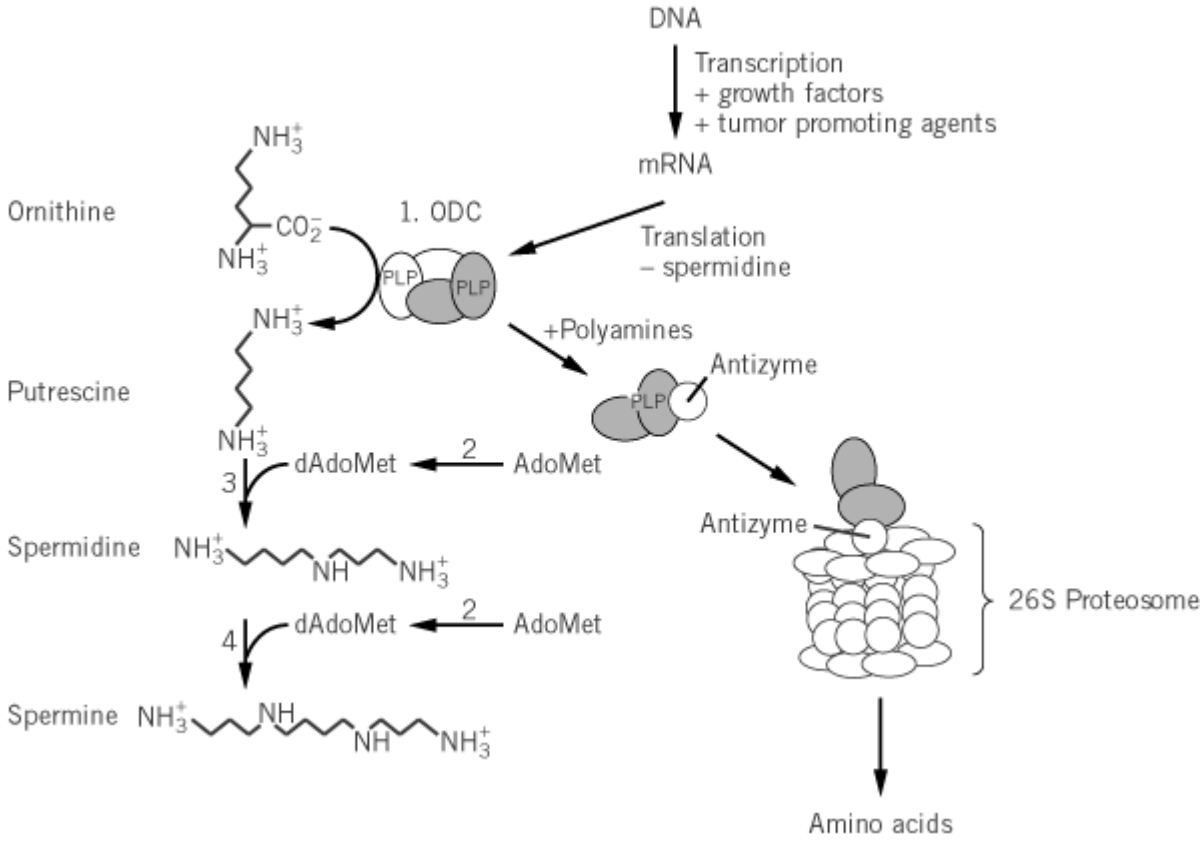
Ornithine Decarboxylase

Ornithine decarboxylase (ODC; EC 4.1.1.17), first discovered in 1968, catalyzes the **pyridoxal-5′ phosphate** (PLP)-dependent decarboxylation of L-ornithine to generate putrescine (Fig. 1), the first committed step in the biosynthesis of polyamines (1-9). The polyamines putrescine, **spermidine**, and **spermine** are ubiquitous to all cells and are required for cell growth and differentiation. Consequently, ODC has been found in almost every cell type studied (4, 10-14). Overexpression of ODC or induction of its biosynthesis by growth stimuli in eukaryotic cells causes cell transformation . Inhibitors of ODC arrest cell growth and are actively studied for their therapeutic potential as anticancer (1, 7, 8, 15) and antimicrobial agents (2, 5). To mediate the consequences of depletion or overexpression of ODC, higher **eukaryotes** tightly regulate levels of the enzyme through **transcriptional**, **translational**, and **posttranslational** mechanisms (reviewed in Refs. 4, 9, 16-19).

Figure 1. The polyamine biosynthetic pathway. Steps 1 to 4 are catalyzed by ODC, S-adenosylmethionine decarboxylase, spermidine synthase, and spermine synthase, respectively. The mechanisms of ODC regulation in mammalian cells are depicted and include transcriptional, translational, and posttranslational control. Not shown is an alternative pathway to putrescine via arginine decarboxylase present in bacteria and plants (4).



0.1. ODC in Tumor Promotion

Deletion of the ODC **gene** renders yeast (12), *T. brucei* (20) or mammalian (21) cells dependent on added putrescine for growth, whereas overexpression of ODC activity leads to mammalian cell transformation (22). Cell transformation caused by a number of **oncogenes**, growth factors, and chemical **carcinogens** is correlated with increased ODC activity. Inhibitors of ODC activity or ODC gene transcription block **oncogene**-induced transformation of rat fibroblasts (22), and 12-O-tetradecanolyphorbol-13-acetate-induced formation of tumors in epidermal cells (23, 24). Overexpression of eukaryotic **initiation factor** eIF-4E, which increases ODC translation, also causes cell transformation, and this transformation is also blocked by ODC inhibitors or by the expression of a dominant-negative mutant of ODC (25). Tissue-specific overexpression of ODC in various **transgenic** mice models causes increased tumor development in skin (26, 27), reduced fertility in testis (28), and hair loss in follicles (29), although overexpression in brain has no long-term effects on tumor incidence or neuronal degeneration (30, 31). Finally, ODC activity correlates with the acquisition of hormone-independent, poorly differentiated tumors in a rat breast cancer model (32) and of a multidrug resistance phenotype (10, 11). Thus, ODC may be useful as a clinical marker.

0.2. ODC as a Drug Target

A wide array of ODC inhibitors have been designed and tested, but by far the most experimentally detailed studies have been done with mechanism-based inhibitors. They and their clinical uses have been extensively reviewed (2, 4-8, 33). The best-characterized of these inhibitors, a-difluoromethylornithine (DFMO; eflornithine), was first described by Metcalf and co-workers. In early studies *in vitro* and in animal models, DFMO was a promising antitumor agent, but clinical studies in humans failed to demonstrate any significant impact on tumor burden. Currently, DFMO is being investigated as a chemoprevention agent for colon and cervical cancer (15, 22, 34-37).

In contrast to the poor potency of DFMO against cancer, in 1980 Bacchi and co-workers demonstrated that DFMO cures mice infected with ***Trypanosoma*** *brucei*, the causative agent of African sleeping sickness. Since this landmark discovery, DFMO has been approved for treating

Gambian trypanosomiasis in humans (reviewed in Ref. 2). The basis for the selective toxicity continues to be debated. Differences in the mammalian and *T. brucei* enzymes' ability to bind DFMO are not involved, but several metabolic differences have been found between mammalian and *T. brucei* cells that are likely to contribute to the selective toxicity:

1. Mammalian ODC is rapidly degraded intracellularly, whereas *T. brucei* ODC is stable, suggesting that differential rates of **protein degradation** are a basis for selective drug toxicity ((2), (38)).
2. Trypanosomes utilize trypanothione, a conjugate of glutathione and spermidine, to maintain cellular redox balance, and this novel role of spermidine may make the cells more sensitive to polyamine depletion (39).
3. DFMO elevates the levels of **S-adenosylmethionine** in trypanosomes, but not in mammalian cells, and may result in building up toxic S-adenosylmethionine metabolites (40).
4. Mammalian cells possess a high-throughput **transporter** for putrescine, whereas *T. brucei* cells do not (39). In contrast, the intracellular parasitic protozoa *Trypanosoma cruzi* rely on scavenged polyamines to sustain growth (39).

0.3. ODC Structure/Function Analysis

The genes (or **cDNA**) that encode ODC have been reported from a wide variety of organisms, including many mammalian sources, **fungi**, parasitic protozoa, and bacteria (Prosite entries PS00878 and PS00703). Interestingly, the eukaryotic and **prokaryotic** enzymes do not share significant sequence identity and differ in their three-dimensional structures. Thus, ODC activity has evolved independently at least twice (41). The eukaryotic ODC are homologous to biosynthetic arginine decarboxylase from bacteria and plants, to diaminopimelate decarboxylase from bacteria (Prosite ID PS00878) and to alanine racemase (41). In contrast, prokaryotic ODC belongs to the same family as lysine decarboxylase and biodegradative arginine decarboxylase (Prosite ID PS00703). The three-dimensional structure of bacterial ODC from *Lactobacillus*, determined **by X-ray crystallography**, has structural similarity to aspartate aminotransferase (42).

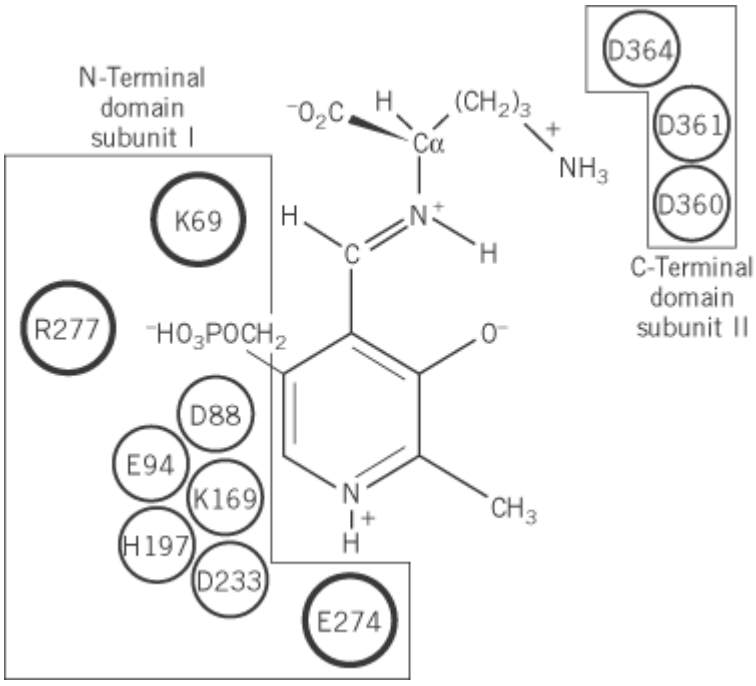
A structural model for the N-terminal domain (300 amino acids) of eukaryotic ODC predicted that it folds into a b/a barrel, and the PLP binding site formed by the C-termini of the b- **strands** is at the center of the barrel (41). This model places Lys69, His197, Asp233, Glu274, the Gly-rich loop (residues 235 to 237), and Arg277 in the PLP binding site and is strongly supported by the available biochemical data (discussed later). Now, both mouse (43) and *T. brucei* (44) ODC have been successfully crystallized, and the mouse ODC structure confirms that it folds into a b/a barrel (M. Hackert, personal communication).

ODC is an obligate homodimer, and each subunit is organized into two domains composed of a large N-terminal domain (residues 1 to 305) and a small C-terminal domain (residues 306 to 425), as demonstrated by the finding that separate polypeptides that represent these domains in *T. brucei* ODC can be coexpressed to yield an active tetramer that has kinetic properties identical to the native dimer (50). Mouse ODC may also be circularly permutated at amino acid 308 without significantly affecting activity (51). Two identical active sites are formed at the dimer interface and are composed of residues from the N-terminal domain of one subunit and the C-terminal domain of the other, as demonstrated by the finding that activity is restored upon mixing the inactive Lys69Ala mutant ODC with the inactive Cys360Ala ODC for the enzymes from mouse (1), *T. brucei* (45), or *L. donovani* (45). The subunits of mouse and *T. brucei* ODC are in rapid equilibrium, and heterodimers are formed immediately upon mixing two different homodimers. In contrast, the subunits from *L. donovani* ODC dissociate only after the enzyme is partially **denatured** in urea. Additionally, fully functional heterodimers can be formed between mouse and *T. brucei* ODC (45). This result suggests that the contacts in the dimer interface, which are essential for dimerization, are conserved between *T. brucei* and mouse ODC.

Three assays have been described to follow the decarboxylation of ornithine: a $^{14}CO_2$ assay (1), a dye-linked **spectrophotometric** assay (45), and a circular dichroism assay (46). The k_{cat} for the decarboxylation of L-ornithine is typically $10 s^{-1}$, and the K_m ranges from 90 to 400 μM (47, 48). The enzyme is also active on lysine, but the K_m is 100-fold higher than for ornithine (48). The reaction of *T. brucei* ODC with L-ornithine proceeds through a quinoid intermediate, and product release, not decarboxylation, was determined as the rate-limiting step (49).

The roles of a number of residues in the active site of ODC have been delineated by biochemical analysis and site-directed mutagenesis. By reduction and peptide mapping, Lys69 was identified as the residue that forms the Schiff base with PLP, and Cys360 was identified as the site of covalent attachment of DFMO (1). Consistent with these findings, mutation of both residues significantly reduces k_{cat} (1). Mutation of Glu274 to Ala decreases k_{cat} 50-fold, but wild-type activity is restored by substituting N-methyl-PLP for PLP in the reaction. This demonstrates that Glu274 interacts with the protonated pyridine nitrogen of PLP to enhance the electron-withdrawing capability of the ring (48). The Arg277 to Ala mutant has decreased PLP binding affinity and an altered ^{31}P-NMR spectra of the enzyme-bound PLP (52), supporting the hypothesis that Arg277 interacts with the 5′ phosphate of PLP. Mutation of Asp361 to Ala increases the K_m for ornithine 2000-fold and has little effect on k_{cat}, suggesting that Asp361 forms part of the substrate-binding pocket (48). Mutation of a number of other conserved residues also results in large decreases in enzyme activity, but the roles of these residues in catalysis remain unknown (1, 48). Taken together, these results produce a picture of the ODC active site in which PLP is bound by the large N-terminal domain and interacts with Lys69, Glu274, and Arg277, whereas the C-terminal domain of the second subunit is likely to contribute to substrate binding through interactions with residues 360 to 364. These results suggest that the substrate binds across the dimer interface (Fig. 2).

Figure 2. Schematic representation of the active site of eukaryotic ODC. PLP is displayed bound to ornithine via a Schiff base. Amino acids necessary for enzyme activity by site-directed mutagenesis are displayed. The three residues that have established functions are outlined in large circles.



0.4. ODC Regulation

0.4.1. Rapid Turnover of ODC and its Polyamine-Dependent Regulation

ODC from higher eukaryotes (e.g., mammals), one of the most rapidly degraded proteins known, has an intracellular half-life ranging from 10 to 60 min (the mechanism has been reviewed in Refs. 18 and 19). Polyamines accelerate the turnover rate from the already rapid basal levels by increasing the concentration of a 26-kDa regulatory protein, termed the *antizyme*, which was first discovered for its ability to inhibit ODC activity. Polyamines regulate antizyme production by inducing ribosomal **frame-shifting** (53). The antizyme binds to the ODC monomer and targets it for ubiquitin-independent degradation by the 26 S **proteosome** (19, 54, 55). The antizyme is further regulated by the presence of antizyme inhibitor, a protein that is structurally related to ODC, but is missing many catalytic residues and cannot dimerize with native ODC (56). Antizymes that share similarity to the mammalian protein have also been found in other higher eukaryotes, for example, *Xenopus laevis* (57), where increased ODC turnover is associated with gastrulation (58). In contrast the ODC inhibitory proteins found in *Escherichia coli* are unrelated to the mammalian protein and are likely to play a very different role in ODC regulation (59).

Structural elements of ODC responsible for its rapid degradation have been delineated. Two **PEST sequences** (mouse ODC residues 298 to 333 and 423 to 461), which are associated with rapidly degraded proteins, are found in mammalian ODC (19) but not in the stable *T. brucei* enzyme (2). The C-terminal PEST sequence (423 to 416) is required for degradation and is sufficient to confer degradation on the stable *T. brucei* enzyme when expressed in mammalian cells. Mouse ODC expressed in trypanosomes is also stable, even in the presence of coexpressed rat antizyme (60), suggesting that trypanosomes lack the cellular machinery necessary to target the mouse enzyme for degradation. The requirement for the C-terminal PEST sequence for degradation in mammalian cell systems is further illustrated by the findings that mouse ODC is stabilized by truncation of as few as five residues from the C-terminus, internal deletions in the C-terminus, masking of the free C-terminus, mutation of Cys441 to Trp, or phosphorylation of ODC (reviewed in Refs. 19 and (61)). In addition to requiring the C-terminal degradation domain, polyamine-dependent degradation requires an additional part of the sequence (residues 117 to 140 in the mouse sequence), which interacts with the C-terminal half of the antizyme (reviewed in Refs. 18 and 19). The N-terminus of the antizyme is required to degrade mouse ODC and further confers lability when fused to the N-terminus of stable proteins in an *in vitro* assay (62, 63). Regulation of ODC in single-cell eukaryotes is less well studied than in mammalian cells. Yeast ODC is rapidly degraded by the proteosome (64). *Neurospora crassa* ODC is also rapidly degraded, but polyamines do not increase the degradation rate. However, in many other lower eukaryotes ODC is stable (reviewed in Ref. 19; see the previous discussion of *T. brucei* ODC).

0.4.2. Transcriptional regulation

Transcription of the mammalian ODC gene is increased in response to a number of growth stimuli. Basal levels of ODC transcription are mediated by several DNA elements in a complex cell type-specific manner, for example, the cAMP-responsive element CRE (65) and Sp1 (66). ODC transcription is stimulated above basal levels by protein kinase A through CRE in adrenal carcinoma cells (67), by c-Fos in PC12 cells (68), by c-**Myc** (69), and by the c-Myc.Max protein complex (70, 71). Overexpression of ODC in a mouse **myeloma** cell line (72) or in mouse myeloid 32D.3 cells induces apoptosis, and ODC is a mediator of c-Myc-induced apoptosis in the latter cells (73). The transcription factor AP-2 acts as a negative regulator of Myc-induced ODC gene transcription (74). The Wilms' **tumor suppressor** represses activity of the ODC promoter and suggests that tumor suppressors may have a role in maintaining normal ODC levels (75). Rotenoids (23) and tyrosine kinase inhibitors (24) inhibit 12-*O*-tetradecanolyphorbol-13-acetate-induced ODC transcription and may have utility as chemoprevention agents.

0.4.3. Translational regulation

Although many factors influence the levels of ODC messenger RNA, it is well established that the levels of mRNA do not always correspond to the ODC activity observed. For example, the growth-related changes in ODC mRNA are 10-fold less than the corresponding ODC activity upon

stimulation of Ehrlich ascites tumor cells. In quiescent cells high mRNA levels contrast with low protein levels. These observations suggest that ODC levels are controlled partially at the level of translation (76). It is predicted that the 5′ untranslated region (5′UTR) of the mammalian ODC gene folds into a stable secondary structure, and deletion analysis demonstrates that the 5′UTR inhibits translation of both ODC and heterologous gene products (reviewed in Ref. 1). Alternative splicing of the 5′UTR relieves the translational suppression of ODC in tumor-derived pancreatic acinar cells and results in constitutive expression (77). The polyamines spermidine and spermine inhibit ODC translation, and this inhibition depends on the presence of the 5′UTR. Insulin-induced ODC translation also depends on the 5′UTR (1, 78). ODC activity or the activity of a reporter construct linked to the 5′UTR are greater in cells that overexpress eIF-4E, a eukaryotic transcription factor that has RNA **helicase** activity which unwinds the secondary structure of RNA. Increased ODC expression in these cells results from changes in polyamine regulation and decreased translational repression (79, 80).

ODC is an essential enzyme that promotes cell growth and controls differentiation. Consistent with its important function, the enzyme is highly regulated in mammalian cells. The continued study of both ODC structure/function and of ODC regulation should lead to a greater understanding the role of ODC in cell function and to the design of additional methods to combat cancer and infectious disease.

Orphons

Orphons are a class of dispersed, solitary genetic elements of the genome derived from tandem multi**gene families**. These displaced elements arise from genes that do or do not code for proteins, including those of histones in the sea urchin *Lytechinus pictus*; **ribosomal** genes in **Saccharomyces** *cerevisiae*; ribosomal genes and H3 histone genes in **Drosophila** *melanogaster* (1); the amylase multigene family of mice (2); the spliced-leader small RNA gene family of *Trypanosoma brucei* (3) and of the nematode *Angiostrongylus cantonensis* (4); and the human 28 S ribosomal DNA (5).

An interesting case is that of the human immunoglobulin V kappa gene regions. They have been **transposed** during evolution from the site of the kappa locus on **chromosome** 2 to chromosomes 1, 22, and other chromosomes. These orphons are very similar and may have derived from a single ancestral gene. The DNA sequences at the junction of chromosome 22 and other orphon regions are direct and inverted repeats and in one case an **Alu sequence** repeat. These unusual features may have predisposed the orphon regions to transposing by serving as target sites for enzymes involved in recombination (6).

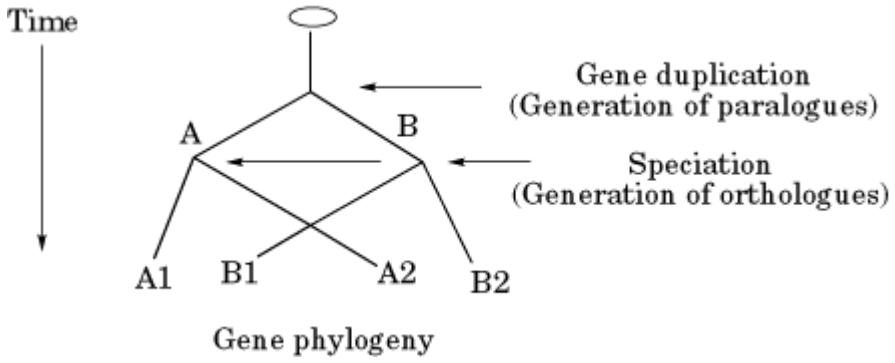
Orthologous Genes

Orthologous genes are two or more **genes** whose follows the speciation process, and they have usually the same function in each resulting species; that is, a particular gene in the ancestral will be duplicated in the two different species following speciation and will usually be maintained in each, because both species will require the function of that gene (Fig. 1) (1). These genes differ from , which diverged before or after speciation as a result of and usually have different functions. For example, the genes for the a and b polypeptide chains of hemoglobin and that for myoglobin are **homologous** but paralogous, whereas the hemoglobin a chains from different species are orthologous; similarly, the b chains and myoglobins from different species are orthologous. Only comparisons of orthologous genes can be used to reconstruct species **phylogenies**.

Figure 1. Generation of orthologous and paralogous genes (1).



It is often difficult to distinguish orthologous genes from paralogous genes. However, analysis has shown that some genes have a single version in a genome. Therefore, if this is the case in two or more species, there is a strong possibility that these genes are orthologous. If the gene is a member of a known , there is a distinct probability that it is a paralogous gene, depending on the number of genes in the family, because the gene could be a product of gene duplication before or after speciation.

Orthologous gene pairs are useful for estimating the rate of nucleotide substitution and species phylogenies. When the time since two species diverged (T_s) is known from the fossil record, it follows that the orthologous pairs should also have diverged at the time of species divergence. Therefore, the rate of nucleotide substitution for the gene (v) can be estimated by dividing the number of nucleotide substitutions (K_n) between orthologous gene pairs by two times of the divergence time between the two species $v = K_n/(2T_s)$.

Two homologous genes sampled from the gene families between two species are often paralogous, rather than orthologous. If the two genes are paralogous, the divergence time of these genes (T_g) must have been earlier than the speciation time ($T_g > T_s$). If the divergence time of those genes is mistakenly assumed to be the divergence time between the species, the divergence time of the genes will be underestimated and will lead to overestimation of the rate of nucleotide substitution ($K_n/(2T_g) > v$). Thus, it is important to use only orthologous genes in estimating the rate of nucleotide substitution and the times of speciation.

There have been many recent advances in genome analysis, and as a result complete genomes are known. Those of two species can be compared to determine whether the physical order of genes in the genomes is conserved between different species. To accomplish this, it is vital to distinguish orthologous genes from paralogous genes. By focusing on orthologous genes, it is possible to trace changes in gene location during evolution because of the one-to-one correspondence in gene location between genomes, unless gene duplication takes place after speciation.

Oskar Gene

The *oskar* is a **maternal effect** gene in *Drosophila melanogaster* whose primary function is to organize a specialized cytoplasm, termed the germ plasm or pole plasm, at the posterior pole of the maturing egg (1). This germ plasm contains factors required for abdomen formation and germ-cell formation. The *oskar* messenger RNA is synthesized during oogenesis. It is deposited into the egg, where it becomes localized to the posterior pole through sequences in its 3′-untranslated region (UTR). Only posteriorly localized RNA is translated into Oskar protein. The site of Oskar protein synthesis determines where germ plasm is assembled, and the quantity of Oskar protein determines how many germ cells form. *oskar* is a member of the posterior group of genes (named for their effect on development of the abdomen in the posterior half of the embryo). Most of the posterior group genes facilitate localization and translation of *oskar* mRNA, while a small number of posterior genes act together with Oskar in the assembly of the germ plasm or are specifically required for either germ cell or abdomen formation.

1. *oskar* Protein and RNA Structure

oskar encodes a 2.9-kb mRNA that is expressed in the germ line of the adult female and is present at the posterior pole of early embryos. *oskar* mRNA has a 14-nucleotide 5′ UTR and a 1045-nucleotide 3′ UTR. Two different in-frame start codons are used to produce Oskar protein isoforms of 606 amino acids residues (69 kDa) and 468 residues (54 kDa). The short isoform has full *oskar* activity, although the long isoform is necessary to maintain localization of the *oskar* mRNA at the posterior of the oocyte (2, 3). The 3′ UTR contains regulatory elements for RNA localization and translation, while the region between the two start codons contains sequences necessary for translational regulation (4). The Oskar protein is novel, in that no known sequence or structural motifs are present. The only known homologue is from *Drosophila virilis* (5).

2. *oskar* RNA Localization and Translation

Oskar protein synthesis is regulated at the level of mRNA localization and translation and occurs during oogenesis. Each *Drosophila* ovary consists of approximately 16 ovarioles, each of which contains a series of developing egg chambers. At the tip of each ovariole, a germ-line stem cell produces a new stem cell and a cystoblast by asymmetric cell division. Each cystoblast undergoes four rounds of division with incomplete cytokinesis, giving rise to 15 nurse cells and the oocyte. The nurse cell–oocyte cluster is interconnected by cytoplasmic bridges called ring canals and surrounded by somatic follicle cells. *oskar* RNA is produced in the nurse cells and deposited into the developing oocyte, where it accumulates from the earliest stages of oogenesis. By late stage 8 of oogenesis, the RNA is concentrated at both the anterior margin and the posterior pole of the oocyte. By stage 10, *oskar* RNA is localized exclusively to the posterior pole, where it remains until it is degraded in the early embryo after germ-cell formation [see Fig. 1 (6, 7)]. Oskar protein is translated once the mRNA becomes localized to the posterior pole, while unlocalized RNA is **translationally repressed**. This ensures that protein is made only at the posterior pole of the oocyte and embryo (2, 3).

Figure 1. A *Drosophila melanogaster* ovariole. *oskar* mRNA is detected by *in situ* hybridization. In the earlier stages of oogenesis (top of figure), *oskar* mRNA accumulates in the oocyte. As each egg chamber matures, the *oskar* mRNA is localized within the oocyte to the posterior pole (center and bottom of figure). Anterior is to the top, posterior is to the bottom.

The site where *oskar* RNA is localized and Oskar protein is synthesized determines where germ cells form and the posterior body region, the abdomen, develops. Therefore processes that lead to the localization of *oskar* RNA are directly linked to the establishment of anterior–posterior polarity within the oocyte. All aspects of *oskar* RNA localization are mediated by sequences within the *oskar* 3′ UTR (8). Early aspects of *oskar* RNA transport into the oocyte and localization to the posterior pole of the oocyte require the correct organization of the microtubule network. Genes involved in the polarization of the early microtubule network that extends from the nurse cells to the oocyte also affect the transport of *oskar* into the oocyte. These genes include *egalitarian*, *Bicaudal-D*, (coiled-coil domain protein), *orb* (an RNA-recognition motif protein with similarity to mammalian CEBP), and cytoplasmic dynein (9). Subsequently, the establishment of anterior–posterior polarity within the oocyte is controlled by cell–cell signaling between the oocyte-bound Gurken protein, a member of the **transforming growth factor-a** (TGF-A) family, and its receptor, the *Drosophila* **EGF receptor** (*DER* or *torpedo*). Mutations in either gene disrupt localization of *oskar* RNA to the posterior pole, presumably by altering the polarity of the microtubule network within the oocyte. Indeed, inhibitors of the microtubule, but not of the microfilament, cytoskeleton disrupt the localization of *oskar* RNA during oogenesis (10). Other maternal effect genes that affect *oskar* localization and affect the microtubule organization in the oocyte include *cappuccino* (for min homologue), *spire*, and *mago nashi* (a novel protein that is highly conserved from plants to humans). A role of microfilaments in *oskar* mRNA localization is suggested by the effect that mutations in the tropomyosin II gene (an **actin-binding** protein) have on *oskar* RNA localization (11). It has been proposed that the actin cytoskeleton is required for high levels of *oskar* mRNA localization or the firm anchoring of the RNA at the posterior pole (11).

Staufen, a double-stranded RNA-binding protein, has been proposed as the best candidate to mediate directly the localization of *oskar* RNA. *staufen* mutants do not affect the organization of the cytoskeleton, and Staufen protein and *oskar* RNA colocalize during oogenesis (12). A direct physical interaction between Staufen and *oskar* RNA has not been demonstrated. Staufen is also required for localization of bicoid mRNA to the anterior of the oocyte and of *prospero* RNA to the apical side of dividing neuroblasts (12).

oskar mRNA that is not localized to the posterior pole is translationally repressed. If the RNA is translated prematurely, posterior body patterning will be specified throughout the embryo. Translational repression is mediated through specific RNA-binding sites in the 3′ UTR of *oskar* mRNA. The RNA-binding protein Bruno (which corresponds to the *arrest* gene independently identified on the basis of its early arrest maternal effect phenotype) binds specifically to Bruno response elements (BREs) in the *oskar* RNA (13). The bicaudal-C protein (a KH-domain protein) has also been implicated in repressing translation of unlocalized *oskar* RNA. Only at the posterior pole, where *oskar* RNA is localized, is the RNA translationally active. Activation of translation depends on derepression mediated through sequences between the two alternative start codons of the *oskar* mRNA (4). Translation of *oskar* RNA or the stability of Oskar protein is further dependent upon the gene *aubergine* as well as upon the Vasa protein, an RNA helicase that interacts physically with Bruno protein (14, 15).

3. Role of *oskar* in Germ Plasm Assembly

Homozygous mutant *oskar* females are viable, but produce embryos that lack germ plasm. These embryos fail to form germ cells and do not develop an abdomen. Mislocalization of the *oskar* coding region (via the RNA localization element in the 3′ UTR of bicoid mRNA) to the anterior of the oocyte results in the assembly of ectopic germ plasm, a mirror image duplication of the abdomen, and formation of ectopic germ cells (16). Thus *oskar* is both necessary and sufficient for assembly of germ plasm and for formation of both the abdomen and germ cells.

Assembly of the germ plasm is also dependent upon other factors that act downstream of *oskar*. Vasa is a **DEAD-box** helicase that physically interacts with Oskar. The products of the *tudor* and *valois*

genes are also required for germ plasm assembly. Vasa, Tudor, and Oskar are components of electron-dense particles, known as polar granules, that are found only in the germ plasm (17).

The effect of *oskar* on abdomen formation is mediated through the **nanos** gene. Oskar is responsible for localizing *nanos* mRNA to the posterior pole of the embryo, where Nanos protein is translated and acts to facilitate abdomen formation through repression of the *hunchback* mRNA. While the mechanism of *nanos* localization to the posterior pole is not clear, *oskar* is both necessary and sufficient for *nanos* localization. Overexpression of *oskar* or mislocalization of the *oskar* mRNA results in an excess of *nanos* activity at the site of *oskar* localization.

oskar also recruits several factors to the posterior pole that play a role in germ-cell formation. These include: *germ cell-less* mRNA, which encodes a protein that associates with the nuclear envelope; mitochondrial large ribosomal RNA (*mtlrRNA*) that is found outside of the mitochondria, where it associates with polar granules during the early stages of embryogenesis; and *polar granule component 1 (pgc1)*, which codes for an untranslated RNA. A number of different experiments suggest that *germ cell-less* and *mtlrRNA* are required for germ-cell formation (18, 19), while **antisense** experiments with *pgc1* suggest a role for this gene in germ-cell migration or development (20). Other maternal factors localized to the posterior pole in an *oskar*-dependent manner include maternal *hsp83* mRNA, whose RNA is stabilized in the posterior depending on the germ plasm; the cell cycle regulator *cyclin B*; *outspread*; and the Fat-facets protein that is a sequence-specific de-ubiquitinating proteinase. The roles of these genes in germ-cell formation, migration, or development are unclear.

Ouchterlony Double Diffusion

A direct extension of the precipitin reaction to immunoassays is the Ouchterlony double diffusion technique (1). Here, two or more wells are cut in an agar slab and filled with either antigen or antibody. The two materials slowly diffuse throughout the slab. As the antibody and antigen molecules encounter each other and react, a precipitate forms in the gel. Because of the highly cooperative nature of immune complex lattice formation, the precipitate forms an extremely sharp line between the two wells. The position of the precipitin line, compared to lines generated from other dilutions of antigen or antibody, gives a semiquantitative measure of the relative concentration of the reactant. However, the true value of the Ouchterlony technique is the remarkable number of details that can be inferred from the precipitin patterns formed. From the presence of multiple lines, or complex precipitin patterns formed at the intersection with multiple antigen or antibody wells in the agar slab, conclusions can be drawn about such properties as antigen heterogeneity, antigen molecular weight, shared antigenic determinants, and cross-reactivity of different antisera (2). The Ouchterlony technique is now obsolete, but it is commonly described in older literature.

Ovalbumin

The major protein in egg-white is ovalbumin. It has the typical highly ordered structure of a serpin

(see Fig. 1 in that entry), but has lost the ability to refold the loop that would correspond to its reactive center; consequently it has no proteinase inhibitor activity. Its smallness relative to other serpins, and its conformational stability, make it suitable as a marker for gel electrophoresis. The stability is only relative, however; its reactive-center loop can be cleaved **proteolytically** to produce a form known as plakalbumin. It is likely that the induced insertion of this loop, like that that occurs in other serpins, explains a conformation, with increased stability, that forms on long-term storage: *S*-ovalbumin.

Overlay Assay: Enzyme Zymography of Plasminogen Activators and Inhibitors

Zymography is a gel-based enzymatic assay useful for detection and semi-quantitative analysis of proteases and is performed using overlay or co-polymerization techniques (1, 2). In overlay assays, samples are fractionated by SDS-PAGE and, after removal of SDS, the polyacrylamide gel is overlaid on an agarose indicator gel containing protein substrate. Enzyme diffusion into the indicator gel occurs during incubation of the gel sandwich and results in degradation of protein substrate. The indicator gel is then stained to reveal zones of proteolysis, which appear as cleared bands on a dark background. In co-polymerization techniques, protein substrate is incorporated directly into the polyacrylamide gel matrix and, after electrophoresis and SDS removal, gels are incubated floating in buffer (2). In either method, specificity or sensitivity is tailored by modification of acrylamide gel pore size, substrate choice, incubation time, buffer conditions, and by inclusion of activators or inhibitors in gels or buffers.

Overlay assays are advantageous when substrate preference involves proteins that either bind poorly to acrylamide (albumin, casein) or are irreversibly denatured by SDS (collagen type I) and, thus, are not amenable to co-polymerization methods; gelatin, in contrast, is readily incorporated into the polyacrylamide gel matrix, and co-polymerization has been used extensively for assay of gelatinases (2). Overlay methods are also more appropriate for initial quantitative evaluations because enzyme activity is confined within the gel sandwich and, thus, not susceptible to diffusional loss to surrounding buffer, as may occur with co-polymerization assays (1). Furthermore, overlay assays are the method of choice for analysis of complex proteolytic systems in which zymogens, co-substrates, or endogenous inhibitors are relevant, as multiple components can be incorporated into indicator gels.

Representative of a complex proteolytic system is application of the overlay assay to analysis of the plasminogen activator (PA), inhibitor (PAI) system (3, 4). Briefly, samples containing PAs (urokinase [uPA], tissue plasminogen activator [tPA]) and their endogenous inhibitor (PAI) are resolved by SDS-PAGE on 10% gels. Gels are washed with Triton X-100, to remove SDS and allow protein renaturation, and then overlaid on an indicator gel containing plasminogen (zymogen) and fibrin (protein substrate). During incubation, PAs diffuse into the indicator gel, cleave plasminogen to form plasmin, a serine protease that degrades fibrin. After staining of the indicator gel, lytic zones (PA) appear as cleared bands on a dark background (zymography). In contrast, if exogenous PA is also incorporated into the indicator gel, then lysis occurs everywhere except where inhibitor is

present; thus, lytic-resistant zones (PAI) appear as dark bands on a clear background (reverse zymography).

1. Materials and Methods

1.1. Materials

Fibrinogen (plasminogen-rich) from Organon Teknika, Holland; SeaKem garose and Gelbond support backing from FMC BioProducts, Rockland, ME; human uPA and tPA from American Diagnostica, Greenwich, CT. All reagents prepared using ultra-pure water.

1.2. Sample Preparation and SDS-PAGE

Samples were prepared, as appropriate, in 2X or 5X Laemmli sample buffer without reducing agent or heating (4). Proteins were resolved by 10% SDS-PAGE (0.75 mm thick slab gels; 20 mA constant current) as previously described (5). After electrophoresis, gels were washed twice (2.5% Triton X-100, 200 mL/gel, 30 min each) to remove SDS and carefully overlaid on indicator gels.

1.3. Preparation of Fibrin Indicator Gel

Plasminogen-rich fibrinogen (5 mg/mL) was solubilized in 0.85% saline (prewarmed to 37°C) with gentle mixing (inversion several times over 1–2 h). Agarose (1%) was separately prepared in PBS (pH 7.4) by heating in a boiling water bath. Dissolved agarose was removed from heat and cooled to 60°C; 15mL of thrombin stock (260 U/mL) and 5 mL fibrinogen solution were then added to the hot agarose (25 mL) in rapid succession and with constant swirling. The agarose-fibrin solution was quickly poured onto the hydrophilic side of a Gelbond support film (~13 × 17cm) using a 25 mL glass pipet and a continuous, vertical motion from left to right; the Galbond support film had been previously stabilized on a glass plate (see below). The agarose indicator gel was allowed to solidify for at least 30 min at room temperature before overlay with the acrylamide gel. Final gel composition was ~0.8% agarose, 0.08% plasminogen-rich fibrinogen, and 0.1 U/mL thrombin (4).

1.4. Fibrin Zymography

Washed polyacrylamide gels were carefully overlaid on fibrin indicator gels and incubated (37°C, 18–20 h) in closed containers containing water-moistened paper towels to provide a humidified atmosphere. After incubation, the acrylamide gel was carefully removed, and the indicator gel was stained (<5min; 0.1% amido black, 70% methanol, 10% acetic acid), destained (70% methanol, 10% acetic acid), and allowed to air dry.

1.5. Reverse Zymography

For detection of PAIs, the indicator gel also contained uPA (0.8 U/mL).

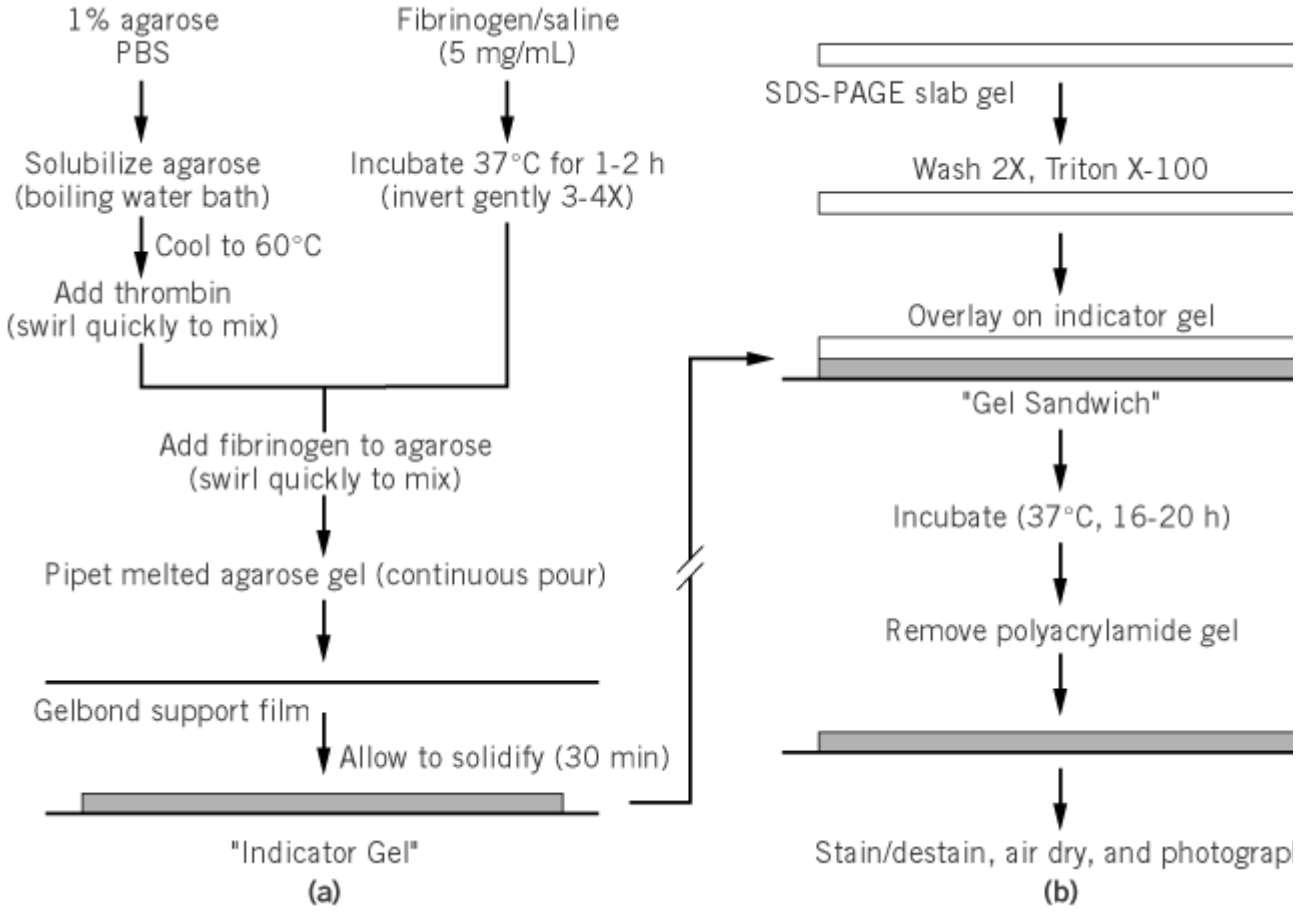
1.6. Notes and Tips

1) Excessive or too vigorous mixing during fibrinogen solubilization results in protein flocculation; 2) volume loss during agarose heating should be reconstituted using ultra-pure water; 3) Galbond has hydrophilic (spreads water) and hydrophobic (beads water) surfaces; water placed in the center of a glass plate adheres the hydrophobic surface of the Gelbond providing a flat stable surface for gel pouring and subsequent handling of gel sandwiches; 4) Work quickly, fibrin polymerization and agarose solidification occur rapidly; delay in pouring produces inhomogeneities within the indicator gel; 5) when disassembling glass plates after electrophoresis, cut the bottom of the acrylamide gel for later orientation; 6) acrylamide gels enlarge and become fragile during washing; handle with care; 7) to position acrylamide gels carefully grasp the upper corners; overlay from bottom to top in a continuous motion to avoid air trapping; 8) avoid repositioning of the polyacrylamide gel when constructing the gel sandwich as artifactual lysis and streaking may result; 9) volumes given are for one full-sized indicator gel; 10) up to two indicator gels can be simultaneously prepared; extra gels can be stored at 4°C for 3–4 days in sealed plastic bags humidified with a damp paper towel.

2. Results and Discussion

Samples containing PAs can be readily analyzed by fibrin zymography using a gel overlay assay (Fig. 1). In such assays PAs and PAIs are resolved by electrophoresis on 10% polyacrylamide gels in the absence of reducing agent or heating. Omission of reducing agent is necessary because SDS may cause artifactual activation of thiol-dependent proteases (i.e., lysosomal thiol cathepsins) as well as inactivation of disulfide-stabilized proteases (i.e., plasminogen activators). Similarly, heating is avoided to preclude artifactual aggregation, activation, or inactivation of susceptible proteases.

Figure 1. Schematic of fibrin overlay assay. (**a**) Preparation of the fibrin indicator gel. (**b**) Overlay of the indicator gel (fibrin zymography). For details see MATERIALS AND METHODS section.



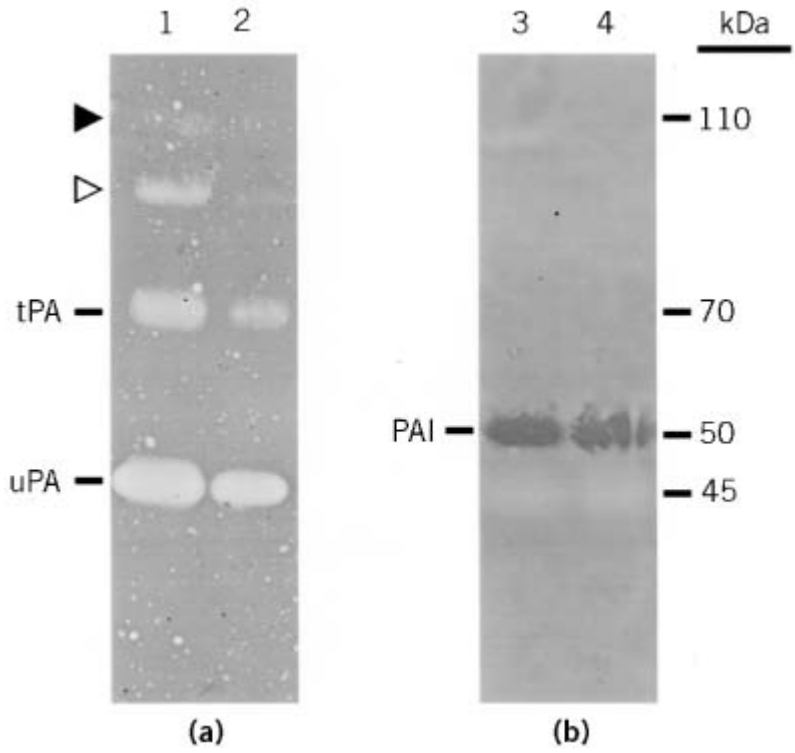
During electrophoresis the partially denatured protease migrates with respect to molecular weight. SDS removal after electrophoresis by the nonionic detergent Triton X-100 allows proteins to renature and regain activity. Wash times should be kept to a minimum and accurately monitored to avoid excessive leaching of protease and to assure reproducibility between experiments, respectively.

The gel sandwich should be constructed without repositioning of the acrylamide gel and should be incubated in a humidified atmosphere to avoid gel drying. Incubation times and conditions (temperature, pH) vary depending on the intrinsic properties of the protease being examined as well as its concentration in biological samples. For quantitative purposes, standard curves should be constructed to determine dose-time relationships with respect to size of the lytic zone. Overlay assay of PAs requires incubation for 6–18 h and is temperature-dependent (37°C).

Indicator gels require only brief staining (<5 min) and, after drying, are readily photographed by

back lighting. Overlay zymography of PAs demonstrates fibrinolytic zones at molecular weights corresponding to uPA (45 kDa) and tPA (70 kDa) as well as some high (110 kDa) molecular weight bands (Fig. 2A), presumably representing complexes of PA-PAI (3,4). In contrast, reverse zymography demonstrates fibrinolytic-resistant zones at a molecular weight (50 kDa) corresponding to PAI (Fig. 2B). Protease/inhibitor identification can be verified by parallel zymograms in which indicator gels contain PA-specific antibodies or inhibitors i.e., amiloride to inhibit uPA and erythina to inhibit tPA, as has been described elsewhere (4).

Figure 2. Amido black-stained indicator gels. (**a**) Fibrin zymogram demonstrating uPA (45 kDa), tPA (70 kDa), and higher molecular weight PA complexes (**open and closed triangles**). (**b**) Reverse zymogram demonstrating PAI (50 kDa) as well as uPA shadow (45 kDa). Samples 1–4) were from conditioned media of bovine corneal endothelial cells at different growth stages (4).



In summary, overlay zymography is a versatile assay for the detection and semi-quantitative investigation of proteases, which is readily applicable to complex systems. Unique to the overlay method is the opportunity to incorporate into the indicator gel multiple components including activators, inhibitors, antibodies, zymogens, co-factors, and allosteric modifiers. This enables highly sensitive and specific assays to be developed and, thus, affords extensive biochemical investigation of diverse proteolytic systems.

Oxidation/Reduction Potential

Many of the fundamental physiologic reactions in a cell, both in the metabolic pathways of degradation and in the storage of energy via production of ATP, involve the transfer of electrons from one molecule, the donor (or reducing agent), to another, the acceptor (or oxidant). They are thus called redox reactions and are catalyzed by redox enzymes.

1. Redox Reactions and Redox Couples

The molecule donating an electron is the reductant (red) and becomes oxidized in the reaction, whereas the molecule accepting the electron is the oxidant (ox) and becomes reduced. In fact, each redox exchange:

$$\mathrm{red}_1 + \mathrm{ox}_2 \leftrightarrow \mathrm{ox}_1 + \mathrm{red}_2$$

is composed of two reactions:

$$\mathrm{red}_1 \leftrightarrow \mathrm{ox}_1 + \mathrm{e}^- \text{ and } \mathrm{ox}_2 + \mathrm{e}^- \leftrightarrow \mathrm{red}_2$$

The reductant and its corresponding oxidized form constitute a redox couple, in which both partners participate in the redox reaction. Each redox couple is characterized by a standard oxidation-reduction potential (E'_o) that quantitatively defines its tendency to loose an electron. In a redox reaction, the redox couple that has the higher affinity for the electron will be the oxidant, whereas the couple having a greater tendency to donate electrons will be the reductant. The same redox couple may therefore be either a reductant or an oxidant, depending on the redox potential of the second redox couple in the reaction. Examples of such a mechanism occur in the **mitochondrial** and the anaerobic bacterial electron transfer chains and in the photosynthesis pathway in **chloroplasts**, where the reductant of the (i)th step is the oxidant of the (i-1)th step.

2. Electrode Potential

The redox potential can be measured electrochemically as the electromotive force generated by connecting a half-cell of the redox sample with a reference half-cell. The reference half-cell consists of a platinum electrode immersed in a 1 *M* H^+ solution and saturated with H_2 gas at 1 atmosphere; the sample half-cell consists of an electrode immersed in a solution of the redox couple under standard conditions (1 *M* of the electron donor and acceptor, 25°C, and pH 7). The electrodes are

connected to a voltmeter. A salt bridge (KCl solution) enables electrical continuity between the half-cells. The electrons flow in the direction determined by the redox potential of the sample relative to the reference. This is the voltage observed at the beginning of the experiment (standard concentration of 1 *M*), as the redox potential of the hydrogen electrode is arbitrarily taken as 0 V. The redox potentials (E'_o) of redox couples are thus expressed relative to the $H_2/2H^+$ couple.

For a redox reaction ($ox + e^- \leftrightarrow red$), the Nernst equation relates the concentration of the redox species with the redox potential:

$$E = E^\circ + (RT/nF \ln[ox]/[red])$$

where E is the redox potential, $E°$ is the redox potential for components in their standard state at pH 0, R is the gas constant (8.3144J K^{-1}mol), F is the Faraday constant (9.65×104J V^{-1}mol), n is the number of electrons transferred, and T is the absolute temperature. In biology, the equation is generally written as

$$E_h = E_{m,x} + (0.06/n \log[ox]/[red])$$

where E_h is the redox potential referred to the standard hydrogen electrode, $E_{m,\,x}$ is the mid-point redox potential (when [*ox*] = [*red*]≠standard state) at a defined pH (of *x*) and 2.303 RT/F = 0.06 for 29.4°C. The value of E_m for a defined redox couple depends on the relative stability of the oxidized and reduced states: the more negative the value of E_m, the more stable is the oxidized form and the stronger is the electron donor. Conversely, any factor stabilizing the reduced form makes the couple a better electron acceptor, having a more positive redox potential.

3. Redox Potential, Free Energy, and Equilibrium Constant

The change in **free energy** associated with a redox reaction ($red_1 + ox_2 \leftrightarrow ox_1 + red_2$) is related to the difference in redox potentials of the reactants by the formula:

$$\Delta G^{\circ\prime} = -\mathrm{nF}\Delta E^{\circ\prime}$$

in which n is the number of electrons transferred, F is the energy change as 1 *M* of electrons falls through a potential of 1 V (23.06kcal$V^{-1}$$mol^{-1}$), and D$E°'$ is the difference in redox potentials of the reactants in volts. D $G°'$ is the free energy change per mole and is expressed in kilocalories.

We know that at constant temperature and pressure a reversible reaction proceeds until an equilibrium is attained, defined by

$$[ox_1]/[red_1] \times [red_2]/[ox_2] = K\mathrm{eq}$$

in which [ox_1], [red_1], [red_2], and [ox_2] are the reactant concentrations, and Keq is the equilibrium constant of the reaction at a certain constant temperature. Keq is related to the D$G°'$ free energy change by;

$$\Delta G^{\circ\prime} = -RT \ln K\mathrm{eq}$$

where R is the gas constant (1.987calmol^{-1}K^{-1}) and T is the absolute temperature (K).

We can also say that:

$$-nF\Delta E^{o\prime} = -RT\ln Keq or \Delta E^{o\prime} = RT/nF \times \ln Keq$$

Knowing the redox potentials of a redox couple, the last relationships make it possible to calculate the equilibrium concentrations. Conversely, the redox potential of a solution can be calculated from the relative concentrations of the redox couples at equilibrium.

4. How to measure the redox potential

The oxidation of a reductant (red_1) by an oxidant (ox_2), at fixed temperature and pH, can be followed potentiometrically by measuring the variation of the electromotive force of a solution of the reductant as it is titrated with the oxidant. In practice, with a Pt electrode connected with a reference electrode (ie, a calomel electrode), the redox potential of the red_1 solution is recorded after each addition of ox_2. The redox potential increases as the value of log $[ox_1]/[red_1]$ increases and is equal to E_m when the initial reductant is half oxidized, $[ox_1] = [red_1] = 50\%$. When $[ox_1]$ is close to 100%, the redox potential varies rapidly, and the titration comes to an end; the point of equivalence has then been reached, i.e. an equivalent of ox_2 has been added to red_1. In biological systems, the redox proteins generally carry colored groups that have substantial absorbance in the visible range of wavelengths. This allows precise determination by absorption spectroscopy of the relative concentrations of the oxidized and reduced species.

Many molecules can act as oxidizing and reducing agents in nonbiological redox reactions, whereas in the metabolic pathways of living organisms, a few molecules have been conserved during the evolution as redox agents for many different substrates.

The oxidation/reduction potentials of some biologically relevant compounds and free redox groups are presented in Table 1.

Table 1. Oxidation/Reduction Potentials of Some Biologically Relevant Compounds and Free Redox Groups

Redox Couple	$E_{m,7}$(mV)
$NAD(P)^+ + H^+ + 2e^- \rightarrow NAD(P)H$	–320
$S + 2H^+ + 2e^- \rightarrow H_2S$	–230
$Riboflavin + 2H^+ + 2e^- \rightarrow Riboflavin\text{-}H_2$	–200
$FMN + 2H^+ + 2e^- \rightarrow FMNH_2$	–219
$Pyruvate + 2H^+ + 2e^- \rightarrow lactate$	–190
$Protoheme\ IX(Fe^{3+}) + e^- \rightarrow (Fe^{2+})$	–115
$2H^+ + 2e^- \rightarrow H_2$	0.0[a]
$Dehydroascorbate\ 2H^+ + 2e^- \rightarrow Ascorbate$	+60
$Ubiquinone + 2H^+ + 2e^- \rightarrow Ubiquinone\text{-}H_2$	+100
$MetBleu + 2H^+ + 2e^- \rightarrow MetBleu$	+110
$Cu^{2+} + 2e^- \rightarrow Cu^+$	+150

$K_3Fe^{3+}(CN)_6 + e^- \rightarrow K_3Fe^{2+}(CN)_6$	+360
$NO_3^- + 2H^+ + 2e^- \rightarrow NO_2^- + H_2O$	+480
$SO_4^{2-} + 2H^+ + 2e^- \rightarrow SO_3^{2-} + H_2O$	+480
$Fe^{3+} + e^- \rightarrow Fe^{2+}$	+770
$1/2O_2 + 2H^+ \rightarrow H_2O$	+820

Oxidoreductases

Oxidoreductases form a large class of enzymes that catalyze the oxidation of one substrate, with the concomitant reduction of another. For these donor-acceptor reactions, the electron acceptor may be a pyridine nucleotide (eg, **NAD**), cytochrome, oxygen, quinone or others. The term dehydrogenase is used to describe oxidation-reduction reactions whenever possible, whereas the term *oxidase* is restricted to enzymes for which oxygen is an acceptor. Dehydrogenases act on primary and secondary alcohols, as well as hemiacetals. They also convert aldehydes to the corresponding acids, and these reactions may involve phosphorylation of the acid or acetylation of coenzyme A (CoA). Oxo groups may be oxidized by the addition of water, followed by the cleavage of a C–Cbond or dehydrogenation. Dehydrogenases can introduce double bonds by direct dehydrogenation at a single C–Cbond. They function as oxidases by utilizing oxygen for the deamination of amino acids that can also undergo direct dehydrogenation reactions. In addition, they can dehydrogenate secondary amines to form C=Ndouble bonds and oxidize NADH or NADPH as well as nitrogenous substrates and donors with sulfur or heme groups.

Oxygen-Binding Proteins

Oxygen-binding proteins are defined as proteins that reversibly bind O_2. They are exclusively metalloproteins.

1. Classification

The classification of oxygen-binding proteins and some of their properties and distribution are

presented in Table 1. Protoheme IX is the common oxygen-binding site for **myoglobins** (Mb), IDO-like Mb, **hemoglobins** (Hb), compact Hb, and FixL. Dioxygen is bound at the ferrous ion at the center of the heme group (see Myoglobin). The vinyl group normally at position 2 of protoheme IX is replaced by a formyl group in the chlorocruoroheme carried by chlorocruorin (Chl). Hemerythrin (Hr), myohemerythrin (myoHr), and hemocyanin (Hc) are nonheme proteins. The oxygen-binding site for Hr and myoHr is a binuclear iron center, and that for Hc is a binuclear copper center.

Table 1. Classification of Oxygen-Binding Proteins

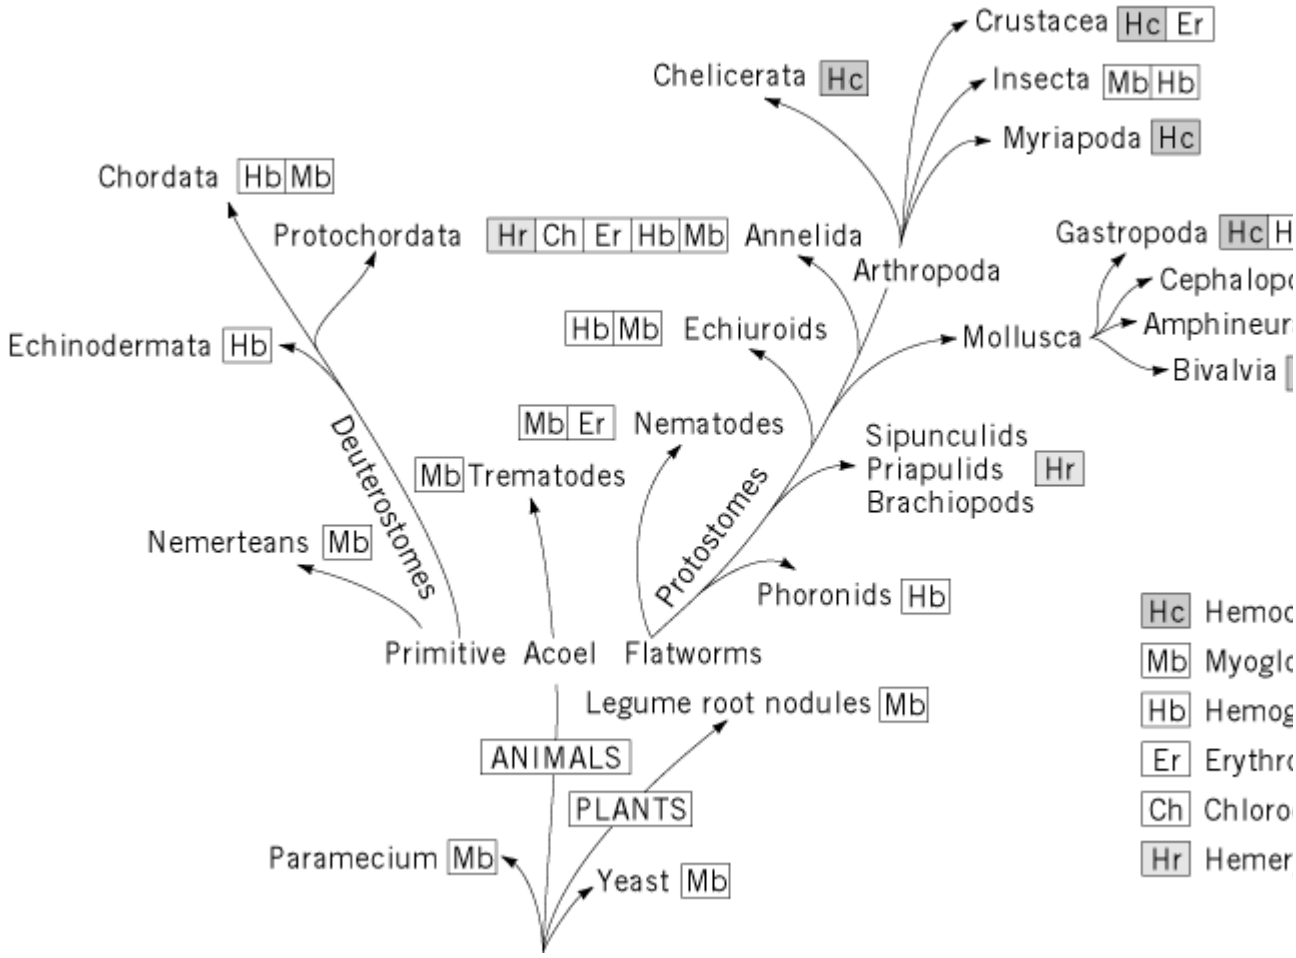
Name	O_2 Binding Site	Protein Folding	Molecular Mass, kDa	Aggregation State	Color		Distrib
					Deoxy	Oxy	
Myoglobin	Protoheme IX	Globin	17 or 34	Monomer or dimer	Purple	Red	Vertebr muscle gastrop radular
IDO-like myoglobin	Protoheme IX	Unknown	40 or 80	Monomer or dimer	Purple	Red	Gastrop buccal r
Hemoglobin	Protoheme IX	Globin	17, 34, or 44	Monomer or dimer	Purple	Red	Bacteri unicellu eukaryo andplan
	Protoheme IX	Globin	65	Tetramer	Purple	Red	Vertebr cell
	Protoheme IX	Globin	3500	144mer	Purple	Red	Annelid plasma
Compact hemoglobin	Protoheme IX	Unknown	13–15	Monomer	Purple	Red	Cyanob protozo green al
FixL	Protoheme IX	Unknown	110	Dimer	Similar to Hb or Mb		*Rhizobi Bradyrh*
Chlorocruorin	Chlorocruoroheme	Globin	3500	144mer	Greenish red	Greenish red	Blood p four pol families
Myohemerythrin	Binuclear Fe center	4-a-Helix bundle	14	Monomer	Colorless	Violet	Sipuncu muscle
Hemerythrin	Binuclear Fe center	4-a-Helix bundle	40–110	3, 4 or 8mer	Colorless	Violet	Red cel phyla o inverteb
Hemocyanin	Binuclear Cu center	a-Helices and b-barrel	450–3300	6, 12, 24, 36, or 48mer	Colorless	Blue	Arthrop plasma
	Binuclear Cu center	Unknown	3500–8700	10 or 20mer	Colorless	Blue	Mollusk plasma

The hemoglobins in protozoa (*Paramecium* and *Tetrahymena*), green **algae** (**Chlamydomonas**), and **cyanobacteria** are not authentic hemoglobins because their polypeptide chains are about 20% shorter and without substantial amino acid sequence similarities. Several pieces of evidence suggest that the structures of these "compact hemoglobins" differ from the "globin fold" (see Globins), and it is generally considered that they arose from a different **evolutionary** ancestor (see Convergent Evolution). Likewise, IDO-like Mb evolved from a common ancestor of indoleamine dioxygenase, a heme-containing enzyme that degrades tryptophan. Based on their gene structures and amino acid sequences, myoglobins and hemoglobins are divided into three distinct evolutionary groups: (1) "universal globins", 17-kDa polypeptide chains, that have about 150 amino acid residues; (2) "truncated globins" or "compact globins", 13 kDa, that have about 120 residues per chain; and (3) "IDO-like Mb" (1). The second group has been known as "truncated globin", but "compact globin" is more appropriate because these proteins have no detectable amino acid homology with the universal globins.

2. Distribution, Structure, and Function

Figure 1 illustrates the distribution of oxygen-binding proteins in a simplified **phylogenetic** tree. Hr and Hc are distributed within certain animal phyla, such as Sipuncula, Brachiopoda, Annelida, Arthropoda, and Mollusca. Hb, the most widely distributed, occurs in **bacteria** to vertebrates, and even in **plants**, but only intermittently. The principal physiological function of the circulating proteins (vertebrate Hb, annelid Hb, Chl, Hr, and Hc) is to transport O_2 from the lungs or gills to peripheral tissues. The function of the noncirculating proteins (Mb and myoHr), and probably also of IDO-like Mb, is oxygen storage and intracellular transport.

Figure 1. Phylogenetic distribution of oxygen-binding proteins. Abbreviations undefined in the text are Er, erythrocruori same as Chl (chlorocruorin). Erythrocruorin was the name used for what is now called annelid extracellular hemoglobin. hemoproteins of yeast, paramecium, and legume root nodules are designated as Mb in this figure, they are sometimes des Hb, because they are not contained in muscle and Hb is a more comprehensive name of an oxygen carrier. From Van Ho Miller (1995) (see Reading List).



See Myoglobin for details of Mb and IDO-like Mb and Hemoglobin for details of Hb. The other oxygen-binding proteins are described here.

2.1. Compact Hemoglobin

Only a limited number of structure and functional studies of compact Hb have been carried out. The physiological role of these proteins is uncertain. It is proposed that Hb from the cyanobacterium *Nostoc cummune* is an oxygen scavenger in nitrogen fixation .

2.2. FixL

The FixL that occurs in *Rhizobium meliloti* and *Bradyrhizobium japonicum* is a chimeric protein consisting of a heme-containing **domain** and a protein kinase domain. Its proposed function is to sense oxygen through its heme domain and to transduce this signal by controlling the phosphorylation of transcriptional activator FixJ, which in turn induces the expression of the genes for nitrogen fixation, thereby providing oxygen-dependent control of nitrogen fixation (2). The heme domain has no significant sequence similarities to the globins, suggesting that it arose independently.

2.3. Chlorocruorin

Chl has only a limited phylogenetic distribution. It is found in the blood plasma of four families of polychaeate annelids, the *Sabellidae*, *Serpulidae*, *Chlorhaemidae*, and *Ampharetidae*. The protein structure of Chl is essentially the same as that of extracellular annelid Hb, except for the change in the heme group (3). The vinyl to formyl replacement at position 2 of protoheme produces the characteristic greenish color and low oxygen affinity of Chl due to the enhanced electron-withdrawing properties of the formyl group. Chl shows highly cooperative oxygen binding. As with annelid Hb, its oxygen affinity is pH-dependent (see Bohr Effect) and is increased by divalent

cations like Mg^{2+} and Ca^{2+} (4).

2.4. Hemerythrin (Hr) and Myohemerythrin

Hr has been found only in four phyla of marine invertebrates: Priapulia, Sipuncula, Brachiopoda, and one family of annelida, Magelonidae. It is contained in red cells called "hemerythrocytes" that float in the coelomic fluid. A noncirculating Hr is found in muscle fibers of sipunclids and is called "myoHr", in analogy to myoglobin. Coelomic Hr is found predominantly as the octamer, but also as tetramers, trimers, and dimers. The octamer is composed of two different subunits that have different amino acid sequences (5). The octamer has a mass of 108 kDa, the shape of a square doughnut, and consists of two rings of four subunits each whose rings are associated in a face-to-face, **isologous** manner (see Quaternary Structure). Each 13.5-kDa subunit consists of four parallel **alpha-helices** twisted in a left-handed bundle (6) (see Four-Helix Bundle Motif). The tertiary structure of myoHr (13.9 kDa) is similar to that of one Hr subunit. MyoHr and each subunit of Hr contains a site that has two iron atoms, which bind one O_2 molecule. The iron atoms are bound directly to seven amino-acid side chains of the protein. One of the O_2 atoms binds to one of the iron atoms, and the other oxygen atom forms a hydrogen bond with the oxo bridge that connects the two iron atoms.

The oxygen affinity of myoHr is higher than that of coelomic Hr of the same species. Octameric Hr from two brachiopods (*Lingula unguis* and *Lingula reevii*) show notable cooperativity in oxygen binding and have **Hill coefficients** of 1.8 to 2.2 (see Hemoglobin), whereas other Hrs are essentially noncooperative, irrespective of their state of aggregation. It has been suggested that the allosteric unit of *L. unguis* octameric Hr is the entire molecule (7). Effects of intracellular cofactors, such as H^+, CO_2, Mg^{2+}, Ca^{2+}, and Cl^-, on the oxygen affinity have been observed with some Hrs, but their physiological significance is not clear.

2.5. Hemocyanin

Hc is found in the blood plasma of two phyla, arthropod and mollusk. The oxygen-binding site of Hc is composed of a pair of copper ions, each of which is liganded by three histidine residues of the protein. It was long thought that O_2 binds as a peroxo ion, serially bridging the two Cu(II) ions, but now there is direct evidence that the mode of O_2 binding is a m-h^2:h^2 coordination, in which both oxygen atoms are bound to both of the copper ions and the O–O axis perpendicular to the Cu–Cu axis.

Arthropod and mollusk Hc exhibit similar optical and ligand-binding properties, but their molecular architectures are quite different. All arthropod Hcs are composed of hexamers. Each 75-kDa polypeptide chain carries one oxygen-binding site. These aggregate into 1, 2, 4, 6, or 8 hexamers, depending on the species, and no intermediate aggregations states are observed in each case. With this mode of assembly, one Hc molecule has from 6 to 48 oxygen-binding sites and a molecular mass ranging from 450 to 3300 kDa. Each hexamer is a "trimer of dimers", and the shape is a trigonal antiprism. Each polypeptide chain consists of three domains. The first and second are a-helical, whereas the third has an irregular structure that contains a 7-strand b-barrel (see Beta-Sheet). The O_2-binding site is in the second domain.

In contrast to the arthropod Hc, those from mollusks are organized entirely differently. The molecule is composed of one or more cylindrical units, each containing 10 subunits. Each subunit is a long polypeptide chain of 350 to 440 kDa composed of seven or eight globular folded regions, each of which binds one O_2 molecule. It is not known whether each such region is composed of more than one domain, so it is called instead a "functional unit." Its three-dimensional structure is not yet known.

The quaternary structures of both arthropod and mollusk Hc are stabilized by many calcium ions. The Hc oxygen affinity varies, depending on the species, especially in the Arthropoda, and reflects

adaptations to the great variety of life styles and environments of the animals. Most Hcs demonstrate a distinct Bohr effect and varying degrees of cooperativity in oxygen binding. The Hill coefficient ranges between 1 and 12. A higher degree of aggregation is not necessarily accompanied by greater cooperativity. The oxygen dissociation curves of Hcs that have large multimeric structures are not compatible with the classic allosteric **concerted model** of Monod, Wyman, and Changeux but are described best by a "nesting" model (8). This assumes that the allosteric units capable of transitions between two states, *r* and *t*, are in turn nested within larger structural units that are in equilibrium between two global states, *R* and *T*. In addition to the structural calcium ions, other calcium ions, plus magnesium ions, regulate the oxygen affinity.

There is very little sequence similarity between arthropod subunits and molluscan functional units. This and their very different molecular architectures indicate that they probably evolved independently.

Oxytocin

Oxytocin (MW 1007) is a peptide hormone released by the posterior pituitary gland that displays a wide spectrum of biological activities, including a role in reproduction and social behavior (1). It stimulates uterine contraction and lactation, activates myometrial GTPase and phospholipase C, and

increases sodium excretion. It consists of only nine amino acid residues, with Cys1 and Cys6 linked by a disulfide bond and with an amidated *C*-terminus:

NH_2-Cys-Tyr-Ile-Gln-Asn-Cys-Pro-Leu-Gly-NH_2

The complementary DNA (cDNA) encoding the precursor for human oxytocin has been **cloned** and **DNA sequenced** (2). This indicated that the **genes** for oxytocin and vasopressin are linked on the same human chromosome, 20, and arose through gene duplication (3). The gene for the oxytocin precursor, pro-oxyphysin, is composed of two **introns** and three exons. The initial gene product contains oxytocin, plus a carrier protein, neurophysin.

The majority of oxytocin is produced in the neurohypophysis and magnocellular neurons of the paraventricular and supraoptic nuclei of the hypothalamus. It is processed **proteolytically** from its precursor form during transport along the axonal projections to the posterior pituitary. The enzymes and the mechanisms of the specific **posttranslational modifications** involved in the production of active peptides from the precursor protein are still not completely known. The process by which the prohormones are packaged into the membrane-bound **secretory granules** and transported down the axon supraopticohypophyseal tract is the subject of ongoing investigation. The hormone and its associated neurophysin are secreted from nerve terminals of the neurohypophysis into the portal system of the neurohypophysis by calcium-dependent exocytosis, although the molecules responsible are not yet known. Oxytocin secretion is initiated by depolarizing electric impulses on the cell membranes. That is followed by calcium influx into the cell, fusion of the secretory granules with the cell membrane, and excytotic extrusion of the hormone.

The relationship of oxytocin to its four types of receptors (4) and subsequent signaling is not completely understood (5). The human receptor has been sequenced (6), however, its structure analyzed, and its binding sites identified (7).

Oxytocin is primarily associated with lactation and parturition in females. It is used clinically to induce labor or augment labor, when appropriate, because it stimulates the contractions of uterine smooth muscle. Oxytocin release is stimulated by a baby's cry or suckling, and this subsequently releases prolactin, which causes milk to be released, by stimulating the contraction of myoepithelial cells in milk ducts of mammary glands and thereby forcing milk from alveoli in the breast. Oxytocin has been implicated in other functions. These include mating and maternal behavior, natriuresis, modulation of the cholesterol/phospholipid ratio in membranes, and even memory. However, the elimination of oxytocin in **transgenic** mice did not change their reproductive and maternal behavior (8, 9). Both male and female homozygous knockouts are fertile, and the females are capable of parturition; cross reactivity of vasopressin with the oxytocin receptors explains this apparent contradiction. Milk release was absent, but it was correctable by oxytocin injection. In males, the importance of oxytocin is even less well understood. It has been suggested that oxytocin is involved in prolactin release, penile erection, and various aggressive sexual behaviors.

P Element

The P element is a transposable element in *Drosophila* that can insert into many different positions in the genome (1). In addition to being an element whose transposition mechanism has been interesting to dissect, its transposition is controlled in interesting ways at several levels. Manipulation of P-element transposition has also been an immensely powerful tool for *Drosophila* genetics (2). One widespread use of P elements is to make physically tagged mutations that have allowed the ready isolation of the affected **genes** through the physical marker provided by the P element. Also, P-element transposition has provided a widely used method for introducing sequences into the *Drosophila* genome.

P elements were discovered by studying the phenomenon hybrid dysgenesis that results when males from certain strains of *Drosophila* are crossed with females of certain different strains. In the germline of the progeny of such crosses, there is a high frequency of mutations and also sterility. Characterization of mutations resulting from such crosses revealed that they resulted from the insertion of a novel 2.9-kbp piece of DNA, the P element (see Fig. 1 in Transposable Elements). Transposition of this element is usually restricted to the germline, because the transposase is assembled from four exons by RNA splicing in the P-element messenger RNA, and factors in somatic cells can both inhibit transcription and block splicing. Hybrid dysgenesis results from a cross of a P-element male with a non-P-element-containing female. The use of the maternal non-P-element strain is important because, in addition to making transposase, the P element also produces a transposition inhibitor from the unspliced P-element RNA, so transposition is inhibited in eggs of P^+ strains.

P-element transposition is promoted by the P-element transposase (3) and a collaboration with at least one host protein that also interacts with the ends of the P element (4). Interestingly, this host protein is related to other proteins involved with DNA repair. The nature of the collaboration between these proteins that promotes transposition is not yet known. P-element transposition occurs via a “cut and paste” mechanism, in which the element is excised from the donor site and then inserted into the target site. The donor gap resulting from transposon excision can be repaired by double-strand break repair using a sister homologue as a template (5).

The P element has been an immensely powerful tool in studying *Drosophila*. Not long after the discovery and molecular characterization of the P element, it was used in a landmark experiment to introduce novel DNA sequences into the *Drosophila* genome (6). A special P-element derivative was constructed that had, in addition to transposase, a further gene whose activity could be scored visually by inspection of flies. It was found that injection of this modified P element into embryos could result in its integration into the germline and expression in adult flies. Such P-element-mediated transformation is now a commonly used method in *Drosophila* analysis (2). P-element derivatives are also widely used as mutagens, so that the mutations generated are physically tagged with the element; this makes isolation of the target DNA containing the mutated gene very straightforward.

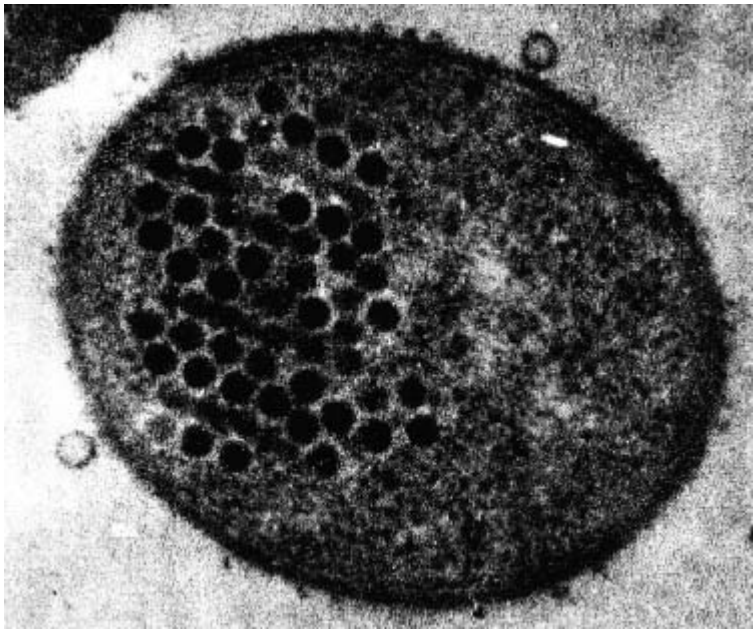
P22 Bacteriophage

The *Salmonella typhimurium* phage P22 is a double-stranded DNA phage of the Podoviridae family that has played a key role in the development of molecular biology. Studies with P22 have contributed to our understanding of genetic exchange, control of gene expression, and biological self-assembly. It has proven itself to be a valuable laboratory tool for genetic manipulation of its host, *Salmonella*. P22 is classified as a lambdoid phage because it shares life cycle similarities with the *Escherichia coli* lambda phage. Comparison of the similarities and differences between P22 and the other lambdoid phage has served to illuminate both the common themes and the range of diversity that nature employs in problem solving (1).

P22 was originally isolated as a lysogen of *Salmonella*, and it has played a key role in the development of bacterial genetics. In 1952, Zinder and Lederberg discovered the phenomenon of generalized transduction of *Salmonella* genes by P22 (2). This observation led to studies on the mechanism of the establishment of lysogeny, which contributed to our current understanding of repressors and anti-repressors. Studies of the assembly of P22 have been instrumental in framing the concepts that guide our thinking about control mechanisms in biological assembly (3). In addition, the well-defined and readily manipulable genetics of P22 have allowed it to lead the way in the development of genetic analysis of **protein folding** and assembly (3-6).

Bacteriophage P22 is a temperate virus, meaning that following infection two distinct life cycles are available to it: the lytic or the lysogenic life cycles. In the lytic life cycle, a series of viral genes are expressed that ultimately result in the production of several hundred progeny virions per cell. The progeny virions are released approximately one hour after infection, through lysis of the host cell (Fig. 1). In the alternative pathway, termed the *lysogenic pathway*, the phage chromosome integrates into the host chromosome, and expression of the phage structural genes is suppressed (see Lysogeny). The integrated phage is called a *prophage*, which is replicated and passed to the daughter cells during cell division. In response to an appropriate environmental signal, such as irradiation with ultraviolet light, the prophage can excise itself, enter the lytic cycle, and generate progeny phage. The decision between whether an infecting phage enters the lytic or lysogenic pathway depends on a number of factors, the most important of which seems to be the number of infecting virions, or multiplicity of infection.

Figure 1. Electron micrograph of a section through a bacteriophage P22-infected *Salmonella typhimurium* cell approximately 30 min after infection. The electron-dense progeny phage within the cell contains double-stranded DNA, whereas the infecting phage that remain attached to the cell at 1 and 8 o'clock do not.



1. Structure

The P22 virion consists of two distinct structural elements: the capsid and the tail. The dsDNA phage genome is contained within the capsid and is thereby protected from environmental insult. The capsid of the P22 virion is a $T = 7$ **icosahedral symmetry** lattice approximately 600 Å in diameter, composed of ~420 identical copies of the 47-kDa **g**ene **p**roduct 5 (gp5) coat protein (7). The capsid itself is a very stable structure, resistant to elevated temperature and drying, as well as to **nucleases** and proteinases. Interestingly, this stability does not arise directly from the coat protein subunits, but rather from their intersubunit contacts (8). The coat protein subunits themselves, prior to polymerization into the capsid, are only modestly stable. The tail is composed of up to six trimers of the 72-kDa gp9 tailspike protein. The tailspike protein serves as the organelle for attachment of the virus to the host cell during infection and is itself also a very stable structure (9).

The 27×10^6–kDa linear dsDNA genome is contained within the capsid of the phage in a highly condensed liquid-crystalline state. The close packing of the phosphate groups in the condensed form requires charge neutralization, which is accomplished through the binding of Mg^{2+} ions. Although the precise packing of the DNA within the capsid is not known, the B form of DNA structure appears to be retained (10).

The structure of the tailed vertex of the phage is surprisingly complex. The tailspike trimers are attached to the capsid through a connector region. The connector is composed of a macromolecular complex composed of 12 subunits of the gp1 portal protein, as well as the connector proteins, gp4, gp10, and gp26. The 83-kDa gp1 portal protein is arranged as a dodecameric complex, approximately 180 Å in diameter with a central channel approximately 30 Å in diameter (11). It is thought that the DNA enters and exits the head through the central channel of the portal complex. Portal complexes have been identified in nearly all the dsDNA-containing bacteriophage. Although there has been debate as to whether portal complexes are composed of 12 or 13 subunits, the existence of the portal complex at an icosahedral vertex poses an interesting structural dilemma: The portal complex exhibits 12- or 13-fold symmetry, but is located at a fivefold symmetrical vertex, resulting in a symmetry mismatch. This means that there cannot be a simple 1:1 interaction between portal and capsid subunits during assembly and function. Although the exact manner in which the portal protein interacts with the capsid is unknown, it has been suggested that such an arrangement would make it possible for the portal complex to rotate within the capsid during DNA translocation

(12).

The tailspike protein folds and assembles independently of the capsid, and then adds subsequently to the capsid to render the phage infectious. The unique biochemical properties of the tailspike protein, coupled with the well-defined genetics of the bacteriophage system, have made it an ideal subject for *in vivo* studies of protein folding. The tailspike folds in a multistep pathway, in which partially folded intermediates associate to form an **SDS**-sensitive protrimer (13). The protrimer then matures into a very stable SDS-insensitive trimer. The reason for this stability is that the central region of each subunit of the trimer is folded into a right-handed **b-helix** structure, and the C-terminal regions interdigitate to form **b-sheet** structures (14, 15). The ability to identify readily and quantify the ratio of partially folded and fully folded proteins by the simple technique of SDS-PAGE analysis has allowed the isolation and characterization of a series of mutations that destabilize the partially folded intermediates. Because these mutations have no effect on the stability of the final fully folded trimer, these mutants have been termed **t**emperature **s**ensitive for **f**olding (*tsf*) mutants. Analysis of these mutants has lent support to the idea that protein folding and assembly takes advantage of transient interactions between amino acid residues that do not play a critical role in the stability of the final structure. At restrictive temperatures, the *tsf* mutant proteins form aggregates, indicating that aggregation occurs through the interaction of partially folded protein molecules and that alterations in the lifetime of the protein folding intermediates can result in aggregation (6, 16-18).

2. The Infection Process

P22 initially infects the host *Salmonella* cell through the binding of the tailspike to the O-antigenic repeating units of the bacterial lipopolysaccharide. The interaction of the tailspike protein with this receptor defines the host range. Once bound, the tailspike slowly destroys the receptor by cleaving the au (1, 3)-*O*-glycosidic bond between rhamnose and galactose units. The virion carries up to six tailspikes, but only three are used for binding during infection (9, 19, 20). Once bound, the phage moves laterally across the cell surface through repeated cycles of binding and release, presumably until it locates a second receptor, at which point binding becomes irreversible (21).

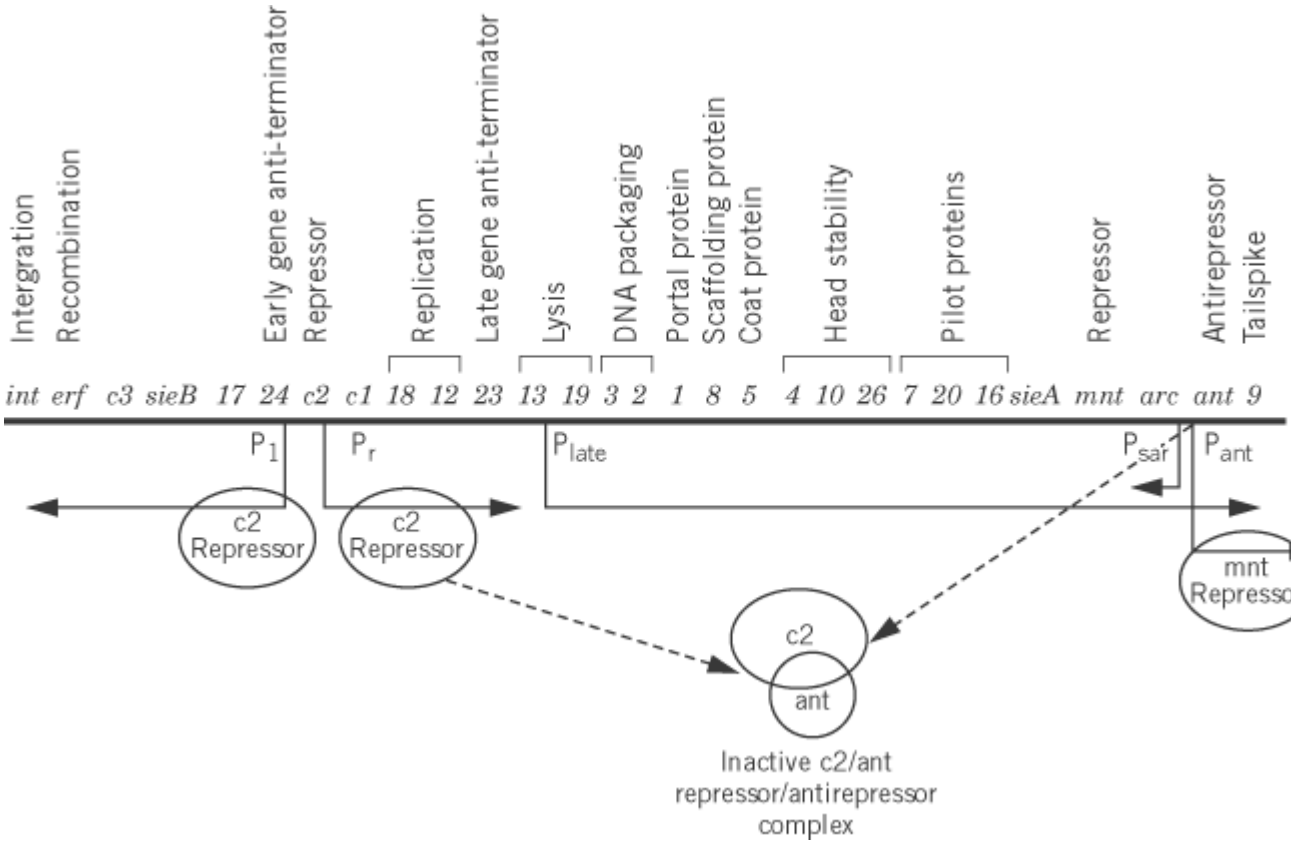
The dsDNA is then injected into the host cell in a linear fashion (22). The phage-encoded pilot proteins gp7, gp16, and gp20 are required to ensure that the DNA crosses the plasma membrane in an infectious form. Although the mechanism of their action remains unknown, they translocate from the phage into the host cell during infection (23). Following infection, the dsDNA circularizes by homologous recombination between the terminal redundancy regions, yielding a circular dsDNA that represents a single copy of the phage genome (24).

3. The Lysogenic Pathway

In the lysogenic state, the bacterial chromosome carries an integrated copy of the bacteriophage chromosome, termed a prophage. In the prophage, the genes responsible for growth of the phage and subsequent death of the host are repressed through the action of a specific repressor system. This repression results in a phenomenon known as *immunity*. If a host cell carrying a lysogen is subsequently superinfected by a phage carrying the same repressor system as the prophage, it too will be unable to grow. P22 maintains the prophage in a quiescent state through the action of two repressor proteins (Fig. 2). In this regard, P22 differs from l phage, which has only a single repressor, *cI*. The two P22 repressor proteins are called *c2* and *mnt*, and they give rise to two immunity systems. The *immC* region is similar to the immunity region of l. The P22 *c2* repressor acts at O_L and O_R to prevent transcription of the early genes. The unique *immI* region includes an antirepressor, *ant*, and its regulators *mnt* and *arc*. *Mnt* acts to repress the transcription of the ant antirepressor. If *mnt* is turned off, ant is synthesized. Ant binds to and inactivates the c2 repressor protein, with the result that the prophage enters the lytic pathway. The production of ant itself is regulated through the action of the *arc* gene. In *arc* mutants, high levels of ant are produced, and these levels block phage development. The arc and mnt proteins are two members of a small family of proteins that use anti-

parallel b-sheet motifs rather than **helix–turn–helix** motifs to bind their operator DNA (25, 26) (see DNA-Binding Proteins).

Figure 2. Genetic map of bacteriophage P22. The genes are positioned above the line (not to scale), with their function indicated above. Promoter regions and the loci of repressor action are indicated below the line. The c2 repressor protein inhibits synthesis of the early genes, P_l and P_r. The anti-terminators 24 and 23 result in expression of the early and late genes, respectively. Notice that genes with related functions are clustered.



The *ant* gene lies downstream of P_{late} and is transcribed during the lytic cycle as part of the late **operon**, but Ant protein is not synthesized. An additional promoter P_{sar} lies within the *ant* gene and directs the synthesis of a 69-nucleotide long **antisense** RNA that binds to the *ant* messenger RNA and inhibits its translation (27, 28).

In order to form a stable lysogen, the phage genome has to integrate into the host; otherwise it would be diluted out during cell division. Integration occurs preferentially at a particular site, attB, in the host chromosome and requires the action of the phage-encoded integrase (Int) protein and the host-encoded integration host factor (IHF). The circular phage chromosome carries a similar site, termed attP (29). A single crossover event catalyzed by the Int protein results in integration. For entry into the lytic cycle, excision proceeds by the reverse mechanism but, to ensure that excision does not take place prematurely, requires the additional function of the *xis* gene product, which overlaps *int* in the genetic map (30).

Entry into the lysogenic pathway is controlled by the genes *c1* and *c3*. These gene products stimulate the production of the c2 repressor protein immediately after infection. C1 binds to the P_{RE} (promoter repressor establishment) promoter as a tetramer and stimulates c2 synthesis (31). High-level

expression of c2 appears to be required for entry into the lysogenic pathway, and this is the probable reason that a high multiplicity of infection favors lysogeny.

In addition to the immunity conferred by the immI and immC repressor systems, the phage employs three other mechanisms to prevent superinfection. The first is a modification of the host O antigen, which inhibits the adsorption of P22. This function is encoded by the *a1* gene (32). The genes *sieA* and *sieB* (superinfection exclusion) block superinfection. Expression of *SieB* appears to lead to abortive infection; while the superinfecting phage enters the cell, and early functions are normally expressed, late function expression is inhibited. The sieA protein is an 18-kDa protein that partitions into the membrane and acts to block DNA from crossing the periplasmic space and entering the host cell (33). It therefore excludes virion DNA from entering the cells, regardless of the identity of the DNA.

4. The Lytic Pathway

In the lytic pathway, P22 enters the *Salmonella* host cell and begins the process of reproduction. In P22, as in l, the proteins involved in the lytic cycle are expressed sequentially. Control of the timing of the production of mRNA transcripts is achieved through the use of **anti-termination** proteins that allow the **RNA polymerase** to ignore encoded termination signals. To take advantage of this, the P22 genome is organized so that these regulatory proteins can exert their influence on a large number of genes (34). The genes themselves are clustered into functional units; for example, all the genes involved in assembly are clustered into the late operon and are under the control of a single regulatory protein. Like lambda, the early genes of P22 are arranged into two operons, P_L and P_R, which flank the P22 c2 repressor gene. The genes in these operons encode proteins involved in DNA replication, recombination, integration, and the regulation of gene expression. Gene 24, which is transcribed off P_L, is similar in function to the lambda N gene. It functions to prevent the termination of transcription at genetically defined sites in the chromosome and allows for complete transcription of the early genes (35, 36). Gene 23, which is transcribed off P_R, is analogous to gene Q in lambda and allows transcription of the late genes (37). The late genes that are driven off the P_{late} promoter code for the proteins necessary for head and tail assembly.

5. Generalized Transduction

Transduction is a process by which bacterial DNA is carried from one cell to another by a phage particle. Generalized transducing particles contain DNA derived entirely from the host-cell chromosome. Bacteriophage P22 transducing particles originate when the host chromosome, rather than the phage chromosome, serves as the substrate for packaging. During a lytic infection, the phage chromosome is replicated as a concatamer, and the concatamers are resolved as the double-stranded DNA is packaged by a headful mechanism. The products of phage genes 2 and 3 are required for packaging and act as a complex. Genetic evidence suggests that gp3 is responsible for recognizing a unique site or region termed a *pac* site. Packaging proceeds in an ATP-dependent reaction until the head is full, at which point the gp2/gp3 complex cuts the DNA; packaging then continues into another empty prohead. This model is the “sequential packaging model.” The P22 head can package 105% of a phage genome, accounting for the observed terminal redundancy and circular permutation of the genetic map (38-41).

Within the *Salmonella* chromosome, there are a minimum of five to six sites, called pseudo-*pac* sites, which are recognized by the gp2/gp3 complex as pac sites. The nonrandom distribution of pseudo-*pac* sites therefore leads to a nonrandom distribution of transduced markers (42). Mutants that map in gp3, termed HT mutants, have been isolated in which up to 50% of the phage heads carry host DNA. These mutants have proven extremely valuable for studying the genetics of *Salmonella*. The 44-kbp length of the packaged DNA corresponds to about 50 genes and has made possible linkage analysis and genetic mapping of the *Salmonella* chromosome.

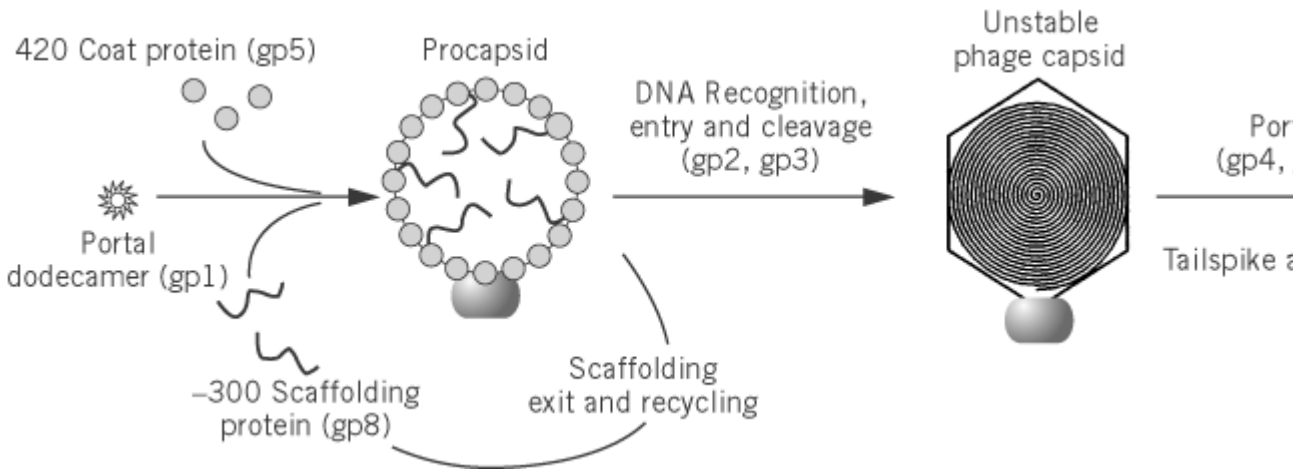
6. Specialized Transduction

Specialized transducing particles carry both host and phage DNA linked in a continuous stretch in a single particle. There are two mechanisms by which specialized transducing particles can arise: from aberrant prophage excision or by insertion into the phage genome of host translocatable elements. P22 has more latitude in its ability to mediate specialized transduction than does bacteriophage l. Because P22 packaging does not use unique end sites, it can package extremely long stretches of DNA by segmenting them into multiple heads. If a host cell is multiply infected, an intact oversized genome can be generated by recombination.

7. Capsid Morphogenesis

During P22 morphogenesis, properly folded and associated tailspike trimers add to the dsDNA-containing head, to generate an infectious virion. However, the filled capsid is not the first structure that is assembled (Fig. 3). The gp5 coat protein subunits are first assembled into a structure termed a procapsid (37). Like the mature virion, the procapsid has $T = 7$ icosahedral symmetry, and the portal protein is present at a single vertex in the form of a dodecameric complex (43, 44). However, the procapsid does not contain DNA. The interior volume is filled with approximately 300 copies of the gp8 scaffolding protein. Studies with **conditional lethal mutants** have demonstrated that the presence of the scaffolding protein facilitates coat protein polymerization and ensures a proper structure. In the absence of scaffolding protein, a variety of morphologically aberrant polymers are formed, while assembly proceeds with high fidelity (45). The procapsid is approximately 10% smaller in diameter and is less stable than the mature head. During DNA packaging, the scaffolding protein exits, and the lattice expands. Three-dimensional **single-particle reconstructions** from cryoelectron microscopy of the procapsid and mature form revealed that there are ~25 Å diameter holes situated at the center of the hexavalent capsomeres in the procapsid and that these holes are closed during expansion. No proteins are added to the procapsid to close the holes; instead, they are closed by **domain** movements within the coat protein subunits (46). These holes are likely candidates for the exit ports for the scaffolding protein during DNA packaging (43). The freed scaffolding protein is recycled to participate in further rounds of assembly (47). Thus, the scaffolding protein functions as an "assembly **molecular chaperone**" whose presence is transiently required to provide positional information. The use of scaffolding proteins is a common theme in the assembly of the lambdoid phages and is also required for the assembly of the **herpesviruses**.

Figure 3. The morphogenetic pathway of the bacteriophage P22 capsid. The first structure formed is a procapsid, which coat, scaffolding, and portal proteins. The "pilot" proteins are also incorporated at this stage. The concatameric DNA is p with the exit of the scaffolding protein. The addition of gp4, gp10, and gp26 stabilizes the head, and tailspike binding rer



The scaffolding protein of P22, as well as all well-characterized scaffolding proteins, is a highly **a-helical** molecule that forms oligomers in solution (48). In the case of P22, dimerization of the scaffolding protein plays a key role in assembly. In both P22 and the herpes virus, the region of interaction between the coat and scaffolding protein has been mapped to the *C*-terminal end of the molecule. In addition to its role in assembly, it has been suggested that the scaffolding protein may function to exclude the chance incorporation of cellular proteins during head assembly, because the presence of cellular proteins within the capsid would result in a decreased internal volume and preclude the encapsidation of a complete P22 genome. P22 scaffolding protein regulates its own levels of biosynthesis, which is decreased if there is a large free pool, but up-regulated if all the scaffolding protein is incorporated into procapsid (49-51). This post-transcriptional control might be a mechanism to insure that all procapsids contain a full complement of scaffolding protein, despite the fact that a full complement is not strictly required for assembly (52).

During morphogenesis, the dsDNA is packed into the procapsid, the scaffolding protein exits, and the capsid lattice expands. The exact sequence of these events is not known, but the expansion is an exothermic process, suggesting that the capsid is "spring loaded" (53). Interestingly, the portal protein is part of the gauge that determines when the head is full; mutants in the gp1 portal protein have been identified that result in packaging a piece of P22 DNA up to 5% larger than normal (54). Following DNA packaging, the portal vertex is closed by the addition of the protein products of genes 4, 10, and 26. These proteins, which add sequentially, serve to stabilize the DNA within the capsid and also to provide the site for tail attachment (55).

There are two genes that are essential for lysis, genes *13* and *19*. Gene *13* encodes an 11-kDa protein whose function is to disrupt the cell membrane by forming pores and to allow the hydrolytic enzymes access to the cell wall. Mutations in gene 13 have been isolated that delay lysis for up to several hours, despite the fact that the phage-encoded lysozyme is being produced. Gene *19* encodes the P22 lysozyme, a 16-kDa monomeric protein that attacks and degrades the peptidoglycan layer of the cell wall, leading to cell lysis. The bacteriophage P22 lysozyme is very similar to the well-studied T4 lysozyme with respect to structure and function.

Procapsid-like particles of P22 can be assembled *in vitro* from purified proteins (52). This has made it possible to perform sophisticated physical chemical studies of virus assembly. These studies have revealed that capsid assembly is a nucleation-limited reaction (56), proceeds along a well-directed pathway (56), and can be inhibited by the binding of small molecules to the coat protein subunits (57).

Over the past 30 years, the bacteriophage P22 system has contributed to our understanding of gene expression, protein folding and assembly, and basic virology. It appears that the lessons that we can learn from these systems is limited only by the creativity of the investigator.

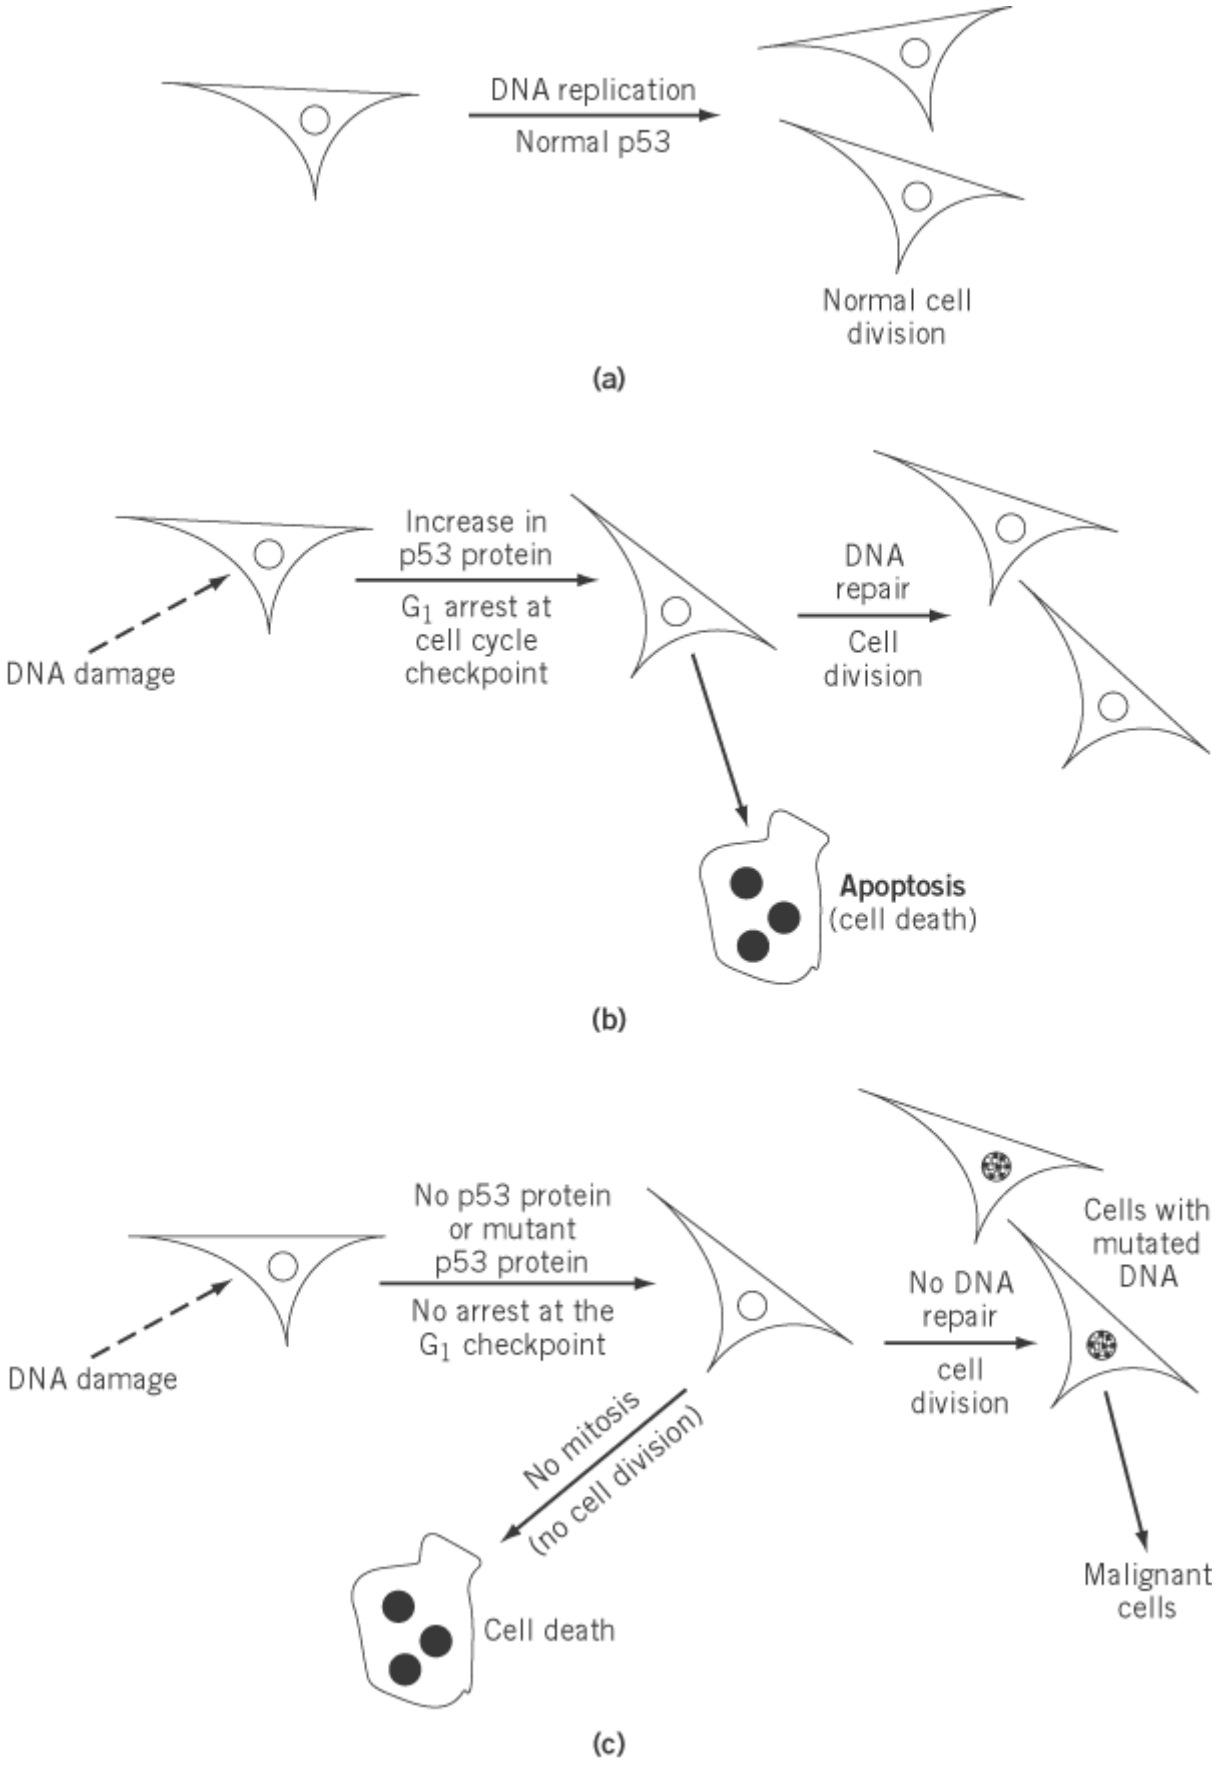
P53

p53 is a well-characterized tumor suppressor gene . It is located on human chromosome 17p13.1 and encodes a polypeptide chain of 375 amino-acid residues. Like the retinoblastoma gene, loss of p53 function results in the onset of oncogenesis (see **Oncogenes** and Neoplastic Transformation). p53 is a transcription factor that regulates the expression of **cell-cycle** regulatory proteins. The p53 protein contains an N-terminal transactivation **domain**, a central **DNA-binding** domain, and a C-terminal regulatory domain. The C-terminal domain of p53 mediates oligomerization of the protein, which is essential for its DNA-binding activity. This domain also mediates its interaction with other cellular factors that enhance the DNA-binding activity of the protein.

P53 plays a pivotal role during the execution of apoptosis (programmed cell death) pathways induced by **DNA damage** caused by agents, such as ultraviolet or ionizing radiation (Fig. 1). Current models suggest that DNA damage results in up-regulating p53 gene transcription and accumulation of this protein in the cell (1). Accumulation of p53 appears to result in the enhanced transcription of a group of genes, such as the cell cycle-dependent kinase inhibitor p21/WAF-1/cip-1, that are responsible for stalling the cell cycle in either the G_1- or G_2/M-phase. This mechanism provide the cell with valuable time to make critical repairs in its genetic material. In the event that the necessary repairs cannot be made, the p53 protein initiates a “suicidal” apoptotic program, resulting in cell death, to prevent clonal expansion of a cell with a mutated genome.

Figure 1. Proposed function of p53. (**a**) P53 is not required for normal cell division. (**b**) In response to DNA damage,

p53 levels increase and arrest the cell at the first of two "checkpoints" in the G_1-phase of the cell cycle. If all of the repairs have been made to the DNA, the cell divides normally and completes the cell cycle. However, if the cell still contains mutated or duplicated DNA sequences, it dies by a suicidal apoptotic mechanism to prevent its expansion. (**c**) In those cells that have mutated or lost p53 genes, the arrest at G_1 does not occur, and the cells that have mutated genomes proliferate and become cancerous.



Malignant cells have evolved novel strategies to destroy p53 function, and approximately 50% of human tumors contain mutations or deletions in this gene. Normal p53 protein binds to DNA and

transactivates the transcription of a distinct set of target genes. Mutated forms of p53 cannot bind DNA in this fashion, however, and therefore behave abnormally. A second mechanism by which normal p53 function is subverted in a cancerous cell is through the MDM2 protein. The MDM2 protein binds to p53, and it is amplified in many tumor cells. When these two proteins are bound, p53 cannot mediate growth arrest at the cell cycle checkpoints (as described previously), which leads to rapid clonal expansion of cells that have unstable, mutated genomes.

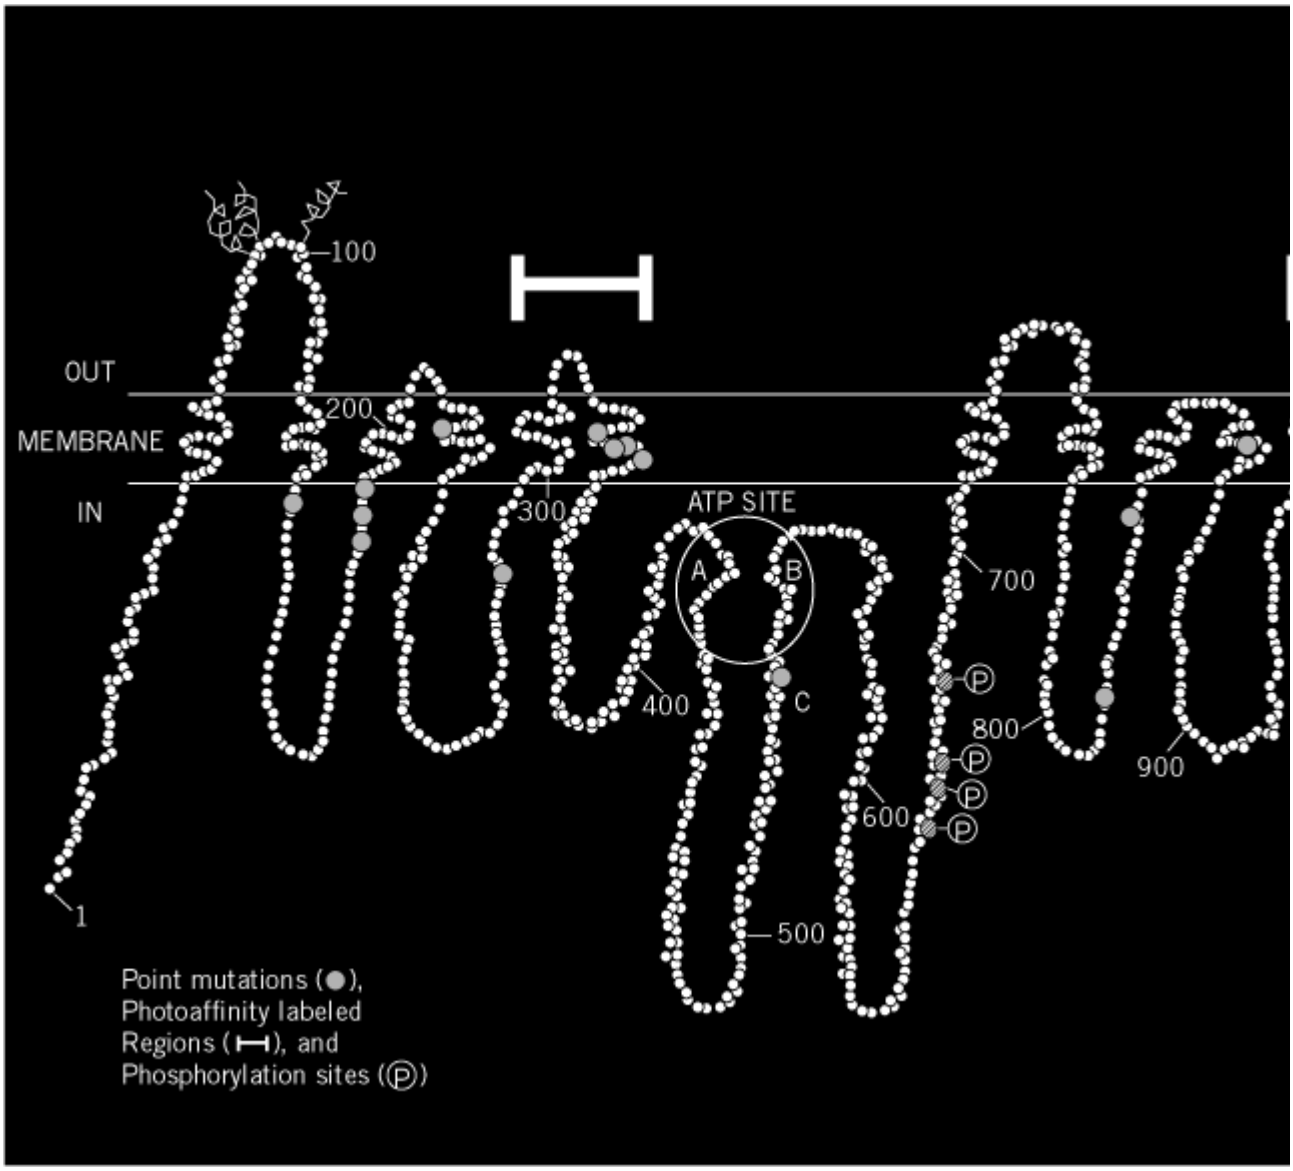
P-Glycoproteins

The best characterized form of drug resistance in human cells is due to the overexpression of P-glycoprotein (P-gp). This 170-kDa plasma membrane protein is a member of the ATP Binding Cassette (ABC) superfamily of transporter proteins; it can extrude a range of hydrophobic anticancer drugs from the cell against a concentration gradient, and thus protect the cell. Consequently, cells that overexpress P-gp show reduced intracellular concentrations of drugs and greater resistance to them (1). Molecular probes developed to identify P-gp in cancer tissues also strongly suggest that, at least in hematological malignancies, P-gp plays a significant role in multiple drug resistance (MDR) in the clinic.

The mammalian *mdr* **gene family** consists of two members in humans and three in rodents (2). Of the two human genes, *MDR*1 and *MDR*2, only *MDR*1 confers drug resistance. The sequences of the mouse *mdr1* and *mdr3* are 80% identical to the *MDR*1 human gene product, and they are also capable of conferring resistance to drugs, as are their hamster homologues, *pgp1* and *pgp2*. The human *MDR*1 gene encodes a 1280-amino acid membrane protein, P-gp. Hydropathy plots of this protein have led to a **secondary structure** model for P-gp (see Fig. 1) in which it consists of 12 putative transmembrane regions, with two **ATP-binding** domains on the cytoplasmic face of the membrane. Each half of the protein consists of six hydrophobic transmembrane putative **alpha-helices** and one ATP-binding domain; the two halves are 43% identical (3).

Figure 1. A hypothetical two-dimensional model of human P-glycoprotein and its functional domains. This model, with ATP sites (nucleotide binding domains), is based on hydropathy analysis of the amino acid sequence. The ATP sites are indicated. The N-linked glycosylation sites are indicated by wavy lines, and the known phosphorylation sites are shown a show the regions labeled with photoaffinity analogues. Filled circles represent amino acid residues in which mutations ha transport specificity. This figure is adapted from Ref. 1.



Drug resistance conferred by the human and rodent P-gp's has been extensively studied. However, there continue to be controversies and alternate models vis-à-vis the mechanism by which an extremely broad range of substrates are expelled from the cells. The most widely accepted model is that the P-gp uses ATP to power a molecular pump to remove chemotherapeutic agents from the cell (1). According to this hypothesis, chemotherapeutic agents diffuse down a concentration gradient into the cell, and the pump either acts as a "flipase" to expel them as they enter the bilayer, or the drugs are first transported from the cytosol to the membrane and subsequently pumped out from the membrane. An alternative mechanism has also been suggested in which changes in the intracellular pH and membrane potential alter the transmembrane partitioning or intracellular sequestering of the drugs (4). As these are the two principal models on which most current work is based, the evidence on which each is based will be considered briefly.

The alternative partitioning model is essentially a passive diffusion model (4). The central notion is that the drugs are sufficiently hydrophobic to cross the membrane spontaneously. The subsequent asymmetric distribution of these drugs is then a consequence of the asymmetry of the chemical potential (pH and membrane potential). It is argued that because the cytosol of tumor cells is acidic, the drugs (most of which are weak bases, with pK_a values 7.4 to 8.2) get protonated and are trapped in the cytosol. Conversely, an increased cytosolic pH would decrease the intracellular accumulation

of drugs. Experimental evidence in support of this scenario comes from a number of observations. In model systems such as phospholipid vesicles, it is possible to modulate the transmembrane distribution of some of the drugs implicated in MDR by altering the pH. The cytosolic pH is higher in tumor cells exhibiting MDR and those transfected with P-gp. Verapamil, which reverses MDR, causes a partial acidic shift in the pH of cells. The model suffers, however, from a number of shortcomings. It cannot explain how drugs that are not weak bases are effluxed. A number of cells exhibiting MDR do indeed show pH shifts in agreement with the model, but a significant number of cells do not show these changes. More importantly, even where these changes in pH do occur, they are in most instances not of a magnitude sufficient to explain the several hundred-fold increase in resistance that these cells display.

The active transport model for MDR is more attractive and based on a large body of currently available evidence (5, 6). Drug binding and photoaffinity studies show a direct interaction between P-gp and many of the substrates. The drugs stimulate the ATPase activity of P-gp in proportion to its ability to transport those drugs. Specific amino acid substitutions alter the substrate specificity of P-gp. Additionally, purified P-gp reconstituted into phospholipid vesicles is capable of drug transport, even in the absence of electrochemical gradients. MDR is a complex phenomenon, and it is conceivable that the change in electrochemical gradients may be the result of epiphenomena during the prolonged selection of cells in cytotoxic drugs. Perhaps the best prospect of resolving this issue lies in the use of transient expression systems. A **vaccinia virus**-based expression system has been developed recently that allows high-level expression of P-gp in many mammalian cells (7). The use of this system clearly excludes the pleiotropic effects associated with the use of drugs in selecting cultured cells.

Studies with both cultured cells and transient expression systems provide compelling evidence that the substrates interact directly with P-gp. Table 1lists some of the agents that interact with P-gp. This has also been demonstrated by the use of diverse substrate analogs that photoaffinity label the P-gp and yielded valuable information on the direct interaction of P-gp with its substrates: ^{125}I-labeled iodoazylazidoprazoin (IAAP), an analog of prazosin (8); ^{125}I-labeled iodomycin, an analog of daunorubicin (9); ^{3}H-labeled azidopine (10); and 6-*O*-[2-[3-(4-azido-3-[^{125}I]iodophenyl) propionamido]ethylcarbamyl] forskolin (AIPPF), an analog of forskolin (11). While the nature of these interactions is still unknown, photoaffinity experiments with these analogs and site-directed mutagenesis analysis indicate that the interaction is probably in the regions of transmembrane segments 5, 6, 11, and 12.

Table 1. List of Selected Substrates and Modulators of P-Glycoprotein

Substrates of P-glycoprotein	Agents that Reverse Multidrug Resistance
***Vinca* alkaloids**	**Calcium channel blockers**
Vinblastine	Verapamil
Vincristine	Dihydropyridines
Anthracyclines	Azidopine
Daunorubicin	Antiarrhythmics
Doxorubicin	Quinine
Epipodophyllotoxins	Quinidine
Etoposide	Antihypertensives
Teniposide	Reserpine
Antibiotics	Yohimbine

Dactinomycin	Antibiotics
Actinomycin D	Hydrophobic cephalosporins
Other cytotoxic agents	Immunosuppressants
Mytomycin	Cyclosporine A
Taxol	FK506
Topotecan	Steroid hormones
Colchicine	Progesterone
Emetine	Megestrol acetate
Gramicidin D	HIV protease inhibitors
Puromycin	Sequinavir
Valinomycin	Indinavir
	Ritonavir

The notion that the energy of ATP hydrolysis is utilized by P-gp to pump drugs actively is central to the active pump model. Consequently, the substrate-stimulated ATPase activity of P-gp has been studied in considerable detail. P-gp consists of two transmembrane segments and two ATP-binding sites. Each ATP site is comprised of three conserved regions: Walker A and Walker B motifs and a hydrophobic dodecapeptide-a signature of ABC superfamily members, also called the "C" region. ATP hydrolysis is abolished by chemical modification with *N*-ethylmaleimide or mutations in the conserved residues of the Walker A or Walker B region. Orthovanadate, which behaves as an analogue of inorganic phosphate, inhibits the ATPase by trapping Mg-ADP at the catalytic site. Mutational analysis and chemical modification have established that both sites can bind and hydrolyze ATP. Moreover, the interaction of the two sites is essential for ATP hydrolysis and drug transport. Purified P-gp catalyzes substrate-stimulated ATP hydrolysis. The protein, however, also has a basal ATPase activity in the absence of substrate, which may be due to activation by endogenous lipids or peptides. Based on current evidence, an alternating catalytic model of ATP hydrolysis proposes that, while both sites bind ATP, only one site at any given time acts as a catalytic site. The conformation of this site is presumed to prevent the other from hydrolyzing ATP (12).

1. P-glycoproteins in normal cells

The wide distribution of P-gp in normal human tissues, such as the blood–brain barrier, liver, kidney, intestine, adrenal glands, and testes, has long prompted speculation on the role of P-gp in normal cells (1, 5). There is also a more urgent need to understand the normal physiological role of P-gp. Effective inhibitors of P-gp-mediated drug transport are being developed and entering clinical trials. The safe use of these inhibitors requires that the functions of P-gp in normal physiology be understood so as to anticipate, and eventually limit, the potential side effects arising from their use. In recent years, the use of knockout mice (see Mouse) with disrupted P-gp genes provided a direct method of studying these functions.

Mice with disruptions of each of the three P-gp-encoding genes (*mdr1a*, *1b*, and *mdr2*) have been obtained (13). Under laboratory conditions, all the knockout mice are healthy, fertile, normal anatomically and histologically, and have a normal life span. The most striking result obtained with the mice homozygous for a disrupted *mdr1a* gene was the role of P-gp as an active extruder of molecules that pass the blood–brain barrier. For example, ivermectin, an excellent P-gp substrate, accumulates to levels over 100-fold higher in the brains of *mdr1a* (–/–) mice than in *mdr1a* (+/+) mice. The tolerance of *mdr1a* (–/–) mice to ivermectin was also reduced 100-fold. The results from

the double knockout mice (*mdr*1*a* + *mdr*1*b*) are particularly important because, unlike humans, mice have two functional drug-transporting genes, and only a double knockout can tell us about the untoward effects that may be expected by the use of powerful MDR reversal agents. The double knockouts have not yet been analyzed in detail, but there are no gross physiological, anatomical, or pathological abnormalities. Particularly important is the fact that gross disturbances in corticosteroid metabolism, pregnancy, and bile formation, which would reasonably be expected to occur based on earlier speculations of the function of P-gp, are absent in these mice. These studies suggest a protective role against chemical toxicity for P-gp in humans.

P-Loop

The P-loop is a fingerprint sequence that characterizes ATP- or GTP-binding proteins and is part of the nucleotide—binding motif (1). The characteristic P-loop sequence is Gly–X–X–Gly–X–Gly–Lys–Thr/Ser, where X is any residue. In the three-dimensional protein structures that have a P-loop sequence, such as adenylate kinase, the loop is located between a **b-strand** and an **a-helix** and forms

a binding site for the phosphate group of the nucleotide—hence the name P-loop. The loop wraps around the phosphate, with the glycine residues adopting conformations that are forbidden for other residues. The backbone amides and the conserved lysine residue interact with the phosphate of the nucleotide.

The P-loop fingerprint sequence is used to identify ATP- or GTP- binding proteins from their primary structure (1). It has also been used to classify a broad group of protein structures, the nucleoside triphosphate hydrolase fold (2), which has a P-loop structure within an a/b domain comprising a central b-sheet surrounded by a-helices. Different families within this classification have varying numbers of b-strands and different connectivities.

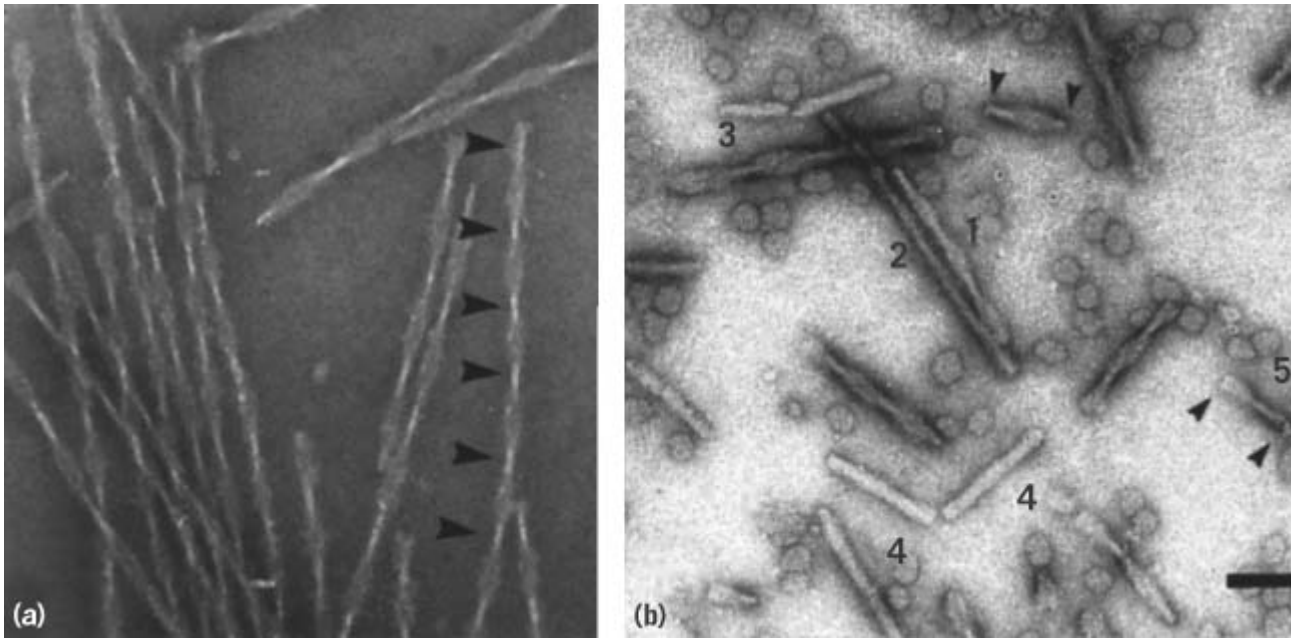
Paired Helical Filaments

Alzheimer's disease is characterized by amyloid plaques and intraneuronal inclusions or tangles in the cell body and the proximal axon and dendrites (1). The tangles are comprised of paired helical filaments (PHFs) (Fig. 1), but these bear no relationship to the neurofilament type of intermediate filaments (IFs). Indeed, PHF are composed of t(**tau protein**), a microtubule-associated protein that is hydrophilic, rich in proline, glycine, serine and threonine residues, and normally highly soluble. In the PHFs, however, the t protein is in an abnormal state of **phosphorylation**. In adult humans, t is not a single protein but a family of six variants encoded by the same **gene** generated by alternative splicing . All of the t chains have a related **domain** structure, a fundamental part of which is three or four tandem repeats, each of which is normally involved in microtubule-binding. These repeats are about 31 or 32 residues in extent and are only imperfectly preserved (2), but they have homology with other microtubule-associated proteins. The human isoforms of t vary also in their *N*-terminal regions, in that some contain an insert of 29 or 58 residues. Trojanowski and Lee (2) thus note that the largest t isoform contains 441 residues and has a 58-residue *N*-terminal insert and four tandem microtubule-binding repeats; the smallest isoform is 352 residues long and has no *N*-terminal insert and only three microtubule-binding repeats. The normal role of t *in vivo* is to stabilize the microtubules in the axon, thus facilitating microtubule-based axonal transport. t can readily be phosphorylated by the action of a variety of **kinases**; however, specific kinases acting on a serine residue in the first repeat domain cause the dissociation of t from microtubules. Although there is no evidence that any part of t adopts a regular **secondary structure**, its assembly into PHF is thought to be mediated through the repeat domains. The paired helical filaments thus formed consist of two filaments, each about 10 nm in diameter. They coil around one another with a pitch length of about 150 nm (Fig. 1). Individual t molecules have been observed in the electron microscope, where they appear as rodlike structures with lengths of about 35 nm. Proteolytic removal of the *N*-terminal region and part of the *C*-terminal region of t results in PHF with their fuzzy coats removed. Each strand in section appears to have a three-domain C-shaped structure. This also implies that the repeat domains form the core of the PHF and that the terminal ends of the t chains lie on the outer surface.

Figure 1. Electron micrographs of paired helical filaments (PHFs) from Alzheimer brains. (**a**) PHF from neurofibrillary
et al. (5), stained with 1% phosphotungstic acid. This preparation contains homogeneous long filaments that still retain tl
coat." The cross-over repeat is 75 to 80 nm, and the width varies between a minimum of about 10 nm and a maximum o
Greenberg and Davies (6). This preparation results in soluble filaments of shorter length than in (**a**) and is more heteroge
nm repeat and a width varying between 8 and 18 nm; (2) is a straight filament with width 8 nm; (3) is a twisted filament
diameter (up to 25 nm); (4) is a straight filament with a wide diameter (18 nm); (5) is a twisted rodlike particle about 80
crossover period. In many cases the particles appear to have broken apart across the filament—for example, the two rods
of (3) and the short stub to the right of it, or the two straight rods above particle (3). Bar = 100 nm. (From Wille et al. (3)
Mandelkow.)



A major problem in this field had been the difficulty in reassembling the entire t molecule *in vitro* into a structure that closely resembles native PHF, although this has now been achieved. Wille et al. (3) and Schweers et al. (4) have described the reproducible formation of PHF from recombinant t protein and from constructs containing three of the repeating domains. Their results showed that the state of phosphorylation of t was not a determinant of PHF formation, that the repeat domain in t can form antiparallel dimers cross-linked by disulfide bonds to their cysteine residues, and that PHF can be formed from these dimers. Inhibition of dimer formation resulted in no PHF formation, indicating that it might be the key initial step. Schweers et al. (4) have concluded that two residues of particular importance in t are the serine in the first repeat (residue 262 in the htau40 isoform) and the cysteine in the third repeat (residue 322 in htau40): phosphorylation of the serine residue leads to dissociation of t from the microtubules and allows other modes of aggregation to occur, whereas oxidation of the cysteine leads to dimer formation followed by PHF assembly.

Pair-rule Genes

Pair-rule genes play critical roles in the formation of the **Drosophila melanogaster** body plan, which consists of fourteen contiguous segments arranged along the anterior-posterior axis. This basic plan is established by a cascade of **segmentation gene** activities that generate spatially repeated patterns of gene expression before the completion of cellularization. Most pair-rule genes are initially expressed in patterns of seven evenly spaced stripes about four nuclei wide that represents the first evidence of a segmental body plan. The striped patterns are established by integrating crude positional cues provided by asymmetrically localized maternal factors and proteins encoded by the **gap genes**. These cues are in the form of gradients of transcription factors that interact directly with pair-rule regulatory regions, resulting in position-specific activation or repression. In several cases, pair-rule genes have been shown to contain discrete enhancers that direct the expression of single stripes of pairs of stripes. Each enhancer responds in a unique way to the asymmetric cues, and the seven stripe entire pattern represents the sum of the effects of all enhancers. Once initial stripes are established, they are refined by interactions among the pair-rule genes themselves, creating a system of overlapping patterns. This system then directs the expression of segment polarity genes in patterns of fourteen stripes about one cell wide. The fourteen stripe patterns mark cells that will form borders between segmental compartments, and, thus, establish the body plan of the mature animal.

Pair-rule genes were first identified as members of a class of zygotic recessive mutations that affect the organization of the Drosophila body plan (1). Loss of function mutants in pair-rule genes contain only seven segments, and close examination of specific defects in the body plan indicates that every other segment is missing. For example, embryos with reduced *even-skipped (eve)* gene function contain only odd-numbered segments (“even” numbered segments are “skipped”). Other pair-rule genes lack odd-numbered segments or contiguous portions of adjacent segments that overlap every other border between two segments. These mutant phenotypes suggest that the fourteen segment body plan is established by a mechanism involving genes that specify patterns of cell fate decisions with a pair-rule periodicity.

Most pair-rule genes encode proteins with well-characterized DNA-binding motifs, and, thus, function as transcription factors in Drosophila development (Table 1). Many of these genes are expressed in patterns that appear as seven or eight transverse stripes that encircle the cellularizing blastoderm (2-4). The stripes are evenly spaced along the anterior-posterior axis in positions coincident with regions of the body plan that are disrupted in loss of function mutants. This suggests that the pair-rule genes function for the most part within their domains of expression. Interstripe

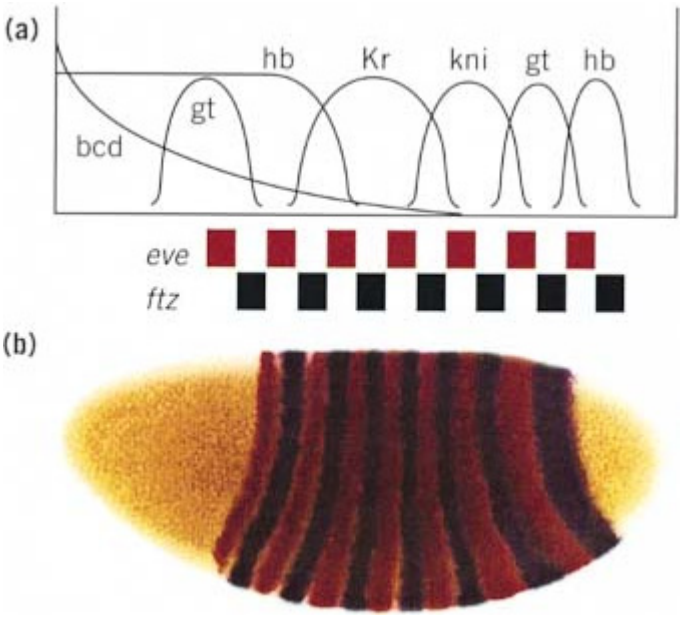
regions where the genes are not expressed are also important for normal development because near reciprocal phenotypes can be generated by ubiquitous expression of pair-rule gene products (5).

Table 1.

Pair-rule Gene:	**Protein Motif:**	**Reference:**
hairy (h)	helix-loop-helix	(68)
even-skipped (eve)	homeodomain	(4, 69)
fushi tarazu (ftz)	homeodomain	(70)
runt (run)	runt-domain	(71)
paired (prd)	homeodomain, paired domain	(72, 73)
odd-skipped (odd)	zinc finger	(74)
odd-paired (opa)	zinc finger	(75)
sloppy-paired (slp)	forkhead domain	(76)
outstretched (os)	secreted protein	(77)
odd Oz (odz)	EFG-repeats, TM tyrosine kinase	(78)
tenascin^{M}(ten^{M})	EGF-repeats, ECM protein	(79)

Since the striped patterns of the pair-rule genes represent the first evidence of a metameric body plan, at least some of them must be generated *de novo*. It has been suggested that reiterated patterns such as stripes might be generated by reaction diffusion mechanisms (6-9). This model is supported by experiments in purely chemical systems that create striped patterns as the result of self-organizing processes (10). However, genetic experiments suggest that pair-rule genes are not self-organizing but are part of a hierarchy of genes that establishes polarity and segmental patterning along the anterior-posterior axis. This hierarchy is initiated by maternal effect genes that establish polarity by depositing mRNAs into the poles of the oocyte during late stages of oogenesis (11). Immediately after fertilization, the mRNAs are translated and their protein products diffuse toward the middle of the embryo creating gradients of proteins with high concentrations at the poles. These gradients direct the zygotic transcription of the gap genes, which are expressed in one or two broad domains along the anterior-posterior axis (Fig. 1). The maternal gradients and gap gene expression domains overlap, creating different combinations and concentrations of these factors according to position along the anterior-posterior axis.

Figure 1. (**A**) Spatial relationship between stripes of expression of the pair-rule genes *even-skipped (eve)* and *fushi tarazu (ftz)* and the positions of gap protein expression domains along the anterior posterior axis of Drosophila. Anterior is to the left. The gap genes hunchback (hb), giant (gt), Kruppel (Kr) and knirps (kni) are expressed in one or two broad domains in response to maternal gradients such as bicoid (bcd) that emanate from the poles of the embryo. (B). A double in situ hybridization experiment detects *eve* (red) and *ftz* (black) mRNAs. These genes are expressed in reciprocal patterns that establish the segmental body plan.

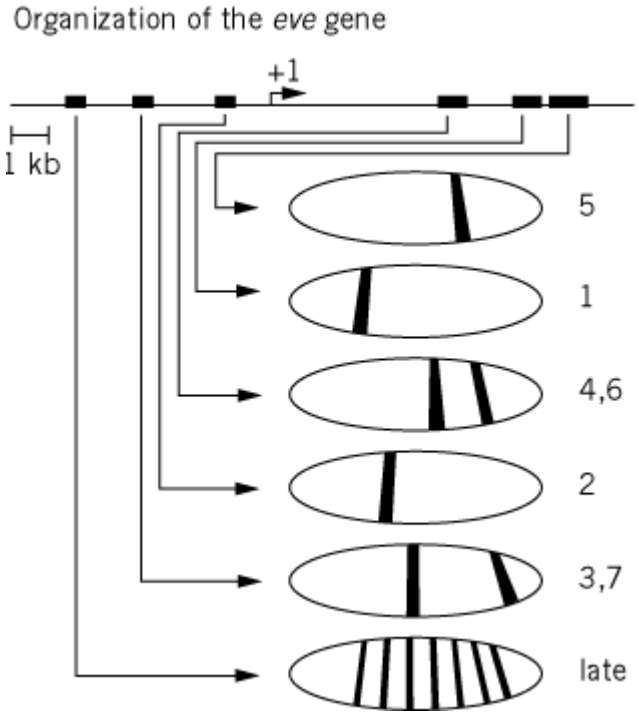


Striped patterns of the pair-rule genes are differentially disrupted in embryos lacking the functions of individual maternal effect, gap, and other pair-rule genes (12-16). These experiments are difficult to interpret, however, because removing the function of a single gene causes pattern shifts and disruptions in many other genes. Several experimental approaches have been used to unravel the mechanisms involved in pair-rule patterning. Regulatory interactions can be inferred from transgenic experiments that ubiquitously misexpress segmentation genes under the control of a heat shock inducible promoter (5, 17-20). When short heat pulses are used and the timing of pattern disruptions carefully monitored, it is possible to determine if a gene directly affects the expression of a given target or if intermediary genes must be expressed to induce the response (21, 22). Ectopic expression is also possible using enhancers that activate position-specific expression during early development (23-25). Finally, promoter truncation and P-element transformation assays (26) have identified two classes of cis-regulatory regions (enhancers) that are important for pair-rule patterning in the blastoderm. Enhancers of the first class specify the placement of individual stripes by responding primarily to gradients of maternal effect and gap proteins. Enhancers of the second class specify complete patterns of seven stripes but are active only after the first striped patterns are established. These enhancers respond to transcriptional cues provided by the pair-rule genes themselves and are thus important for mechanisms that maintain and refine initial patterns.

1. Regulatory Mechanisms That Control the Initiation of Individual Pair-Rule Stripes

An important breakthrough in understanding how pair-rule patterns are established arose from the analysis of *hairy (h)* mutations caused by translocation breakpoints in the 5' regulatory region of the gene (27). Breakpoints located near the transcription start site cause the deletion of seven segmental units (like *h* null alleles), but those further away delete only a subset of segments. Thus, the regulatory elements controlling *h* function at different positions along the anterior posterior axis are physically separable, suggesting that individual *h* stripes are independently controlled by discrete enhancers. This hypothesis was confirmed by a series of P-element transformation experiment with *h lacZ* reporter genes, which identified discrete enhancer elements that independently control the expression of single stripes or pairs of stripes (28, 29). Similar studies led to the identification of modular enhancers in the *eve* regulatory region (30-32). Interestingly, enhancers that control stripes 2, 3, and 7 are located upstream of the *eve* coding region; those that control the other four stripes are located downstream (Fig. 2).

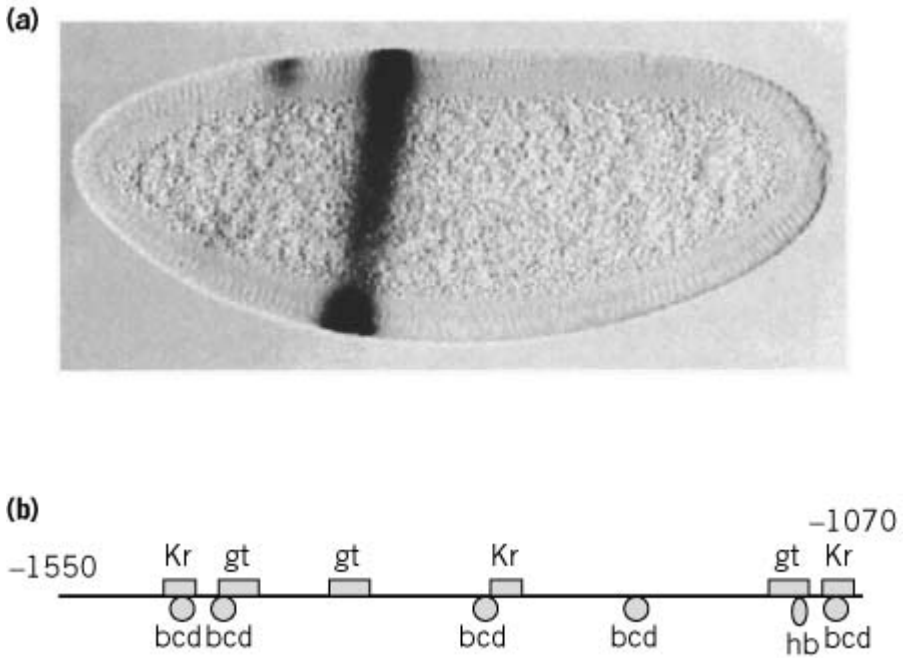
Figure 2. Stripe-specific enhancers in the *eve* locus. A map shows the positions of enhances (**rectangles**) identified by promoter truncation and P-element mediated transformation experiments. Simple patterns of one or two stripes of reporter gene expression are driven five discrete enhancers. The initial patterns of seven *eve* stripes represents the sum of the activities of these enhances. A separate enhancer directs a seven stripe pattern that appears after the initial pattern is established. This enhancer is important for maintaining and refining the pattern.



These enhancers control the positioning of individual stripes or pairs of stripes by responding to positional cues set up by the maternal effect and gap genes. The best characterized stripe enhancer controls the expression of *eve* stripe 2. Truncation analysis has narrowed this enhancer to a 480 base pair (bp) sequence that is sufficient to drive a stripe of *lacZ* reporter gene expression at the position of stripe 2(33) (Fig. 3A). Trans-acting factors involved in regulating this enhancer were identified by crossing flies containing the stripe *2-lacZ* transgenes into embryos lacking maternal and gap-gene functions. These experiments suggest that the maternal effect gene *bicoid (bcd)* and the gap gene *hunchback (hb)* are required for activation, while the gap genes *giant (gt)* and *Kruppel (kr)* are required for setting the anterior and posterior borders of the stripe (13, 34). The expression patterns of the proteins encoded by these genes are consistent with their genetically identified functions (Fig. 1A). bcd and hb completely overlap the position of stripe 2, and gt and Kr about the anterior and posterior borders, respectively. Repressive interactions between gt and Kr are important for maintaining the spacing where stripe 2 is expressed (20, 25). All four proteins contain DNA-binding domains and have been shown to bind in vitro to multiple sites in the stripe 2 enhancer (34, 35) (Fig. 3B). Most binding sites for activator proteins are located within 50 bp of repressor sites. Mutating binding sites for bcd or hb causes a reduction in expression levels, and deleting gt sites causes a dramatic expansion of the stripe response into anterior regions of the embryo (33, 36, 37). These experiments suggest that the stripe 2 enhancer functions as a binary switch that controls region-specific activation by directly responding to combinations of asymmetrically localized regulatory factors.

Figure 3. (**A**) *lac Z* reporter gene expression directed by the 480 bp *eve* stripe 2 enhancer. Genetic experiments suggest that this enhancer is activated by bicoid (bcd) and hunchback (hb). The anterior and posterior borders of this stripe are

set by repression involving the gap proteins giant (gt) and Kruppel (Kr), respectively (see Fig. 1). (**B**) Positions of binding sites for proteins that regulate this enhancer. Activator sites are shown below the line, with repressor sites above. These sites enable the enhancer to make on/off decisions based on the combinations and concentrations of these proteins in a given nucleus.



Several other stripe-specific enhancers have been characterized in detail (38-40). These analyses suggest a general model for the initial establishment of individual stripes (41). In this model, factors involved in activating individual stripes are broadly distributed, and stripe borders are set by repressive interactions mediated by gradients of gap proteins. Activations and repression events involve direct binding to closely linked sites within each enhancer. The close linkage of repressor to activator sites suggests that the repressors function over short distances to interfere with the binding or activity of activator proteins. Consistent with this hypothesis, increasing the spacing between activator and repressor sites to an interval greater than ~100 bp can prevent gap protein-mediated repression from occuring (42, 43).

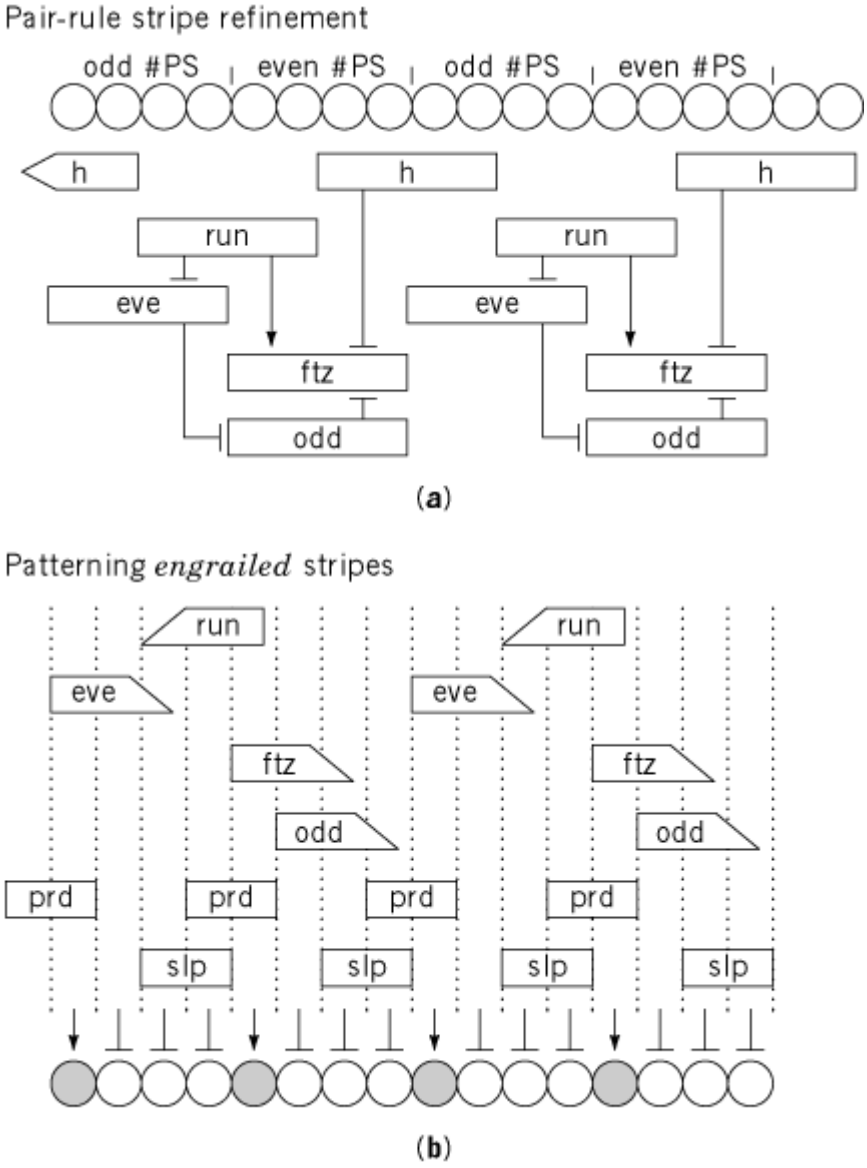
Short-range repression is also important for ensuring that individual enhancers function independently in the context of complex promoters. This has been tested by transgenic experiments using reporter genes that contain the *eve* stripe 2 enhancer and another 500 bp enhancer that regulates stripes 3 and 7 (40). In the wild-type gene, these two enhancers are separated by a ~1,700 bp sequence. When this sequence is deleted so that the enhancers are juxtaposed, there is a severe disruption of the pattern driven by the reporter gene (44). Inserting shorter spacer sequences (160 bp and 300 bp) between the enhancers restores the correct expression pattern. These results suggest that transacting factors bound to one enhancer interfere with the activity of other enhancers and that spacing between enhancers prevents such interface in the wild-type gene.

2. Regulatory Mechanisms That Maintain and Refine Striped Patterns

Because different mechanisms control the establishment of individual *eve* and *h* stripes, they are expressed in a specific temporal order while the embryo is going through the process of cellularization. Each enhancer contributes to a final pattern of seven stripes that are each approximately four to five nucleus diameters wide (Figure 4A). By the end of cellularization, these initial patterns are refined until individual stripes are two or three cells wide. During this process, some seven stripe patterns are replaced by fourteen stripes, either by splitting the initial stripes or by

activating new stripes in interstripe regions. Precise overlaps between specific genes are established so that each row of nuclei within a segmental unit contains a unique combination of pair-rule proteins. Genetic experiments suggest that positive interactions among the pair-rule genes maintain the stripes during this process, while negative interactions control spatial refinement. For example, there is a premature loss of *eve* stripes in *eve* and *paired (prd)* mutants, suggesting roles for these genes in maintaining the striped pattern (45, 46). In contrast, there is a significant posterior expansion of *eve* stripes in run mutants, suggesting that repression by *run* is important for refining the stripes (13, 31). Ubiquitous expression of *run* via heat shock causes a rapid repression of *eve*, consistent with this hypothesis (22). In contrast, *ftz* stripes are prematurely lost in *ftz* and *run* mutants, and expanded in *h* mutants, suggesting that these genes maintain and refine the *ftz* pattern (12, 47, 48).

Figure 4. (**A**) Interactions among pair-rule genes that maintain and refine initial striped patterns. Four parasegmental units are shown. **Arrows** represent positive interactions, **blunted lines** negative. The process of maintenance and refinement narrows stripes from four to five nuclei wide to two to three wide. (**B**) Spatial relationship between refined pair-rule patterns and the expression pattern of the segment polarity gene. *en*. *en* is expressed in cells that contain specific combinations of pair-rule proteins. B is colinear with A.



The molecular mechanisms involved in these interactions are only beginning to be understood. Promoter truncation and P-element transformation experiments have identified enhancers in *eve* and *ftz* that direct reporter gene expression in patterns of seven stripes (31, 32, 49). These stripes appear late in the process of cellularization, persisting through the stages of gastrulation and germ band elongation. This timing is consistent with a role for these enhancers in maintaining and refining initial striped patterns. An example is a 300 bp *eve* enhancer that directs a late pattern of seven stripes coincident with the endogenous pattern (46, 50). This enhancer is inactive in embryos that lack *eve* or *prd* function, suggesting that a combination of autoregulation and cross regulation by *prd* activates transcription of this enhancer. The enhancer contains binding sites for both proteins; mutating these sites causes a loss of expression, suggesting that direct DNA-binding is required for activation (46, 50).

Another autoregulatory element involved in pair-rule refinement is 430 bp *ftz* enhancer (AE) that contains multiple *ftz* binding sites; when these sites are mutated, the enhancer is inactivated (51). Further experiments strongly indicate that the *in vivo* activation of this enhancer involves direct binding by *ftz*. These experiments take advantage of the fact that the *ftz* protein, which contains a glutamine residue at position 50 of the homeodomain, binds *in vitro* with high affinity to a specific class of binding sites (CCATTA) (52, 53). Other homeodomain proteins, such as bed, contain lysine at this position and prefer a different sequence (GGATTA). Changing a single CCATTA binding site in the *ftz* AE to GGATTA causes a significant loss of AE activity (51). However, activity is restored in trans by a *ftz* rescue construct in which the glutamine at position 50 is replaced with a lysine residue. This experiment confirms the importance of this residue in specific DNA recognition by homeodomain proteins and demonstrates conclusively that direct DNA-binding by *ftz* is required for the activity of this enhancer.

It is worth noting, however, that the 430 bp AE represents only a small part of a complex 2,600 bp upstream element (UE) that is important for *ftz* stripe maintenance (54-57). A separate enhancer, the zebra element (ZE), also direct reporter gene expression in late cellularizing embryos (49). Together, these enhancers integrate positive inputs provided by *ftz*, the ftz-cofactor Ftz-F1, and run, as well as negative inputs mediated by h that refine the stripes from the posterior (48, 58, 59). Binding sites for gap proteins and other ubiquitously distributed factors such as tramtrack (ttk), have also been identified in these regions, but their exact roles in *fiz* pattering are still unclear (56, 60).

3. Functions of the Striped Patterns of the Pair-Rules Genes

Precise overlapping patterns of the pair-rule genes are established by the end of cellularization. These patterns comprise a coordinated system that controls the expression of the segment polarity class of segmentation genes. An example is the segment polarity gene *engrailed* (*en*), which is expressed in fourteen stripes one cell wide (61, 62). Cells that express *en* will remain segregated from neighboring cells lacking *en* throughout development. This segregation establishes a border between the anterior and posterior compartments within each parasegmental unit. Genetic and misexpression experiments suggest that odd and even-numbered stripes within the *en* pattern are regulated by different mechanisms involving pair-rule genes (21-23, 63-66) (Fig 4). Oddnumbered stripes are activated in cells that contain eve and prd protein, and the anterior and posterior borders of these stripes are set by sloppy-paired (slp) and run respectively. Even numbered stripes are activated in cells than contain ftz and prd protein, and the anterior and posterior borders of these stripes are probably set by slp and odd-skipped (odd), respectively. Very little is known, however, about the cis components that control the expression of either set of *en* stripes or any other segment polarity gene.

In summary, the pair-rule genes make up an integrated system that transduces asymmetrically localized positional information into fourteen stripe patters that establish the segmental body plan of Drosphila. Significant progress has been made in unraveling certain aspects of the mechanisms involved, but the complexity of the system suggests that a full understanding will not possible using only a reductionist approach. Recent attempts have been made to use computer modeling to integrate

individual components of the pair-rule system into a gene circuit method (67). This method has successfully generated a complete pattern of seven stripes at the *eve* position using quantitative data representing the expression patterns of the maternal and gap proteins. In the future, this type of analysis will be important for synthesizing molecular data and predicting mechanisms that can then be tested experimentally.

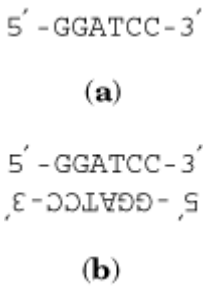
Palindrome

A palindromic word or text reads the same in both directions. Strictly speaking, this definition applies only to the same line of the text. The term “palindrome” is traditionally applied to double-stranded **DNA** (which is “two lines”) when the **nucleotide sequence** is read forward from one strand and backward from the other, complementary strand. The reading proceeds in the same direction in terms of chemical polarity, 5′ to 3′, because DNA is an antiparallel duplex. A more appropriate name for such double-stranded palindromes that is also frequently used is a “sequence or element with complementary symmetry.”

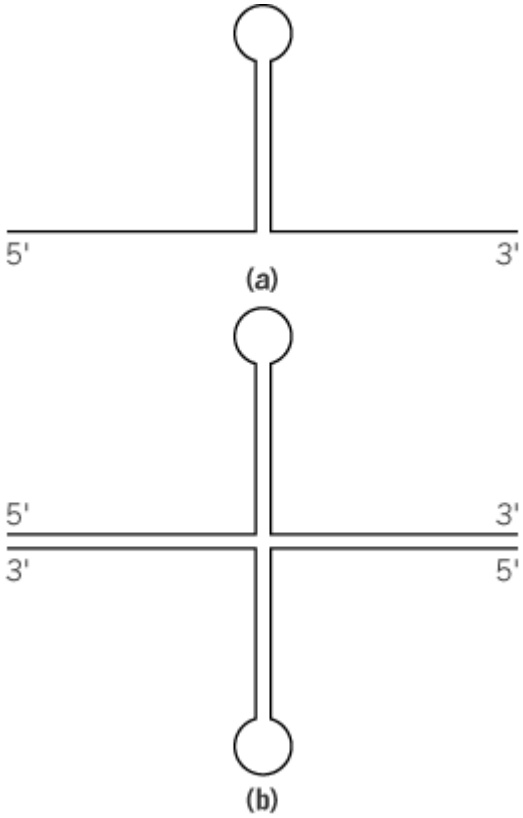
The palindromes in the double-stranded sense as discussed above are not only built of two identical sequences, but they also have complementary symmetry (twofold rotational symmetry). One example, the recognition site for the Bam HI restriction enzyme, is shown in Fig. 1. Such a peculiar structure is typical of restriction sites. It guarantees that both strands—not just one—will be cut by the enzyme, either simultaneously or after a second approach by the enzyme. Nucleotide sequences of various lengths with complementary symmetry are rather common. For example, they comprise the **consensus sequences** of many **repressor**-binding sites, or **operators** (1).

Figure 1. A nucleotide sequence with complementary symmetry (**a**) and a double-stranded palindrome (**b**)—the element with twofold rotational symmetry. Hydrogen bonds between the strands in (**b**) are not shown.



The condition of identity and complementarity of the two strands of the palindrome also makes the halves of each strand complementary to one another, with the potential for each strand to fold back on itself, forming a hairpin structure. In a palindromic DNA duplex, such hairpins could be made in both strands, so that a cruciform structure is formed (2) (see Fig. 2). The loops of the cruciforms generally could be any size and not necessarily complementary symmetric as the sequences in the stems of the cruciform. Another obvious property of palindromes is the identity of their double-stranded halves, except for their being placed in opposite polarity, like in inverted repeats, but without interruption between the repeats. (Various types of repeats are compared in the scheme presented in Tandem Repeats.) Generally speaking, any head-to-head (or tail-to-tail) fusion of identical fragments of a double-stranded DNA would generate a palindrome. For example, very long palindromes are formed in the process of gene amplification (3), in the size range of many kilobases. Complementary symmetries generally separated by rather long interruptions are characteristic of many transposable elements (4). A whole family of transposable elements also exists: the **foldback element** transposons, which are about 1 kb in size. These transposons are essentially made of inverted repeats with a very small middle loop region—almost a palindrome.

Figure 2. Schematic presentation of a hairpin structure in a single-stranded DNA or RNA (**a**) and of a cruciform structure (**b**). The double lines correspond to antiparallel complementary strands in the duplex parts of the structures.



Palindromes that read the same in both directions of *the same strand*, ie, proper (or true), palindromes also are known. These sequences possess a mirror symmetry, for example, ATGAGTA. Such elements are frequently encountered in intervening sequences, or **introns** (5), and may be interpreted as a device to avoid complementary folding of the sequence. Indeed, the absence of complementary sequence elements in the mirror-symmetric sequences of the true palindromes like AT¼TA and TG¼GT causes the sequences to be located in the single-stranded regions of the RNA secondary structure.

Another class of mirror-symmetry palindromes are the polypurine and polypyrimidine stretches in the H-form structure (6, 7). This partially triplex structure is formed in a normal DNA duplex at lowered pH or under torsional stress. The locally separated polypyrimidine strand folds back and binds to the duplex by Hoogsteen hydrogen bonds. The sequence of this third strand can be incorporated into the structure only if it is mirror-symmetric to the sequence of the polypyrimidine strand of the Watson-Crick duplex.

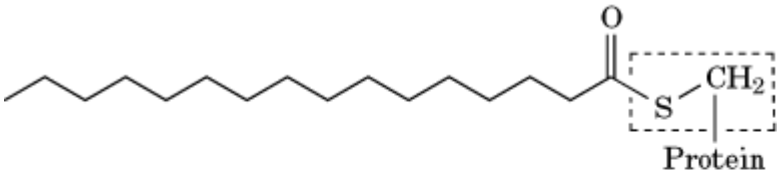
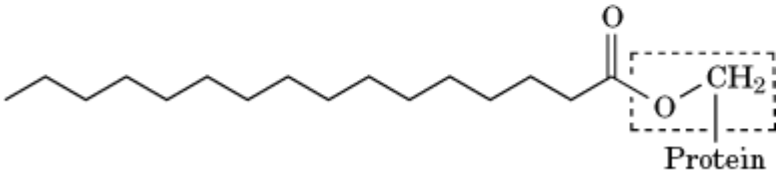
Palmitoylation

Palmitoylation is a post-translational modification process in which eukaryotic and viral proteins become ester- or thioester-linked to the 16-carbon saturated fatty acid, palmitic acid. Palmitoylation occurs on the thiol group of cysteine residues (S-palmitoylation) or on the hydroxyl group of serine and threonine residues (O-palmitoylation). S-palmitoylation (see Fig. 1) of cysteine residues close to the N- or C-terminus provides a membrane anchor for some cytosolic proteins, and is important for their correct localization within the cell. However, S-palmitoylation also occurs on polypeptide-anchored and integral membrane proteins, and its role in these proteins is uncertain.

Figure 1. Modification of a cysteine or serine residue by a palmitoyl group. An internal cysteine residue in the protein is thioester-linked to the 16-carbon saturated fatty acid, palmitic acid to give an S-palmitoyl group. Palmitic acid can also be ester-linked to serine (or threonine) residues to given an O-palmitoyl group. The cysteine and serine residue in each figure is indicated by a dotted line.



S-Palmitoyl group



O-Palmitoyl group

In contrast to the other lipid modifications of proteins (see Membrane Anchors), palmitoylation has proven relatively difficult to study. Even though palmitoylation was discovered more than 20 years ago and occurs on at least 50 different types of proteins, this process is still poorly understood at the biochemical level [for a comprehensive description of the early work in this area, see the review articles by Schmidt (1989) and Towler et al (1988)]. Apart from detailed studies on S-palmitoylation of cysteine residues in signal transduction components (eg, Src family **tyrosine kinases, G-protein** ÿ subunits, Ras proteins, etc; see below), many of the initial reports of protein palmitoylation have not been substantiated in the last decade, and their functional significance is difficult to assess. There is essentially no recent information on O-palmitoylation of proteins. The lack of recent progress in these areas is due to several reasons.

1. For most of the "palmitoylated" proteins, the evidence for palmitoylation is based solely on the incorporation of ^{3}H-labeled palmitate into cellular proteins followed by **immunoprecipitation, SDS-PAGE**, and autoradiography. It is usually possible to distinguish ester, or O-palmitoylation of serine and threonine from thioester or S-palmitoylation of cysteine in the ^{3}H-labeled proteins by selective chemical deacylation procedures. However, more detailed analysis of ^{3}H-labeled palmitoylated peptides is generally not practicable, because their unpredictable chromatographic behavior makes them very difficult to purify. This technical problem has thwarted attempts to identify the precise location of the incorporated ^{3}H-label in most of the palmitoylated proteins. Indeed, for several "palmitoylated" proteins, it was subsequently shown that the incorporated palmitate is part of a completely different structure, the GPI anchor.
2. The ^{3}H-labeled palmitate can be converted to other fatty acids before incorporation into some of the proteins. This suggests that the acyltransferase responsible for acylating the protein may be non selective and/or that different cells contain variable amounts of distinct acyltransferases with different specificities.
3. Protein S-palmitoyltransferase activities that can catalyze the transfer of a palmitoyl group from palmitoyl CoA to cysteine residues in protein or model peptide substrates have been identified in mammalian membrane fractions (1–5). Removal of the palmitoyl group by thioesterase activities has also been described. However, none of these activities has been thoroughly characterized at the molecular level, and it is difficult to tell if they are responsible for palmitoylation/depalmitoylation *in vivo*. Non enzymatic palmitoylation (autoacylation) of cysteine residues by palmitoyl CoA was also reported for several proteins, and this may account for some of the difficulties encountered in isolating and characterizing the protein S-palmitoyltransferase(s).
4. The criteria that determine which particular cysteine residue(s) in a protein will become palmitoylated are also uncertain. The presence of other lipid anchors (eg, prenyl or myristoyl groups; see below) on neighboring residues will facilitate cysteine palmitoylation presumably as

a result of transient anchoring to membranes. These observations suggest that localization of "exposed" cysteine residence close to the bilayer surface, rather than a well-defined sequence motif, is the determinant for palmitoylation (4). S-palmitoylation of cysteine residues in polypeptide-anchored and integral membrane proteins could simply be the accidental result of proximity to the bilayer surface, where palmitoyl CoA and other molecular species of acylCoA are likely to be abundant.

As a consequence of the experimental problems identified above, there is relatively little information on the functional significance of palmitoylation for most proteins. However, site-directed mutagenesis studies, on a small number of proteins that are involved in signal transduction, demonstrated that a palmitoyl group can act as a membrane anchor and may play a role in regulating distribution of proteins between membranes and the cytoplasm as well as their association with lipid rafts (6) (for a general discussion of factors that can affect membrane affinity of lipid-anchored proteins, see Membrane Anchors). In some G protein ÿ subunits and *src*-related tyrosine kinases, it has been shown that palmitoylation of cysteines near the N-terminus is dependent on prior myristoylation of the N-terminal glycine (7-9). Palmitoylation of ÿ subunits can also be increased by receptor activation (10, 11). Similarly, palmitoylation of cysteine residues near the C-terminus of some Ras proteins is dependent on prior farnesylation (see Prenylation). Because farnesyl and myristoyl groups are both relatively weak anchors, the increase in membrane affinity resulting from palmitoylation has a major effect on the amount of these proteins bound to the membrane (12, 13). Furthermore, biophysical studies indicate that addition of palmitate not only increases binding affinity, but also increases the stability of membrane anchoring by reducing the rate of dissociation from the membrane (14, 15). Palmitoylation also occurs on cysteine residues in polypeptide-anchored proteins (eg, the transferrin receptor and CD4; see Table 1) and integral proteins with multiple transmembrane regions (eg, rhodopsin and some types of **adrenergic** receptor). As expected, preventing palmitoylation of these proteins by mutagenesis of the appropriate cysteine residues has no discernible effect on membrane anchoring. However, cysteine mutagenesis often has no, or relatively subtle, effects on the functional properties of the protein either, and the biological significance of palmitoylation remains uncertain in these cases.

Table 1. Examples of Palmitoylated Proteins

G protein ÿ subunits
Src family tyrosine kinases (e.g. $p59^{fyn}$,$p56^{lck}$ etc.)
GAP-43 (neuromodulin)
H- or N-Ras proteins
G protein-coupled receptors (e.g. rhodopsin, $ÿ_{2A}$,$ÿ_2$–adrenergic receptors etc.)[a]
Transferrin receptor[a]
CD4[a]
Viral envelope proteins[a]
Myelin proteolipid protein[a, b]
Mucus glycoproteins[b]

[a] Integral or polypeptide-anchored proteins.

[b] O-palmitoylation; all other examples are S-palmitoylation.

Papain

Papain is a thiol proteinase that is obtained from the latex of the papaya tree (1) (Fig. 1). It has an essential cysteine residue at its active site that must be in the reduced form in order to be active. For this reason, it is often used in the presence of a reducing agent, such as b-mercaptoethanol or **dithiothreitol**. Papain has broad specificity and will hydrolyze peptide bonds adjacent to almost any amino acid residue, although it shows a **trypsin**-like preference for arginine and lysine residues. Its activity is optimal around pH 6. It is inactivated by reagents that react with thiol groups, such as **iodoacetate** or **iodoacetamide**, as well as silver and mercuric ions and *p*-chloromercuribenzoate.

Other inhibitors include leupeptin, a peptide aldehyde that is a general thiol proteinase inhibitor, and E-64, an epoxide compound isolated from *Aspergillus japonicus* (Fig. 2). Leupeptin also inhibits some serine proteinases, whereas E-64 is more specific and has a strong affinity only for thiol proteinases. The epoxide group of the latter forms a thioether with the active site thiol group of the enzyme. It has little reactivity for thiol groups not in active sites.

Figure 1. The three-dimensional structure of the thiol proteinase papain. Only the polypeptide backbone is indicated schematically as a ribbon, with arrows for b-strands and coils for a-helices.

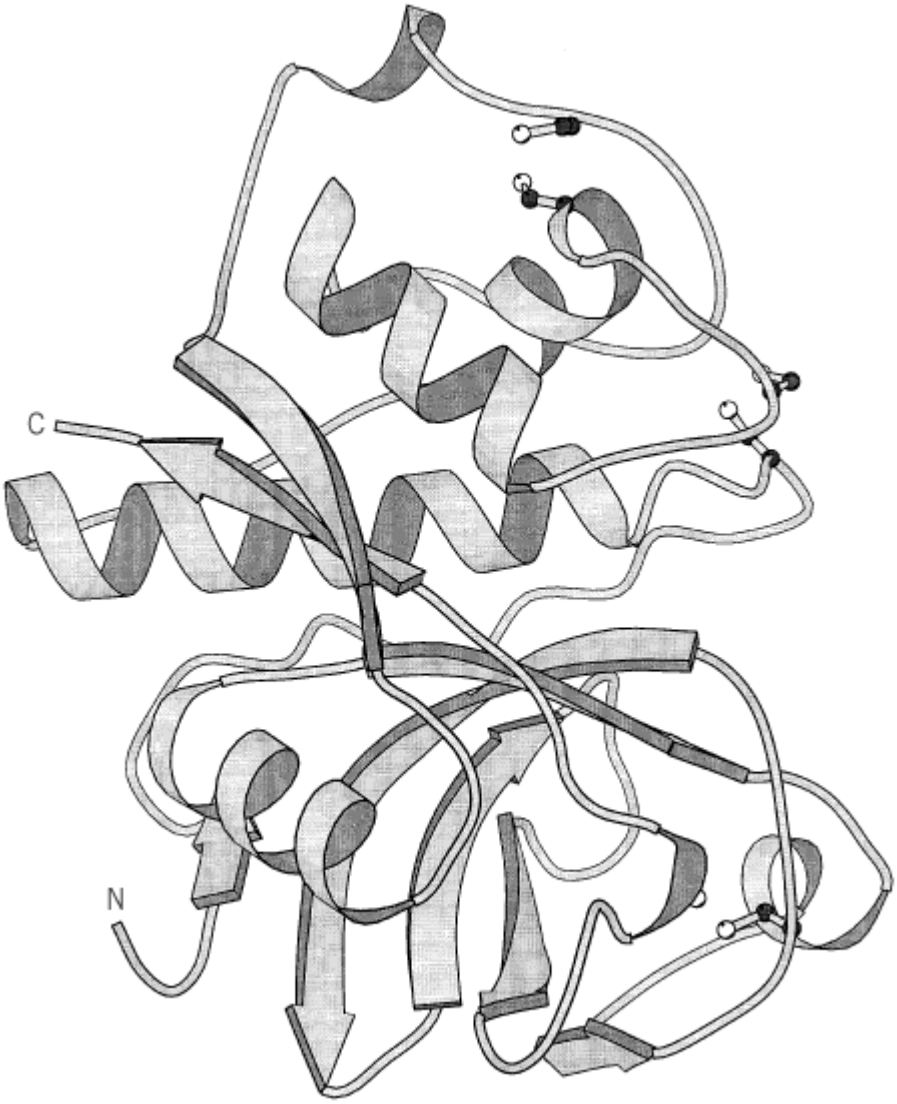

Figure 2. Chemical structure of E-64, an inhibitor of some thiol proteinases. Its chemical name is L- *trans*-epoxysuccinyl-leucylamide-(4-guanidino)-butane. The epoxy group forms a thioether linkage with the active-site thiol group of papain or cathepsin B.

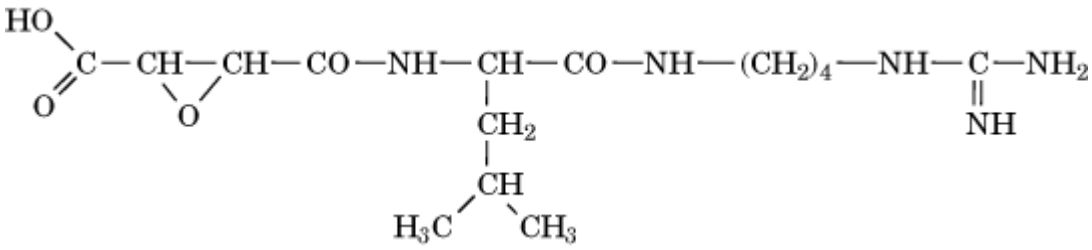

Papain is used to degrade proteins in the presence of a reducing agent (2). Because it has broad specificity, it can generate many small peptides from a large protein. For this reason, it is usually employed to digest the intermediate-sized peptides that are generated by treating a protein with a proteinase of narrow specificity such as trypsin (see Peptide Mapping). Papain is used commercially in a popular brand of meat tenderizer.

Papovavirus

The virion of the *Papovaviridae* family of **viruses** contains a double-stranded circular DNA as the genome, has an icosahedral capsid, and can induce tumors in animals. The name papovavirus is derived from papillomavirus, polyomavirus, and vacuolating virus (the old name of SV40). The particle and genome sizes of papillomaviruses are slightly greater than those of polyomaviruses, measuring 55 nm in diameter instead of 45 nm, and about 8000 base pairs in length instead of about 5000. On this basis, the papovaviruses are divided into two genera, *Polyomavirus* and *Papillomavirus*. BKV, JCV, SV40, LPV, murine polyomavirus, hamster polyomavirus, and many others are classified in the former genus.

Papillomaviruses were isolated as agents that can induce warts in many animals, including rabbits, goats, cattle, dogs, deer, and so on. Papillomaviruses were also isolated from human warts in late 1970s. Presently, more than 70 viruses are classified as human papillomavirus (HPV). A subgroup of about 20 HPVs has been associated with lesions of the anogenital tract. These HPVs can be further divided into two groups: the low-risk HPV group, including HPV 6 and HPV 11, which are associated with benign lesions, such as condyloma acuminata, and the high-risk group, including HPV16, HPV18, HPV33, and others, which are associated with malignant lesions that can progress to cancer. The high-risk HPV can efficiently immortalize human squamous epithelial cells *in vitro* and transform established rodent cells. The genes of the high-risk group HPVs that are responsible for the transforming activity are E6 and E7, which are ubiquitously conserved among all papilloma viruses, including those of animal origins. The E7 gene products of the high-risk HPVs bind and inactivate **retinoblastoma** family proteins more efficiently than those of the low-risk HPVs and HPVs associated with benign skin lesions. This binding is mediated through the amino acid sequence of the E7 gene product, which is commonly detected in the large **T antigens** of SV40 and polyomaviruses. The only E6 gene products of the high-risk groups bind to p53 protein through an

interaction with cellular E6-AP protein, and they subsequently cause the **ubiquitin**-mediated **protein degradation** of the p53 protein. The consequent deregulation of cellular growth control by E6 and E7 genes is considered to be the molecular basis of carcinogenesis by the high-risk HPVs.

Paralogous Genes

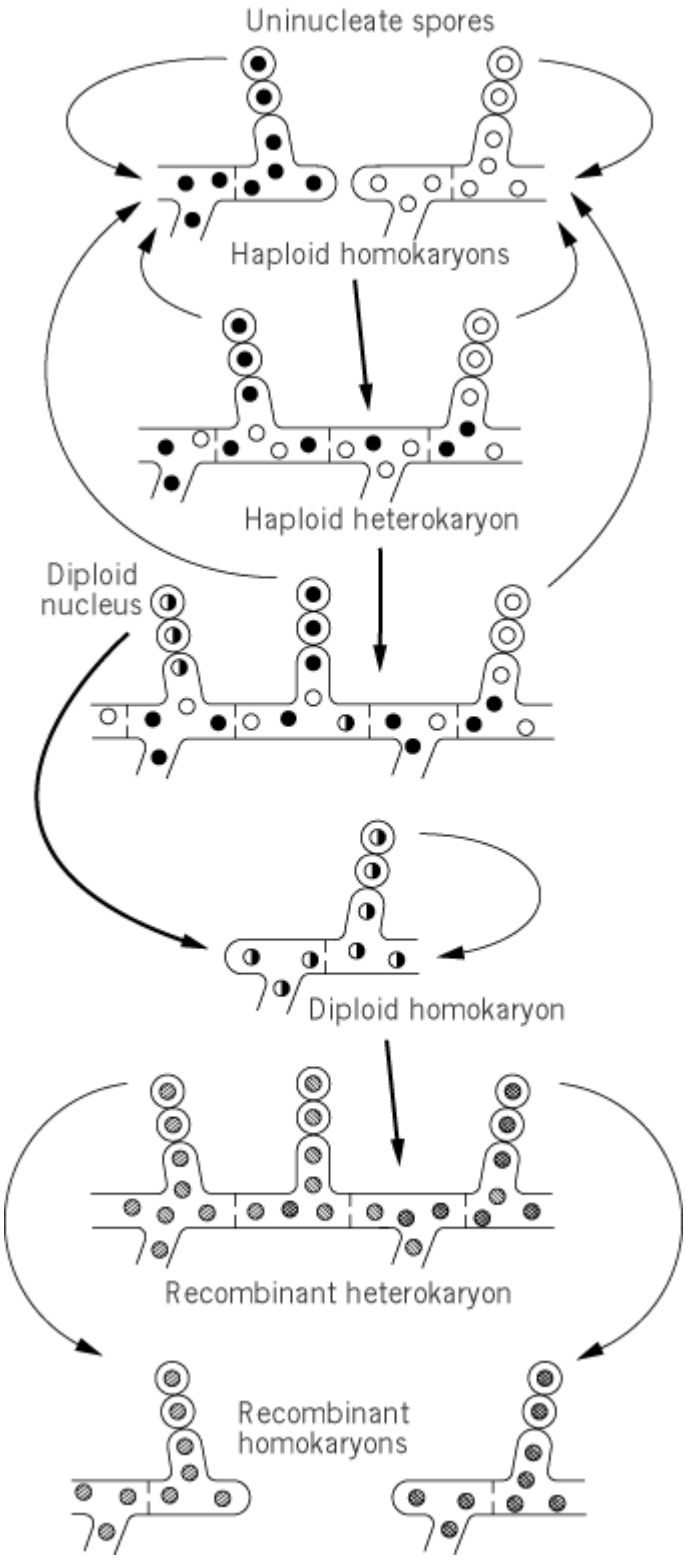
Paralogous genes are two or more **genes** that emerged during evolution from a common ancestral gene by gene duplication within a species. Usually, they acquire different functions; well-known examples are the a and b-hemoglobin polypeptide chains and that of myoglobin. They contrast with **orthologous** genes, which have not been duplicated within a species, but retain the same function and have descended during evolution by the process of speciation only. Both orthologous and paralogous genes are **homologous**, but a comparison of paralogous genes from different species will not reflect the process of species divergence. Paralogous genes are usually present as members of a **gene family** within a genome. For more details, see Orthologous Genes.

Parasexual Cycle

The parasexual cycle allows new **allele** combinations to be formed independently of whether the organism can undergo a sexual cycle and meiosis. The parasexual cycle involves the fusion of haploid nuclei, mitotic recombination, and random chromosome losses. Parasexuality was discovered by Giorgio Pontecorvo (1) and has been demonstrated with several **fungi** and, in a modified form, with cultured cells of multicellular animals.

The parasexual cycle is sketched in Fig. 1, taking a filamentous Ascomycete as a model. Fusion of haploid cells to form a heterokaryon occurs spontaneously in many fungi in a process called hyphal *anastomosis*. In many fungi this process occurs with certain pairs of strains said to be *vegetatively compatible* and fails with others. Compatibility requires the strains to carry certain combinations of alleles at certain genes. Heterokaryons can be prepared in the laboratory by fusion of protoplasts and other techniques in fungi without anastomosis and in many other organisms.

Figure 1. Parasexual cycle in filamentous *Ascomycetes* . Nuclei are followed from the haploid parents above to the haploid segregants below, through cell fusion, nuclear fusion, and haploidization. Recombinant nuclei are indicated by different shading patterns.

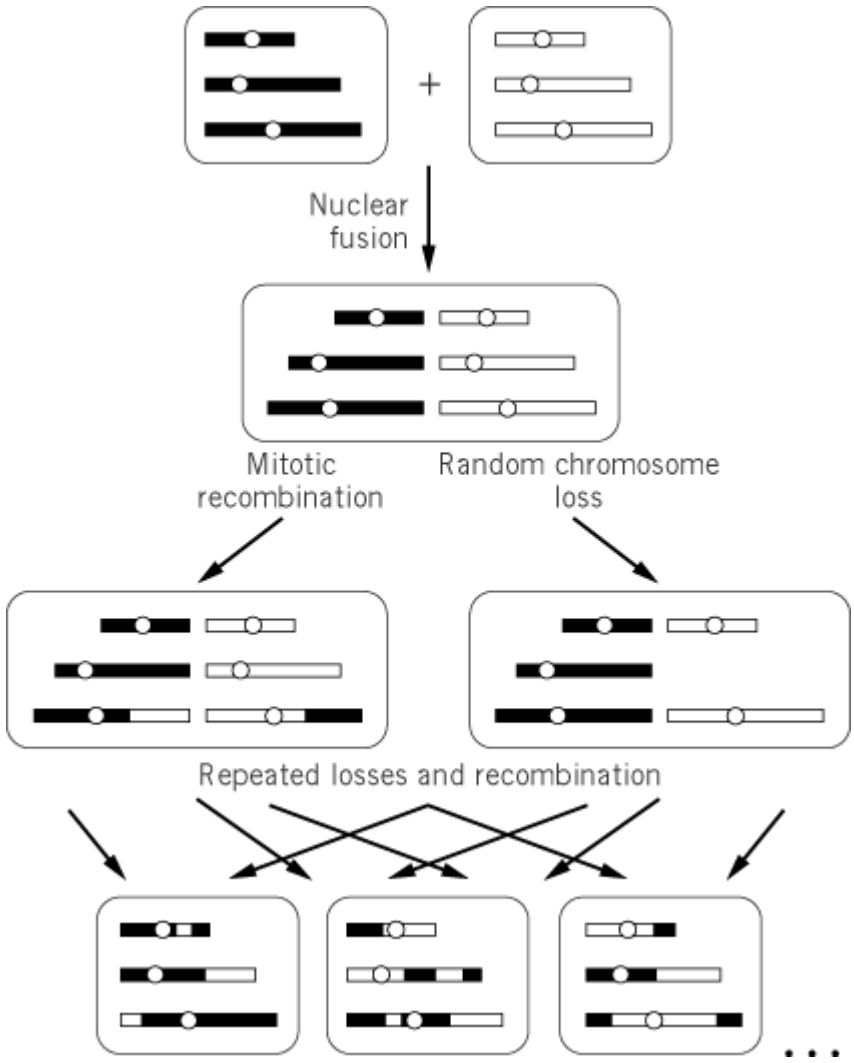


Two haploid nuclei in a heterokaryon may fuse to form a **diploid** nucleus. This process occurs seldom or not at all in vegetative heterokaryons, although it may be very quick after the fusion of gametes in the sexual cycle. Diploid cells are usually very hard to distinguish from heterokaryotic cells carrying the same genetic markers, but they may be very easily distinguished from haploid cells. In fungi in which all spores are uninucleate, colonies grown from diploid and haploid spores are distinguished easily with the help of appropriate genetic markers.

The diploid nuclei of many fungi are unstable because the loss of one chromosome of each pair is not deleterious. A slow process of haploidization takes place during mitotic growth as random chromosome losses convert the diploid into haploids through intermediates called **aneuploids**. The resulting haploid nuclei contain random combinations of the chromosomes of the two original haploid nuclei. The frequency of chromosome loss is increased by treatments with benomyl and other agents.

In addition, mitotic recombination occurs sporadically between the duplicated chromosomes of the diploid and the aneuploids and produces new combinations of their genetic markers (see Mitotic Recombination). The chromosomes in the final haploid nuclei are composed of random combinations of chromosome segments from the two original haploid nuclei (Fig. 2).

Figure 2. Chromosome events during the parasexual cycle. Three chromosomes are followed from the haploid parents above to the haploid segregants below, through diploidization, mitotic recombination, and chromosome loss.



As a result of the parasexual cycle, genes in different chromosomes exhibit recombination frequencies of 50 % while those that are close to each other in the same chromosome appear more or less tightly linked.

Fusion of cultured cells from different mammals gives rise first to heterokaryons and then to

anfiploid nuclei, which contain all the chromosomes of the original cells. Chromosome losses reduce the number of chromosomes in these anfiploids, but not necessarily at random: chromosomes of *Homo sapiens* are lost more frequently than those of *Mus musculus* from their anfiploids. The correlation between the presence or absence of certain genetic markers and certain chromosomes in the segregants is a powerful technique for the quick assignment of genes to chromosomes (see **Cell fusion**, Hybridomas).

Parsimony

Parsimony is one of the principles of phylogenetic tree reconstruction in which the phylogeny of a group of species or genes is inferred to be the branching pattern that requires the smallest number of evolutionary changes (1). Of course, no one knows whether evolution actually occurred in this way, but the parsimony principle appears to work reasonably well, particularly for comparisons of closely related species or genes, but it tends to lose its effectiveness in comparison to more remotely related species or genes. For the latter comparisons, hidden mutational changes (due to reverse mutations) have accumulated to such an extent that the parsimony principle cannot detect all changes.

The merit of using the parsimony principle is that we can infer the amino acid or **nucleotide sequences** of all the intermediate stages in the continuous lineage between the ancestor and the present species. The intermediate stages may be trustworthy, however, only when closely-related genes are compared.

Parthenogenesis

Parthenogenesis is the development of a zygote without fertilization. Parthenogenesis can be induced experimentally by a number of procedures (1), but it occurs naturally in some species. A special case of parthenogenesis is called *arrhenotoky*. This is the mechanism of sex determination in many

insects. Fertilized eggs develop into **diploid** females, while unfertilized eggs develop parthenogenetically as haploid males. Arrhenotoky occurs in the four insect orders: Hymenoptera, Homoptera, Thysanoptera, and Coleoptera (2). In the Hymenoptera, arrhenotoky is the only mechanism of sex determination.

In addition to arrhenotoky, or male haploidy, is another form of parthenogenesis, called *thelytoky*, in which the unfertilized eggs develop as females. It can be either (a) cyclic, in which parthenogenetic and bisexual generations alternate, or (b) complete (3). Cyclic parthenogenesis is found among some insects, such as aphids (4), and in a few vertebrates (5). Complete parthenogenesis has appeared many times during evolution in a variety of phyla. The phylum Rotifera appears to be entirely parthenogenetic. There are even parthenogenetic species of vertebrates (6).

In arrhenotoky, the unfertilized eggs develop as haploid males, but in thelytoky the unfertilized eggs develop as diploid females (or polyploid females in some cases). In order for the unfertilized haploid eggs to develop as diploids, the genetic content of the cells must be doubled. Because parthenogenesis has arisen independently many times during evolution, this problem has been solved in a variety of ways (7). The failure of the second meiotic division during gametogenesis results in the production of diploid eggs. Meiosis can also proceed normally, with the fusion of two of the meiotic products producing a diploid egg. In other species, haploid eggs are produced, but fusion of haploid nuclei occurs during the early cleavage stages to restore diploidy.

Partial Specific (Or Molar) Volume

The volumes of macromolecules can be determined from their structures in several different ways (see Molecular Surface, Volume; Isoleucine (Ile, I); Accessible Surface). In solution, the volumes relevant to thermodynamics are the partial specific and partial molar volumes. They involve not only the volume of the macromolecule itself, but also the contribution of solute–solvent interactions (hydration). In general, macromolecule solutions are systems with two or more components, containing the macromolecule, water, salts, etc. However, it is more convenient to reduce any such system to a binary one; one component is the solvent, ie water plus salts, etc., the other is the solute,

ie a protein. At constant temperature T and pressure P, the total volume V of such a binary solution comprising g_1 grams of solvent and g_2 grams of solute is expressed as follows:

$$V = g_1\bar{v}_1 + g_2\bar{v}_2 \quad (1)$$

where v_1 and v_2 are partial specific volumes of solvent and solute, respectively, as defined by

$$\bar{v}_1 = (\partial V/\partial g_1)_{T,P,g_2} \quad (2)$$

$$\bar{v}_2 = (\partial V/\partial g_2)_{T,P,g_1} \quad (3)$$

These parameters measure the change in volume upon adding further solvent or solute to the aqueous system.

The partial specific volume can be determined experimentally by measuring the densities of the solution containing the macromolecule (in units of g cm^{-3}) as a function of its concentration. A variety of techniques have been used for density measurements: The majority of specific volume data have been obtained by pycnometry and digital densimetry (mechanical oscillator technique). Except for some rare cases, the plot of V vs g_2, which should be a straight line according to Equation (1), is not straight, due to solute–solute interactions. This means that the specific volumes of the solvent and solute are not the same as those of the pure phases of these components in most cases, and it is necessary to measure directly the values of v_1 and v_2. In practice, the apparent specific volume f_2 is defined instead of the partial specific volume, by assuming the specific volume of solvent in the solution to be the same as that of solvent in the pure phase v_1^0:

$$V = g_1 v_1^0 + g_2\phi_2 \quad (4)$$

The relation between apparent and partial specific volumes is as follows:

$$\bar{v}_2 = \phi_2 + g_2(\partial\phi_2/\partial g_2)_{g_1} \quad (5)$$

From this equation, it is apparent that the apparent and partial specific volumes become equal at infinite dilution ($g_2 = 0$). Usually, values of v_2 and f_2 at infinite dilution (denoted as v_2^0 and f_2^0) are used as the appropriate quantity for a protein molecule in solution not involved in intermolecular interactions with other protein molecules. When the molecular weight M_2 of a solute is known, the partial and apparent molar volumes V_2 and F_2, respectively, can be calculated using the equations $V_2 = v_2M_2$ and $f_2 = f_2M_2$, respectively.

In two-component solutions, the partial specific volumes of folded proteins fall in the range of 0.69 to 0.76 cm^3 g^{-1}, depending on their structure and amino acid composition (see Table 1 of Compressibility). The majority exhibit values in the range of 0.72 to 0.75 cm^3 g^{-1}, which are within the range of the partial specific volumes of amino acids, which range from 0.559 cm^3 g^{-1} for aspartic acid to 0.819 cm^3 g^{-1} for leucine and isoleucine (Table 1). If we assume the additivity principle of volume, the apparent specific volume of a protein may be estimated from its amino acid composition by using the equation $f_2 = Sf_iw_i/Sw_i$, where f_i is the apparent specific volume of the ith amino acid residue (Table 1) and w_i its weight percent (Ref. 1). In spite of a number of simplifications and assumptions, this method yields relatively rather accurate results. It should be noted, however, that

the partial specific and apparent volumes are thermodynamic quantities, and changes in the environment (solvent composition, temperature, pressure, etc.) may cause significant changes in this volume.

Table 1. Apparent specific volumes of amino acid residues at 25°C (Ref. 1)

Residue	Apparent specific volume (cm^3g^{-1})
Ala	0.732
Arg	0.756
Asn	0.610
Asp	0.573
Cys	0.630
Gln	0.667
Glu	0.605
Gly	0.610
His	0.659
Ile	0.876
Leu	0.876
Lys	0.775
Met	0.739
Phe	0.766
Pro	0.748
Ser	0.596
Thr	0.676
Trp	0.728
Tyr	0.703
Val	0.831

The partial specific volume of a protein in water is expressed as the sum of three contributions (Ref. 2): (1) the constitutive volume estimated as the sum of van der Waals volumes of the constitutive atoms (v_c); (2) the volume of the cavities in the molecule due to imperfect atomic packing (v_{cav}); (3) the volume change due to solvation or hydration (Δv_{sol}).

$$\bar{v}_2^0 = v_c + v_{cav} + \Delta v_{sol} \qquad (6)$$

The value of Δv_{sol} is usually negative, because hydration processes involve the contraction of solvent water. The volume change on transferring a protein from one solvent to another is calculated as the difference in v_2^0 between the two solvents. The volume change due to any conformational change of protein is also defined as the difference in v_2^0. In such a case, v_c does not change, so the observed volume change is ascribed primarily to differences in v_{cav} and Δv_{sol}. In general, processes

increasing the solvent accessible surface area, eg, unfolding and dissociation into subunits, are expected to produce negative volume changes due to increased hydration. Most experimental data meet this expectation, but some data show no change or even slightly positive volume changes. It is noteworthy that the volume change observed at a given protein concentration, which is based on v_2, may differ, even in its sign, from the result obtained at infinite dilution.

The partial specific volume measured at constant molality of the added cosolvent (eg, salts or organic compounds) is a useful quantity, as it is a truly thermodynamic volume. In practice, however, the measurement of this volume often accompanies difficulties in sample preparation, and most experiments (especially in **ultracentrifugation** or **small-angle X-ray scattering**) are usually done with solutions that have been subjected to dialysis to equilibrium against the solvent. At equilibrium, the chemical potentials of diffusible components are equal on the two sides of a membrane, but the molalities of the components are not necessarily identical mainly due to Donnan effects and preferential binding of solvent components to protein. The apparent isopotential specific volume $f_2^{0\prime}$, which is measured at constant chemical potential of the solvent components (equilibrium dialysis systems), can be obtained from the density differences between the protein solutions and the dialyzate by the same procedures as used for f_2^0. However, $f_2^{0\prime}$ is not a partial quantity in the thermodynamic sense, since the molalities of the diffusible components are not held constant, but this specific volume is operationally very useful because it reflects preferential protein–solvent interactions. In a two-component system or a dilute buffer system where Donnan effects and/or preferential solvent interactions are absent, f_2^0 and $f_2^{0\prime}$ should be identical. In the presence of high concentration of a third component, however, large differences between these two specific volumes occur, as is shown in Table 2. The difference between f_2^0 and $f_2^{0\prime}$ was derived theoretically by Casassa and Eisenberg (3):

$$\phi_2^0 - \phi_2^{0\prime} = (\xi_1 1/d_0 - \bar{v}_1) = \xi_3(1/d_0 - \bar{v}_3) \tag{7}$$

where v_1 and v_3 are partial specific volumes of components 1 (water) and 3 (cosolvent), respectively; x_1 and x_3 represent preferential interaction parameters in terms of the number of grams of component 1 (or 3) that must be added per gram of component 2 to maintain components 1 and 3 at constant chemical potential. Then, the values x_1 and x_3 can be calculated with two specific volumes f_2^0 and $f_2^{0\prime}$, which are usually measured by digital densimetry within an accuracy of $\pm 0.002 cm^3 g^{-1}$ at isomolal and isopotential conditions of solvent components (Ref. 4). Positive values of x_3 or negative x_1 indicate the preferential binding of component 3 to protein; the opposite, negative x_3 or positive x_1, indicates that water interacts more favorably with the protein, ie, there is preferential hydration (Fig. 1). Whether preferential binding or preferential hydration occurs depends on the affinity of the cosolvent for the protein. As seen in Table 2, preferential hydration is observed for cosolvents having a potential ability to stabilize and **crystallize** proteins, whereas preferential binding occurs with **denaturants**. Thermodynamic properties such as solubility (phase separation), stability, and chemical equilibrium are subject to preferential solvent interaction, because it is directly linked to the chemical potential of the protein.

Figure 1. Schematic illustration of solvent component distributions in mixed solvents. (**a**) Preferential binding: Cosolvent (additive) is present in the solvation shell of protein at a greater local concentration than in the bulk solvent. (**b**) Preferential hydration: Exclusion of cosolvent from the protein surface results in enrichment of water in the solvation shell. [Taken from G. C. Na and S. N. Timasheff (5).]

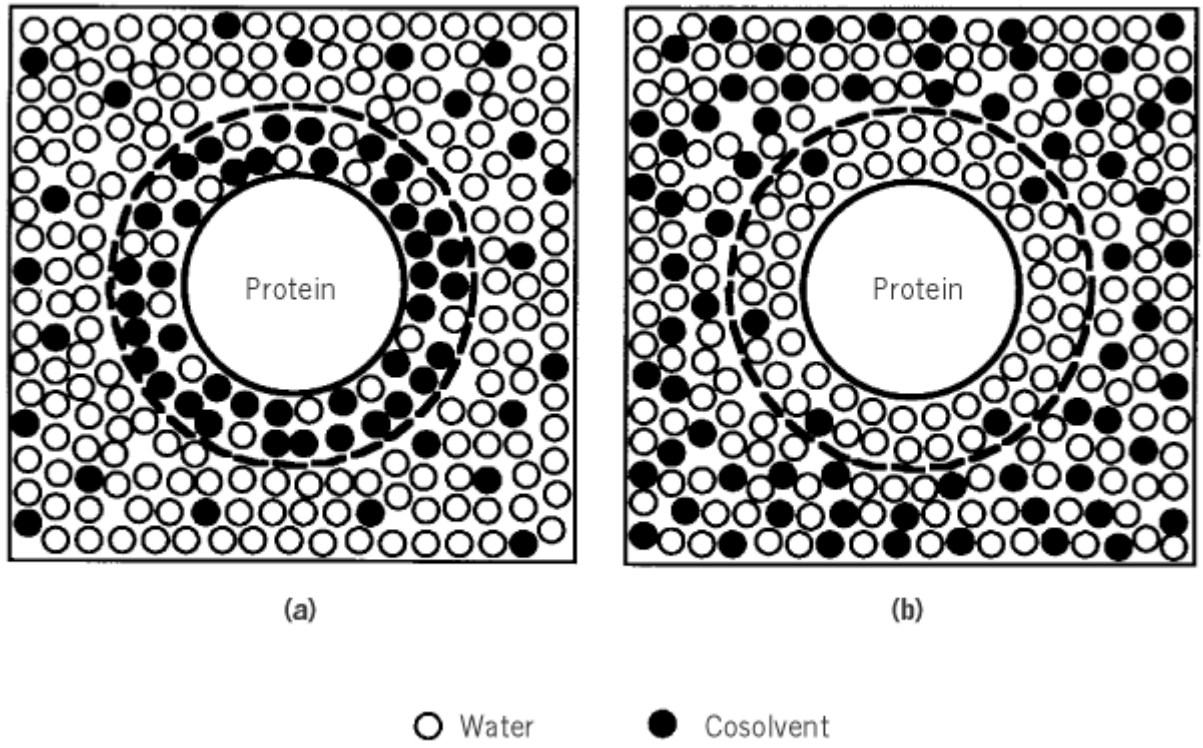

Table 2. Apparent specific volumes of proteins and DNA at constant molality and constant chemical potential of various cosolvents (Ref. 6)

Solvent	Temperature (° C)	f_2^0 (cm^3 g^{-1})	$f_2^{0\prime}$ (cm^3 g^{-1})	x_3 (g^{-1})
	Chymotrypsinogen A			
30% glycerol, 10 *mM* HCl	20	0.727	0.745	–0.123
1 *M* sucrose, 1 *mM* HCl	20	0.736	0.773	–0.138
10% PEG1000, pH 3	20	0.732	0.743	–0.07
6 *M* GdmCl	20	0.729	0.712	0.15
8 *M* urea	20	0.730	0.720	0.08
Bovine serum albumin				
1 *M* Na_2SO_4, pH 5.6	20	0.735	0.788	–0.074
2 *M* glucose,pH 6	20	0.727	0.750	
30% glycerol	25	0.729	0.744	–0.101
30% sorbitol	25	0.738	0.761	–0.092

20% propylene glycol, pH 2	25	0.740	0.726	0.211
1 *M* GdmCl	20	0.735	0.729	0.025
6 *M* GdmCl	20	0.717	0.724	0.06
DNA (calf thymus)				
0.20 *M* NaCl (NaDNA)	25	0.503	0.540	
0.20 *M* CsCl (CsDNA)	25	0.446	0.503	

The specific volumes f_2^0 and $f_2^{0\prime}$ of nucleic acids are very small (around 0.5 cm ^{3} g^{-1}) and remarkably influenced by solvent composition (especially salt concentration) because they are polyelectrolytes with high charge densities (Table 2).

Particle Electrophoresis

As a result of the rising interest of molecular biologists in cells and **organelles**, the analytical separation and the preparative fractionation of those species by electrophoresis becomes increasingly important. Their large size makes gel electrophoresis difficult, as gels with very large pores are required. Specialized electronic devices for their separation on an analytical scale have been developed (1). Common capillary zone electrophoresis instrumentation has also been applied to particles up to 10 μm in diameter (2). Effective resolution of particles on the basis of differences in their size and shape, using solutions of polymers of various types and molecular weights for **molecular sieving**, is possible (3), but the selection of the appropriate polymer is arbitrary at present. The resolving power is best when the particle diameter is less than the effective pore size (or "screening length") of the polymer network in solution, and the separation of different particles is due to a differential occupation of available spaces in the network. By contrast, resolution is poor when the particle diameter exceeds that pore size, and separation is then due to a differential displacement of the network by the particle.

On preparative scales, separations in free solutions are compatible with available instrumentation, such as free-flow electrophoresis apparatus (4) or automated gel electrophoresis apparatus in its preparative mode in conjunction with polymer solutions is feasible (5). In both analytical and preparative electrophoresis, sedimentation of the particles becomes an impediment to electrophoretic resolution only when the particle size surpasses about 8 μm in diameter (2). In those applications, electrophoretic separations in a microgravity environment are feasible (6).

Partition Coefficient

A molecule's *partition coefficient* is the equilibrium constant for its transfer between two phases that are immiscible (eg, water and cyclohexane). This equilibrium constant is measured by analyzing both phases after equilibrium has been achieved by stirring or shaking, and then dividing the molar concentration in the first phase by the molar concentration in the second. To avoid (or detect) the occurrence of aggregation (eg, formation of dimers) in either phase, the experiment must be carried out at a series of concentrations and the results extrapolated to infinite dilution. Aggregation in either phase is signaled by a tendency of the apparent equilibrium constant to increase in favor of one phase, that in which aggregation is greatest, as the total concentration of solute increases. Such partition coefficients depend on the particular temperature at which they were measured and are used in determining hydrophobicity. See also Transfer Free Energy.

Parvalbumin

Parvalbumin binds calcium with high affinity and appears to be involved in buffering of intracellular Ca^{2+} signals. It is a small protein (10–12 kDa) that is present in muscle, brain, kidney, testis, and adipose tissue. The various parvalbumin proteins can be classified into two evolutionarily distinct groups: the a-lineage and the b-lineage. Both types of proteins have, however, similar structures and

functions. Parvalbumins are members of the EF-Hand Motif family of calcium-binding proteins.

1. Biological Function

Parvalbumin was first identified in skeletal muscle cells, and its function is best understood in these cells. For muscle cells to relax after a stimulus, the Ca^{2+} signal must be quenched by **active transport** of the Ca^{2+} ions into the sarcoplasmic reticulum. Parvalbumin has been implicated in skeletal muscle relaxation after a single twitch, as well as after a tetanic (continuous) contraction, and it may facilitate Ca^{2+} translocation in the sarcoplasm. There is still some controversy, however, over whether parvalbumin can exchange Ca^{2+} and Mg^{2+} ions fast enough to be involved in relaxation after a single twitch.

The function of parvalbumin in other cell types is less clear. It may act as a Ca^{2+} buffer to protect cells from damage due to calcium overload, particularly in the nervous system. It may also play an indirect role in Ca^{2+} signal transduction by affecting the nature of the incoming signal. For instance, it could modulate how quickly the signal builds, or how long the signal lasts. Parvalbumin may also be involved in cell growth and the cell cycle.

Oncomodulin is a b-lineage parvalbumin of particular interest, because it is found in abundance in certain cancer cells. It is normally found only in the preimplantation embryo and in the placenta. The function of this protein is completely unknown. However, its expression is cell cycle-dependent, and oncomodulin antisense oligonucleotides inhibit cell growth when injected into chemically transformed fibroblasts.

2. Ion-Binding Properties

Parvalbumin's two functional EF-hands will bind either Ca^{2+} or Mg^{2+} ions. Two main types of metal-binding loops are found in parvalbumins. The most common is the Ca^{2+}/Mg^{2+} "mixed" binding loop. These sites bind Ca^{2+} with high affinity ($K_{Ca} = 10^7$ to $10^9 M^{-1}$), and Mg^{2+} with moderate affinity ($K_{Mg} = 10^3 10^5 M^{-1}$) (1). Binding is competitive, and at basal physiological ion concentrations ($[Ca^{2+}] = 1 - 10 \times 10^{-8} M$;$[Mg^{2+}] = 1 \times 10^{-3} M$), mixed sites are occupied by Mg^{2+}. Exchange between bound Ca^{2+} and Mg^{2+} is slow (2, 3). The second type of binding loop is the Ca^{2+}-specific loop. The Ca^{2+} affinity of these sites is lower than in mixed sites ($K_{Ca} = 10^5 - 10^7 M^{-1}$), and the Mg^{2+} affinity is significantly reduced ($K_{Mg} = 10^1 - 10^2 M^{-1}$) (4). These sites are metal-free under basal physiological conditions, and can therefore bind Ca^{2+} quickly. Oncomodulin is the only member of the parvalbumin subfamily that has a Ca^{2+}-specific site paired with a mixed site.

3. Structure

Parvalbumins are the only known members of the EF-hand family with three such motifs (a prototypical functional domain is composed of only two). However, the *N*-terminal EF-hand of parvalbumin does not bind Ca^{2+} and is therefore considered to be a nonfunctional ancestral site. The protein is largely helical, with six *alpha*-**helices**, labeled A through F. The functional calcium-binding loops occur between helices C and D and between helices E and F. The loop between helices A and B is shorter than the functional loops (10 residues rather than 12), and as mentioned above, does not bind metal ions.

Parvalbumin was the first EF-hand protein whose high resolution three-dimensional structure was determined (5). To date, all the known parvalbumin structures have metal bound. Structures of parvalbumin bound to both Ca^{2+} and Mg^{2+} are available (6-13). The overall structure of the protein

is very similar irrespective of which ion is bound. The two a-helices flanking each functional binding loop (the C/D pair and the E/F pair) are nearly perpendicular to each other, while the A and B helices, which flank the non-functional binding site, are nearly antiparallel (Fig. 1). However, there are some differences between the binding loops with bound Ca^{2+} and those occupied by Mg^{2+}, particularly in the position of the highly conserved glutamic acid residue that is the final residue of the binding loop. In parvalbumin and all other EF-hand calcium-binding proteins studied to date, this glutamic acid is a bidentate calcium ligand. In the Mg^{2+}-bound parvalbumin structures, this glutamic acid is a monodentate ligand (14). This difference reflects the preference of the Mg^{2+} ion for six ligands, whereas the Ca^{2+} ion can accommodate seven or even eight ligands. The apo structure is of questionable physiological importance, since almost all parvalbumin binding loops are occupied by Mg^{2+} under basal physiological conditions. NMR studies indicate, however, that apo-parvalbumin has a structure very similar to that seen for the ion-bound states (15). This is consistent with its proposed role as a calcium buffer, which requires high Ca^{2+} affinity but not the conformational change associated with the transduction of a calcium signal into a mechanical or metabolic response (see Calmodulin).

Figure 1. Ribbon representation of $(Ca^{2+})_2$-parvalbumin using the coordinates of 1PVA (7).

Pathogenesis In Fungi

1. Pathogenesis and Virulence

To understand how a given organism is able to infect its host, it is important to determine which aspect(s) of the biology of the fungus differs from nonpathogenic **fungi**. According to Bulmer and Fromtling, “Pathogenicity is the capacity of an organism to damage, ie, to produce disease in another animal or plant” (1). This property is the result of a direct interaction between the pathogen and the host. In many ways, pathogenicity and virulence are very broadly defined terms. If one considers all the possible gene products required for growth on or within a host, those that contribute to disease symptoms and host-range specificity, and those that govern their regulation, then we may be considering hundreds (or thousands) of potential components. Furthermore, the ability of an organism to adapt quickly to new environmental challenges is itself likely to be an effective virulence mechanism, in that it enables the pathogen to take advantage of new opportunities.

One of the most cited examples of virulence in the fungal world is the ability to switch morphological forms. While some fungi are pathogenic as yeast or conidial forms [eg, *Histoplasma capsulatum*, *Coccidioides immitis*, and *Blastomyces dermatitidis*, and Coccidioides immitis (2-4)], numerous correlations between hyphal growth and pathogenicity have been cited for many of the fungal pathogens. In fact, mutants incapable of switching to hyphal growth are often revealed as nonpathogenic *cpg-1* deletions in *C. parasitica* (5), deletions of *fuz7* in *U. maydis* (6), or *cph1/efg1* homozygous deletions in *C. albicans* (7). The ability to switch morphological forms is referred to as dimorphism and is governed by a number of external factors including nitrogen, pH, temperature, and intracellular biochemical pathways (eg, level of cAMP) (8). Similarly, correlations between a strain's ability to myceliate and its virulence (defined by the LD50, lethal dose to obtain 50% killing of the host) have also been cited as strong virulence factors.

Pathogen-produced products which contribute in some way to either the establishment or continuation of the disease process have also been cited as virulence factors. Historically, secretion of degradative enzymes such as elastase and certain proteinases (9, 10) have been cited as potential virulence factors using a variety of methods to correlate disease progression with levels of expression. *Paracoccidioides brasiliensis* has been shown to alter its level of virulence with the production of a-1,3 glucan, suggesting that this polymer may act as a protective layer (11). Genes

that contribute to adherence of the fungus to its host have also been regarded as virulence factors (12). Numerous genetic mutations or strain isolates have been analyzed in *in vivo* experiments to identify underlying gene products causing changes in pathogenicity. In fungus–plant interactions, the pathogen may produce a substance that specifically detoxifies plant-secreted antifungal compounds. For example, *G. graminis* deletion mutants have been generated that are relatively resistant to the production of avenacin by oat roots but retain full pathogenicity to wheat, which does not synthesize saponins (13); isolates of *Nectria haematococca* are similarly able to detoxify the pea phytoalexin, pisatin, using a cytochrome P450 mechanism (14). Furthermore, the biosynthetic pathway leading to melanin production in *M. grisea* correlates with altered virulence in this fungus; strains with reduced melanin content are less virulent (15). In some instances, these factors are reported to increase the pathogen's ability to penetrate host tissue (as in the case of melanin or proteinase production), while in others they may simply contribute to the overall fitness of the organism *in vivo*. For example, some auxotrophies are known to decrease virulence *in vivo* but play little or no role *in vitro*. Mutations in the *URA3* and *ADE2* genes *of C.albicans* and *C. neoformans* attenuate virulence *in vivo* (16, 17).

Alternatively, pathogen-induced factors that result in direct attacks upon the host are also known. The best-characterized system of host-selective toxin production by a plant fungus is in *Cochliobolus*. Different species of this genus are known to produce plant-specific toxins: T-toxin, HC-toxin, and victorin, of which only HC-toxin production has been deleted and shown to be nonpathogenic on maize (reviewed in Ref. 18).

One area in which there is sparse molecular information, but a great deal of inferential information, is in the interactions between the host immune system and pathogen. Research directed toward understanding the role of the unique polysaccharide capsule of *Cryptococcus neoformans* pathogenicity has uncovered a large difference in ability to phagocytose capsulized versus acapsular *C. neoformans* mutants *in vitro*, although it is not yet clear whether the ability to engulf a cell correlates with killing (4). Additionally, macrophages appear to recognize and engulf wild-type, single, and double mutants of the MAPK pathway in *C. albicans* equally well; however, only wild-type strains were able to switch morphologies, adding further support that dimorphism plays a significant role in virulence in this organism (7). It is tempting to speculate that in the *chs3 C. albicans* cell wall mutant, prolonged survival *in vivo* (19) had more to do with a change in its interaction with the host immune system than with any other factor. If, in fact, the host defense system plays a more significant role in disease progression than has been realized, it will be interesting to determine whether other factors such as increased lipid content cited as a virulence factors in strains of *Coccidioides immitis*, *Histoplasma capsulatum*, and *Blastomyces dermatidtidis* (1, 20) is a result of an alteration in the interaction rather than a simple defense on the part of the fungus.

2. Signal Transduction and Pathogenesis

Signal transduction pathways play an important role in cellular biology of all eukaryotic organisms, including fungi. The ability of a pathogen to receive signals from its environment and transmit those signals intracellularly to alter development or entire biochemical pathways so as best to take advantage of those changes has been recognized as a significant partner in pathogenesis of the organism. Some of the pathways have been carefully worked out in *S. cerevisiae* and *S. pombe* with regard to cell cycle, filamentation, stress, and the pheromone response. It appears that the molecules required to relay a signal from the external environment to the appropriate transcription factors within the nuclei of many of the filamentous fungi are highly **homologous** to those described in other organisms. Some of the molecules have been identified and isolated on the basis of sequence homology, and some by complementation or the use of similar screens. While the precise targets of many of these molecules have yet to be discovered, it is becoming clearer that many of the pathways in yeast are similarly conserved in more distantly related organisms.

Virulence and signal transduction pathways are inescapably intertwined in the biology of fungi and

their pathogens. In the filamentous fungi, signal transduction pathways have been identified that regulate conidiation in *A. nidulans*, virulence in *C. albicans*, *C. parasitica*, *U. maydis*, and *M. grisea*, and mating. While only a few of the components have been identified in the filamentous fungi to date, there is much anticipation that most, if not all, of the players will eventually be isolated and characterized. Although their exact developmental pathways may be very different in the different fungi, it is important to keep in mind the similarities in order to appreciate the conservation of function across the biological world.

2.1. MAP Kinase Pathway

Signal transduction involves the activation of a receptor molecule at the surface of a cell, which transmits the signal inward toward associated proteins at the cytoplasmic interface of the plasma membrane. Changes in these proteins are relayed via a small number of known pathways (either by a cascade of kinases or by the release of a second messenger) which in turn activate a number of protein targets, some of which are themselves transcriptional activators. Subsequent alterations in transcription of whole sets of genes then reprogram the cell's "transcriptome," resulting in a particular cellular response to the initial signal. That signal may be any of a number of ligands that tells the cell something about its external environment: for example, nutritional availability, osmolarity, presence of compatible mating partners, or light. In one common pathway observed in all eukaryotes, a heterotrimeric G protein activates a mitogen-activated protein (MAP) kinase module that results in the further activation of target proteins, among which is a transcription factor. In some cells, multiple MAPK signaling pathways can be operating simultaneously, altering the organisms' transcriptome moment-by-moment. A MAP kinase pathway influence on pathogenicity has been shown for the corn smut, *U. maydis*, in which tumor production and completion of the sexual cycle is dependent upon successful compatible mating (21). Appressorium formation and pathogenic growth of *M. grisea in planta* also require a functional MAP kinase pathway (22). Because the components of these pathways are so highly conserved, one of the central questions that remains unanswered is how specificity is achieved and how that affects the pathogenicity of the organism.

2.2. Cyclic AMP Pathway

A second common pathway that impinges upon pathogenicity is the **cyclic AMP**-mediated pathway, which begins with a plasma membrane-bound sensor molecule (none of which has been isolated for the filamentous fungi to date). Upon a functional receptor–ligand interaction, a signal is transmitted to a heterotrimeric GTP-binding protein, possibly through a conformational change in the membrane protein. Second messenger cyclic AMP (cAMP) is produced via adenylate cyclase, which then alters the activity of cAMP-dependent protein kinase A (PKA) by binding to the regulatory subunit of PKA. This releases the catalytic subunits, which continue to activate downstream targets (including transcriptional regulatory proteins). A few components of this pathway have been identified in filamentous fungi. Mutants in *uac1* (adenylyl cyclase of *U. maydis*) have been shown to be defective in their ability to switch from budding to filamentous growth and, in addition, were unable to cause disease on corn (reviewed in (Ref. 23); disruption of *adr1* (catalytic subunit of PKA) results in nonpathogenesis, whereas inactivation of *uka1* (catalytic subunit of PKA) has apparently little or no effect on growth, morphology, or pathogenesis. Disruption of *fil1* (G a subunit of *U. hordei*) also prevented normal hyphal to bud switching. Interestingly, of the four G a proteins isolated from *U. maydis*, only one, *gpa3*, was shown to be required for pathogenic development, disruption of the other three displayed no obvious phenotypes. Furthermore, *gpa3* mutants were unable to respond to pheromone signals strongly suggesting that a single G a subunit may play a role in multiple signaling pathways as has been observed in *S. cerevisiae* and *C. albicans*. Mutants disrupted in the catalytic subunit of *M. grisea* (CPKA) were shown to be unable to form appressoria on artificial surfaces, and they were also unable to infect rice unless exogenous cAMP was administered (23).

3. Strategies to Identify Virulence Factors

3.1. Gene Knockouts

There are a number of molecular genetic strategies that can be used to identify genes responsible for virulence in fungi (24). In a standard experiment, genetic manipulations are made such that the

chromosomal copy of a gene in question is replaced by a marker gene. The growth rate of these strains is then compared to the normal wild-type strain and subsequently tested *in vivo* to determine the potential of the "knocked out" gene to cause disease. Proper controls wherein additional strains containing the chromosomal knockout, but also harboring a transformant carrying a reintroduced wild-type copy of the gene, or a heterozygote, is also compared in order to ensure that the effects observed are due to the presence or absence of a specific gene product and not some other underlying mechanism. It should be noted that due to the frequency of ectopic integration in filamentous fungi, these experiments may be difficult to interpret. They have been successfully accomplished for a wide variety of gene products in the dimorphic fungus, *C. albicans*. Using a modification of the original "ura-blaster" strategy (25), it is possible to knockout both copies of a given gene in this perpetually diploid organism. Genes in cell wall biosynthesis, signal transduction, and so on, have been identified as involved in virulence in such tests (7, 19, 26). This directed approach to virulence determination has also been successful in *A. nidulans* (27), *Gaeumannomyces graminis* (28), and *C. neoformans* (29), for example. Using this approach, there is the potential to knockout each gene in a given organism systematically and test its pathogenicity *in vivo*.

3.2. Gene Transfer

Virulence factors have also be identified by their ability to confer pathogenicity upon a related species or strain that was previously nonpathogenic. In this approach, a library is constructed and **transformed** into a nonpathogenic organism. Entire library pools are then tested for changes in related events that are suspected of having influences upon pathogenicity (adherence properties, toxin production, proteinase activity, etc.), and gene products are identified and then retested for altered virulence relative to the starting host strain. This approach has been successful in identifying a gene conferring adhesion properties from *C. albicans* to *S. cerevisiae* (30).

3.3. Gene Expression

This may be accomplished in a number of different ways. First is to identify all the genes expressed during an infection, by complementary DNA cloning, differential display analysis, or **promoter** fusions (all of which are technically feasible in the filamentous fungi). The idea is that crucial genes will be expressed sometime during or immediately prior to the establishment of an infection. These genes can then be further screened for their relative virulence, using a variety of knockout or deletion strategies. The *MPG1* protein of *M. grisea* was identified using this approach and confirmed to be important in the development of fungal infection structures (31). Using a differential display approach, two genes from *U. maydis* (32) and six genes from *C. albicans* have been identified that are differentially induced during infection (33). As additional sequence information becomes available for other fungal genomes, the use of promoter fusions as an approach will probably become somewhat more popular. Following the initial identification of clones that express a viable fusion, sequence analysis of the upstream sequences directing the fusion will reveal the target gene. Conceivably, libraries in which the reporter proteins are cell surface-directed will aid in the initial identification of positive clones in this type of model.

One of the most fascinating stories concerning pathogenicity in fungal biology involves the interaction between *Cryphonectria parasitica* (chestnut blight fungus) and a hypovirus. These fungi, which have wreaked havoc upon the chestnut forests of the northeastern United States, are themselves infection-susceptible to a hypovirus that causes reduced virulence of the fungus for the plant. In addition to causing reduced virulence, the virus causes altered colony morphology, reduced pigmentation, and attenuated asexual sporulation. Differential display analysis of infected and noninfected isolates identified a candidate gene *cpg1* whose reduced expression in infected isolates appears to correlate with pathogenicity (5, 34).

3.4. Mutagenesis

Historically, a traditional genetic approach in which mutations are isolated and further characterized has proven beneficial in the understanding of pathogenesis of fungi. One of the more recent strategies to understanding and defining virulence factors has come from alterations in **transposon**-mediated mutagenesis screens. Transposons are relatively small fragments of DNA that are capable

of recombining nearly randomly into different sites within a single genome. They have proven useful in creating large number of "insertional" mutant libraries that are easily screened for loss-of-function phenotypes. Unfortunately, filamentous fungi appear to lack such elements. However, **restriction enzyme**-mediated integration (REMI) has been be used to create insertional mutants in filamentous fungi. Pathogenicity genes were identified for *Cochliobolus heterostrophus* (35) and *Ustilago maydis* (36) using REMI.

A modification of this method, called signature-tagged mutagenesis, has been used successfully in bacterial pathogenesis to identify insertional mutants that fail to grow *in vivo* (37). In this method, every insertional mutant carries with it a unique oligomer tag that identifies it from all other mutants. After inoculating a mouse and recovering all survivors, DNA is prepared and hybridized to colony blots of the original input pool. Mutants not surviving are not recovered and are easily identified as not hybridizing. Identification of the gene into which the insertional tag is present is performed by sequencing. One of the only drawbacks to this approach is that only nonessential genes may be recovered, because insertions into essential genes are by definition lethal in culture.

3.5. Use of *In Vivo* Models

The use of *in vivo* models to confirm the role of individual genes in virulence is an important aspect of this field. However, it is important to recognize the difference between the establishment of infection and the maintenance of infection. Both are clearly critical factors in host–pathogen interactions, yet targets should be different, although somewhat overlapping. Second, the size of the inoculum is a well-established variable in disease models. It is not inconceivable that certain genes play a more significant role at low inocula in certain situations while other virulence genes are turned on under conditions of high inocula. Third, it is important to remember that virulence is multifactorial and results from a balance between the pathogen and the host immune system. Comparisons across different fungal backgrounds or different host models should proceed with caution.

4. Fungal Virulence Genes as Targets for Antifungal Therapy

It is not enough that we understand how an organism grows and develops or produces disease; it is our ability to use this information to circumvent those processes that will enable humanity to control and manage diseases produced by microorganisms. Compounds aimed toward inhibiting functions of known or suspected virulence factors have been suggested as likely to be effective in reducing disease even though many of the virulence genes identified to date have been shown to be nonessential for growth and reproduction of the organism *in vitro*. A compound directed toward such a nonessential target would likely prevent fungal growth until the compound were either removed or inactivated. In clinical situations where prophylaxis is appropriate, a reduction in anticipated fungal pathogen virulence could significantly influence patient outcome, because the disease will not likely gain entry initially. Unfortunately, the human patient population that often contracts fungal diseases is often immune-debilitated. From an agricultural view, inhibition of fungal growth will probably lead to increased production over a short season, making these attractive targets. Another consideration in choosing virulence factors as targets is the likelihood that parallel and/or redundant pathways may exist. With all of this, virulence genes are important to consider as potential drug targets.

Strategies for identifying fungal virulence genes as potential targets for drug development and/or vaccine development include many of the cloning strategies identified earlier. Furthermore, the use of bioinformatics and genome sequencing has made it possible to identify potential candidates based on previously known motifs, which may then be tested *in vivo* for specific disease.

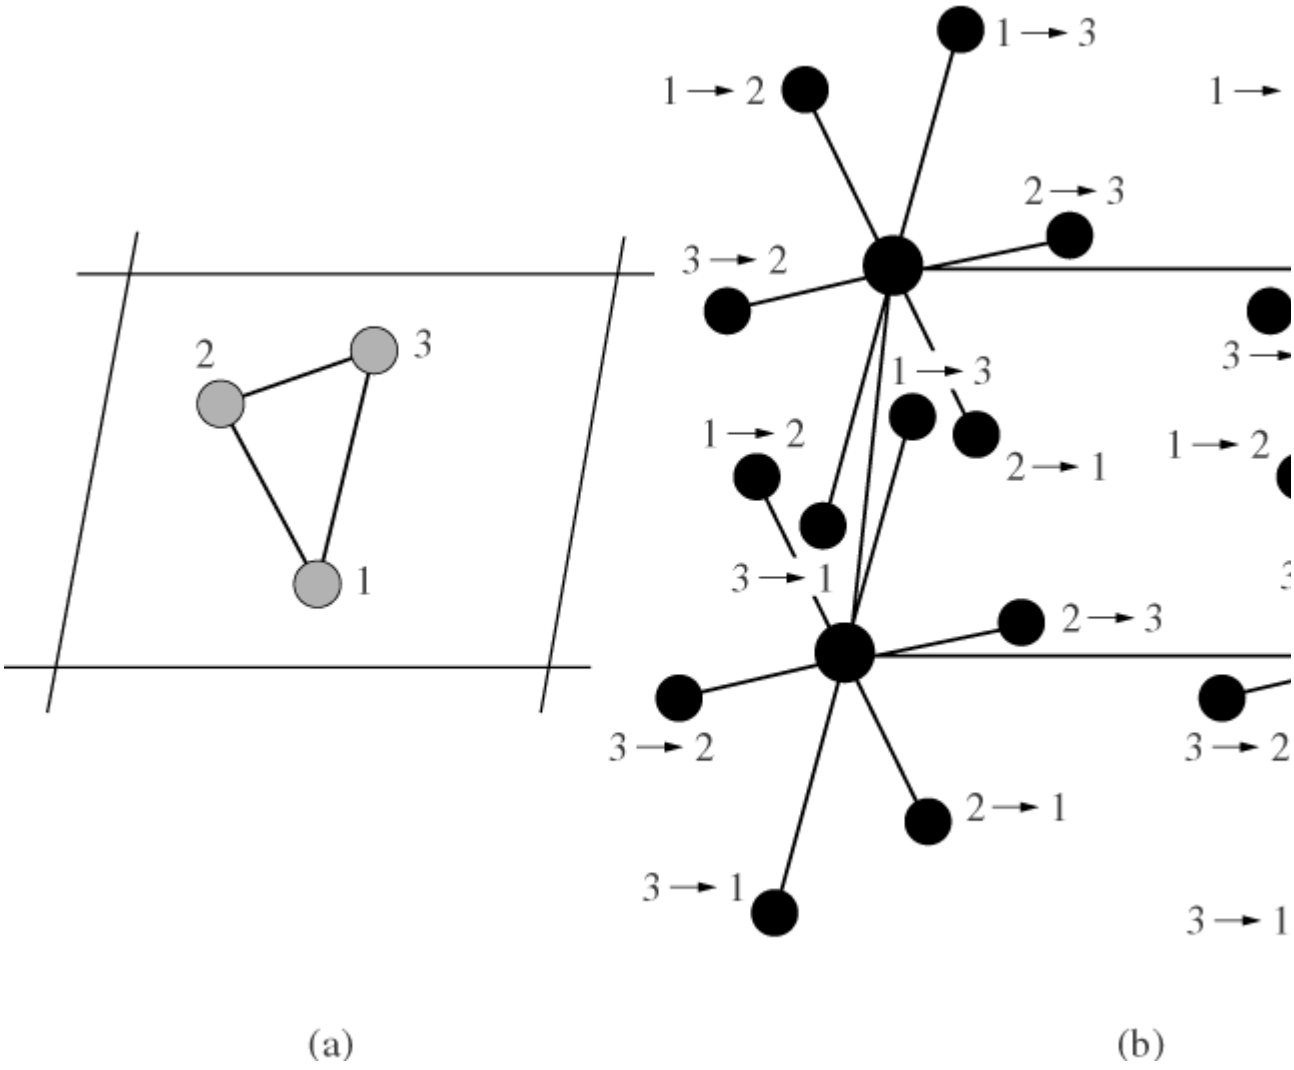
Patterson Map

Patterson maps give structural information in X-ray crystallography, even if the phases of the reflections are not known (see Phase Problem). With the Patterson function $P(uvw)$, a vector map is calculated. Vectors between atoms in the real structure show up as vectors from the origin to maxima in the Patterson map (Fig. 1). The size and shape of the unit cell in this map is identical to the crystal unit cell.

$$P(uvw) = \frac{1}{V}\sum_{h}\sum_{k}\sum_{\ell}|F(hk\ell)|^2\cos[2\pi(hu+kv+\ell w)] \qquad (1)$$

where u, v, and w are relative coordinates in the Patterson cell; h, k, and ℓ are the indices of the reflections; V is the volume of the unit cell; and $|F(hk\ell|$ is the amplitude of the structure factor of reflection $h\ k\ \ell$. Calculation of the Patterson function from Eq. 1 does not require knowledge of the phase angles of the reflections and can always be calculated from the experimental diffraction data because, apart from correction factors, $|F(hk\ell| = \sqrt{I(hk\ell)}$, where $I(\ h\ k\ \ell)$ is the intensity of reflection $hk\ell$.

Figure 1. Example of a simple Patterson map. (**a**) A two-dimensional unit cell with three atoms. (**b**) The corresponding l



For very simple chemical compounds, it is possible to derive the real structure from the Patterson map. A protein Patterson map, however, has too many overlapping vectors to extract any structural information. However, protein Patterson maps are extremely useful for understanding the molecular replacement technique. They are also employed in isomorphous replacement to locate the attached heavy atoms. The difference between the amplitudes of the reflections for the native and heavy atom crystals is used in the calculation, to produce a difference Patterson map. Such a map should result only from the heavy atoms, and it should be interpretable because the number of heavy atoms attached is usually small and therefore they form a simple structure.

Pax Genes

Nine *Pax* genes have been isolated from vertebrates through sequence homology to a region in the

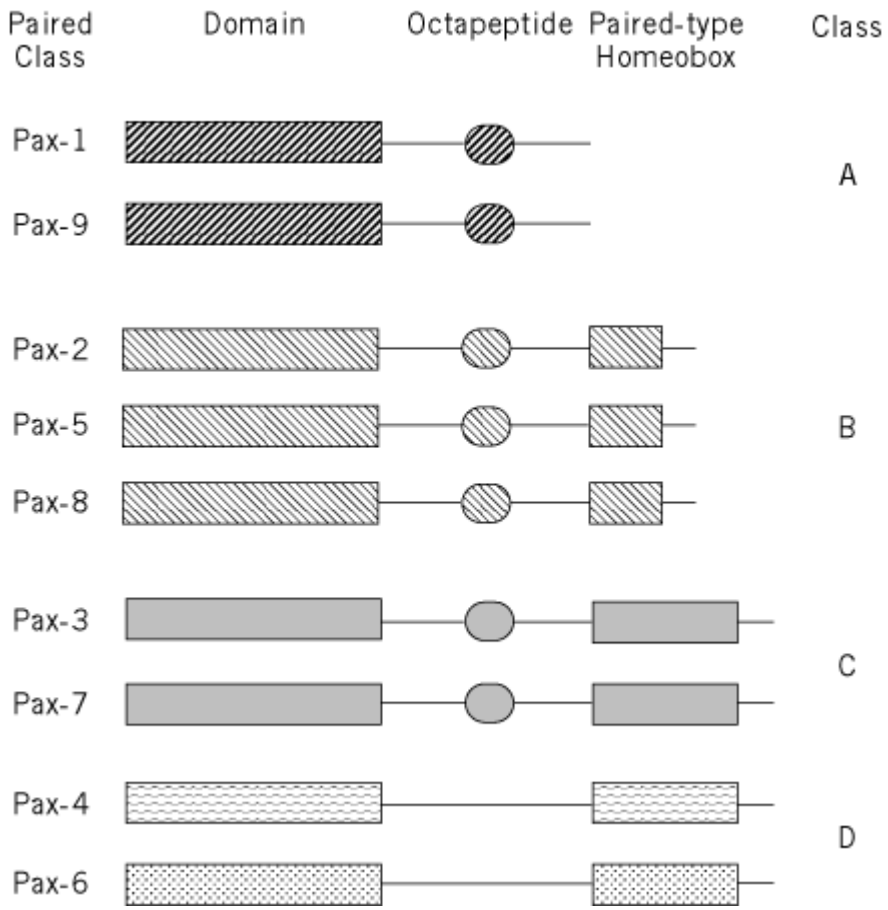
Drosophila gene *paired*, which codes for a DNA-binding domain. This domain of 126–amino acid residues is highly conserved and is known as the paired box. Binding sites for Pax proteins have been found in the promoter regions of genes coding for proteins as functionally varied as other transcription factors, crystallins, receptors, peptide hormones and cell adhesion proteins. Pax proteins are expressed in restricted regions during embryonic development. *Pax* genes are subdivided on the basis of the presence or absence of two further conserved sequences: a paired-type homeobox and an octapeptide coding region. These two elements are keys to the functions of Pax proteins in morphogenetic processes such as (*1*) establishing the competence of tissues to particular developmental fates, (*2*) commitment of cells to particular developmental fates, and (*3*) the regionalization of the central nervous system.

1. Structure and Biological Activity of Pax Proteins

1.1. Classes of Pax Proteins

Pax proteins are transcription factors that regulate gene transcription. All nine Pax proteins contain the paired box, a 136–amino acid residue domain with DNA-binding activity that has sequence similarity to a domain found in the Drosophila protein paired (1) (reviewed in (2)). As well as the paired domain, Pax proteins also carry one or both of two other conserved domains: the paired-type homeodomain and the octapeptide sequence (Fig. 1). The presence or absence of these other conserved domains is used to classify the Pax proteins into four groups (Fig. 1). The amino acid sequences of the conserved domains of a Pax protein are more similar to those within the same class than those of Pax proteins from different classes (2). Additionally, when Pax proteins have similar functions in a particular tissue, for example, Pax-2 and Pax-5 in the midbrain/hindbrain boundary, they come from the same class.

Figure 1. Structure of Pax proteins.



1.2. Pax Proteins Directly Regulate the Expression of Many Types of Genes

Pax proteins regulate gene transcription by binding to specific sequences in the enhancer and promoter regions upstream of the coding regions of the gene. This results in the initiation of transcription, which subsequently results in synthesis of the protein. The paired domain binds to DNA; thus it is crucial to the regulation of gene transcription. Changes to the amino acid sequence in this domain have been demonstrated to strongly inhibit the binding of Pax proteins to DNA (3, 4). The specific DNA sequences that Pax proteins bind to have been found in the enhancer and promoter regions of genes coding for many classes of proteins (Table 1). This is consistent with the fact that Pax genes are important regulators of organogenesis in the developing embryo.

Table 1. Types of Genes Whose Expression is Regulated by Pax Proteins

Gene	Protein Product Type	Promoter Bound By	Reference
En1	Transcription Factor	Pax-2, -5, -8	(105)
En2	Transcription Factor	Pax-2, -5, -8	(105)
Crystallin (various)	Structural Protein	Pax-6	(106)
NCAM	Cell Adhesion Protein	Pax-6	(107)
Insulin	Peptide Hormone	Pax-6	(69)
Glucagon	Peptide Hormone	Pax-6	(69)
Thyroperoxidase	Enzyme	Pax-8	(84)
IgH	Immunoglobulin Subunit	Pax-5	(79)
CD19	Receptor	Pax-5	(76)
c-met	Receptor	Pax-3	(60)
p53	Cell Cycle/Apoptosis Regulator	Pax-5	(101)

2. Developing Processes Regulated by Pax Proteins

Pax proteins have important roles in regulating organogenesis, commitment of cells to particular developmental pathways, and the regionalization of the central nervous system (summarized in Table 2). Pax proteins help mediate these processes by (*1*) enabling an embryonic tissue to be competent to interact with other tissues, (*2*) conferring regional identity to a portion of tissue that later forms a new embryonic structure, (*3*) commitment of cells to a lineage with a particular differentiation pathway, (*4*) maintenance of boundaries between regions that have separate developmental fates, and (*5*) conferring multipotency to precursor cells (15, 85).

Table 2. Summary of *Pax* Gene Null Mutation Phenotypes in Mouse Mutants

Gene	Null Mutation	Heterozygous Phenotype	Homozygous Phenotype	Reference
Pax-1	*Undulated*, targeted	Normal	Hypoplasia of vertebral bodies and discs	(52, 53, 108)
Pax-2	*KrD*, targeted	Small kidneys, optic coloboma	No kidneys or genital tracts, optic oloboma	(25, 26, 28, 30, 31, 73)
Pax-3	Splotch	Lack of pigmentation	No limb muscle, neural crest derivatives absent or hypoplasic, persistent truncus arteriosus	(45, 58-64, 22-60, 62, 109, 110)
Pax-4	Targeted	Normal		(66)
Pax-5	Targeted	Normal	No B cells, cerebellar and inferior colliculous defects	(26-28, 77, 78)
Pax-6	*Sey, Sey*^{Neu}, *rSey*, targeted	Microphthalmia, corneal and iris defects	No eyes or olfactory bulbs, forebrain and motorneuron/interneuron specification defects	(7-9, 14, 15, 30, 31, 35-38, 47, 67)
Pax-7	Targeted	Normal	No muscle satellite cells, maxillary process, nasal capsule	(22, 46, 85)
Pax-8	Targeted	Normal	Absence of thyroid	(83)
Pax-9	Targeted	Normal	Absence of teeth	(55, 81)
Pax-2/Pax-5	Double homozygous	—	Absence of isthmic organizer, cerebellum and inferior colliculus	(26, 28)
Pax-3/Pax-7	Double homozygous	—	Neuronal specification defects (somitic derivatives not reported)	(22)
Pax-1/Pax-9	Compound heterozygous, double homozygous	—	Absence of vertebral bodies and discs, teeth	(51)

The roles of Pax proteins in these processes have been studied in mice having natural or targeted mutation of the *Pax* genes (Table 2). One property of *Pax* genes is that, for some developmental processes, two fully functional copies of the genes are required for normal differentiation of the tissue. Thus, developmental abnormalities in the kidney, optic nerve, eye and pigmentation are found in mice heterozygous for mutations in particular Pax genes. These defects are broadly consistent with human syndromes in which one copy of the corresponding *PAX* genes are mutated. This characteristic, known as haploinsufficiency, results in autosomally-dominant phenotypes that are not the result of novel gene function but, rather, the consequence of depleted levels of functional protein. Increased levels of Pax protein can also alter developmental fate; extra *Pax-6* genes results in developmental defects of the eye (5).

2.1. Pax-6 is Necessary for Early Eye Development

The embryonic eye is formed from an extension of the developing forebrain known as the optic vesicle, which is the precursor tissue for the retina, and a portion of the ectoderm, the lens ectoderm, that overlies this optic vesicle (reviewed (6)). A crucial early process of eye development is the induction of the lens ectoderm by the optic vesicle to form firstly a lens placode, then a vesicle and finally the mature lens. In animals homozygous for the natural Pax-6 null mutations *Sey* (7-9), Sey^{Neu} (9) and rat rSey (10), lens development fails to occur. Pax-6 is expressed in the presumptive lens ectoderm and in the induced lens placode (11, 12). This pattern of expression strongly suggested that Pax-6 proteins is part of the mechanism that allows the ectoderm to respond to a lens induction signal from the optic vesicle. This notion was supported by explant recombination experiments between homozygous rSey and wild-type tissue which showed that the homozygous ectoderm failed to respond to optic vesicle interactions but that homozygous mutant optic vesicle could still induce lens ectoderm (13). A conclusive study of this interaction employed conditional knockout in mice to specifically ablate functional *Pax-6* genes in the lens while leaving fully functional *Pax-6* in the optic vesicle and other tissues (14). Lens ectoderm with no functional Pax-6 underwent an initial response resulting in increased expression of the transcription factor Sox-2, then its development arrested. Although optic vesicle development is arrested in the natural *Pax-6* mutants, optic vesicles in the conditional knockout mice underwent development to form not one but several retinas. Thus, the optic vesicle is also required for correct placement of the retina, but not further development of the retina.

Development of the optic vesicle into the retina is characterized by the sequential generation of mature retinal cell types from stem cells in the original neuroectodermal layer (reviewed in (6)). An important feature of this process is the prevention of differentiation of all the stem cells into differentiated cells, so that a stem cell population is retained for the generation of later appearing cell types. However, specific ablation of *Pax-6* in the retina by conditional knockout, results in all the stem cells of the retina differentiating into the first cell type to appear, the amacrine cells, and the consequent arrest of further retinal development (15). Thus, *Pax-6* is necessary for maintenance of this stem cell population.

2.2. Pax Proteins and Patterning in the Central Nervous System

Pax proteins are one of many classes of regulator proteins that control the generation of neural tissue. They are part of the mechanism that specify certain neuronal populations. Moreover, some structures in the CNS require Pax proteins for their survival. Pax proteins also modulate the extracellular environment of certain structures resulting in well-demarcated boundaries with neighboring tissues.

The neural tube and hindbrain exhibit particularly striking patterns of Pax gene expression. *Pax-6* is expressed in most of the neural tube but is missing in the most dorsal and ventral margins (11, 16). *Pax-3* and *Pax-7* are expressed in the dorsal neural tube (17, 18). Combinations of transcriptional regulators including the Pax proteins are specified in individual cells on the basis of positional information provided by opposing concentration gradients of secreted peptide factors (reviewed in (19)). Sonic hedgehog, is secreted from the ventral margin of the neural tube, known as the floorplate, and from the notochord while BMP proteins diffuse from the dorsal margin of the neural tube (the roofplate) and the overlying ectoderm is the second group of signals. Additionally, transcriptional regulator expression can be modulated by other transcriptional regulators. Gain or loss of function for individual transcriptional regulators can change the specification of restricted neuronal types. Deletion of functional *Pax-6*, which is normally expressed in the middle of the neural tube, results in the respecification of the motor neurons supplying the hypoglossal nerve and some ventral interneurons (16, 20). Inappropriate expression of Pax-6 in the ventral neural tube respecifies a population of Nkx-2.2-expressing neurons by repressing expression of the transcriptional regulator (21). Loss of functional Pax-3 and Pax-7 genes results in one population of neurons inappropriately expressing the transcriptional regulator En-1 and the respecification of some ventral commisure neurons to other fates (22). Ectopic expression of Pax-3 in the ventral neural tube prevents the formation of the floorplate (23).

Pax-2 and Pax-5 are required for the maintenance of the isthmic organizer, which forms the

boundary between the midbrain and hindbrain. This structure is required for the development of the inferior colliculus and the cerebellum (reviewed in (24)). Development of regions of the optic tectum and cerebellum were hypoplasic in both Pax-2 (25, 26) and Pax-5 null (27) mutant homozygous mouse embryos. These results suggested that Pax-2 and Pax-5 had similar, but not redundant, functions in the maintenance of the isthmic organizer. Generation of Pax-2/Pax-5 double null mutant homozygotes led to the complete absence of the isthmic organizer, colliculus and cerebellum (26, 28, 29) and the extension of tissues adjoining the missing structures into the consequent space.

Pax proteins have an instructive role in the establishment of the boundary between the developing optic nerve tract and the retina. Both these structures form from the optic vesicle. The more medial portion, the optic stalk, is the optic nerve tract anlage and the more lateral, the optic cup, forms the retina. The developing optic nerve tract is characterized by expression of Pax-2 (25, 30). Absence of functional *Pax-2*, results in the extension of *Pax-6* expression into the more medial portion of the optic vesicle and ultimately the generation of retinal epithelial cells (25, 30, 31). When functional *Pax-6* is missing, the *Pax-2* expression domain is shifted into the lateral optic vesicle (30). Furthermore, binding of Pax-6 protein to the *Pax-2* promoter represses transactivation and binding of Pax-2 protein to *Pax-6* promoter also represses transactivation (30).

In the forebrain, Pax-6 has been shown to establish the correct boundaries between the structures in the forebrain and between the forebrain and the midbrain. In Pax-6 null mutant homozygotes, the caudal forebrain develops markers characteristic of the midbrain (32-34). The dorso-anterior aspect of the forebrain, the telencephalon, develops into the cerebral cortex and the striatum. Lack of functional Pax-6 leads to alterations in its boundary with the thalamus (35), defects in the developing cortical-striatal boundary (36, 37) and altered radial glia differentiation (38). The telencephalon phenotype is, in part, a function of modulation of the levels of the extracellular matrix proteins R-cadherin and tenascin (36) resulting in the loss of a well demarcated boundary with neighboring tissues.

2.3. Pax Genes Regulate Migration of Neural Crest Cells

The neural crest lays a crucial role in vertebrate development. Structures derived from neural crest cells include many peripheral neurons, including those in the spinal ganglia (dorsal root, sensory and autonomic), some of the bones of the skull, elements of the inner ear, cardiovascular structures and melanocytes (the pigmented cells) (reviewed in (39)). Neural crest cells migrate from the dorsal region of the neural tube and brain vesicles just after the fusion of their neural folds. This migratory process is influenced by three Pax proteins: Pax-3, Pax-6 and Pax-7. The migration of neural crest cells is blocked at thoracic and lumbar levels in homozygous splotch Pax-3 null mutant embryos and is severely impaired in cervical regions (40-42). This results in small or absent spinal ganglia, deficient ensheathing of peripheral nerves and the absence of melanocytes (43). Lack of neural crest migration into cardiac tissue results in the failure of the separation of the aorta and the pulmonary artery into two separate blood vessels (44, 45). Pax-7 and Pax-6 play similar roles to Pax-3 in the generation of more anterior neural crest-derived craniofacial structures. The maxillary process and nasal capsule are missing in Pax-7 null homozygotes (46)and *Pax-6* null allele homozygotes lack lateral nasal processes (47).

2.4. Pax-1 and Pax-9 and Vertebral Body Formation

The vertebral column is derived from the sclerotome compartment of somites (48). *Pax-1* and *Pax-9* are expressed in the sclerotomes of the differentiated somite (1, 49), as a result of sonic hedgehog protein signaling from the notochord and the neural tube (50). Some *Pax-1* expressing cells then migrate ventromedially to surround the notochord and differentiate to form the vertebral bodies and intervertebral discs (1, 49). The cells fated to form the vertebral bodies condense to form cartilage in a process known as chondrogenesis as evidenced by *Sox-9* and *collagen II* expression (51). It is the fate of this cell population that Pax-1 and Pax-9 regulate. Mouse embryos homozygous for the natural null *Pax-1* mutation *undulated* (52, 53) and the targeted *Pax-1* null allele (54) exhibit vertebral body hypoplasia and fusions due to inhibited chondrogenesis and agenesis of the intervertebral discs. Hypoplasia is particularly pronounced in the posterior portion of each vertebra,

and heterozygotes for *Pax-1* null alleles have hypoplasic cervical and lumbar vertebrae (54). When embryos are homozygous for targeted null alleles of both *Pax-1* and *Pax-9*, chondrogenesis does not occur because decreased proliferation and increased apoptosis leads to the disappearance of the vertebral body fated cell population (51). However, homozygotes for the Pax-9 targeted null allele have a normal vertebral column (55). These studies show that Pax-1 and Pax-9 have partially redundant roles in the vertebral bodies, but that Pax-1 acts uniquely in intervertebral disc formation and in normal chondrogenesis of the posterior of each vertebra.

2.5. Pax-3 Requirement for the Migration of Limb Muscle Precursor Cells

The skeletal muscles of the trunk and limbs are derived from the dermomyotome of the somatic mesoderm (reviewed in (48)). The myotome, which develops from the dermomyotome, forms the muscles of the back and ribcage. Precursors of the limb muscle migrate from the leading lateral edge of the dermomyotome into the developing limb bud and coalesce into dorsal and ventral premuscle masses. These premuscle masses then form the mature musculature. Both Pax-3 (56, 57) and Pax-7 (18, 46) are expressed in the dermomyotome with Pax-3 expressed more strongly in the lateral portion and Pax-7 in the medial portion. Loss of functional Pax-3 results in the failure of limb muscle precursors to make the transition from epithelium to mesenchyme and migrate into the limb (58, 59). This failure in migration is due in part because Pax-3 transactivation is required for the expression of the SF/HGF receptor c-met (60-62). SF/HGF protein is expressed in the limb buds and limb muscle precursor cells do not migrate in embryos homozygous for the null allele for *c-met* (63). Additionally, apoptotic cells are seen in the somites of mice homozygous for the Pax-3 null allele splotch at the developmental stages that limb muscle precursors emigrate from the somite (64).

2.6. Pax-4 and Pax-6 Mediate Endocrine Cell Specification in the Pancreas

The endocrine cell populations of the pancreas are found in the Islets of Langerhans (reviewed in (65)). The a, b, d and PP cell lineages synthesize glucagon, insulin, somatostatin and pancreatic polypetide, respectively. *Pax-4* is expressed in the b (insulin-producing) and d (somatostatin-producing) cells (66), and *Pax-6* is expressed in all four lineages (67). Inactivation of both copies of the *Pax-4* gene resulted in the failure of insulin- and somatostatin-producing cell populations to differentiate and resulted in increased numbers of glucagons-producing cells (66). The latter finding is consistent with the discovery that Pax-4 protein binding to the enhancer of the glucagon gene represses transcription (68). Pax-6 homozygous null mutants lack glucagon-expressing cells and fail to form islets of Langerhans (67, 69). Moreover, Pax-6 protein transactivates the glucagon and insulin promoters and also binds to the somatostatin promoter (69). In embryos lacking both functional *Pax-4* and *Pax-6* genes, endocrine pancreatic cells fail to develop altogether (67). Hence the actions of Pax-4 and Pax-6 are required to generate the full complement of endocrine pancreas cell types from a single endocrine pancreatic progenitor population.

2.7. Pax-2 is Required for Mesenchymal-to-Epithelial Transitions in the Urogenital System

The development of the definitive kidney commences when a mesenchymal structure, known as the metanephric mesenchyme, induces the ureter to bud out from the caudal Wolffian duct (reviewed in (70)). Contact by the ureter induces the metanephric mesenchyme to differentiate into the glomerulae which are the proximal and distal tubular epithelial structures seen in the nephrons of the kidney. The metanephric mesenchyme expresses *Pax-2* (71, 72). Pax-2 is necessary to allow the metanephric mesenchyme to undergo mesenchymal-to-epithelial transitions since mice that are homozygous for either the targeted *Pax-2* null mutation (73) or the natural *KrD* mutation (31). Moreover, genital structures of epithelial morphology such as the vas deferens and seminal vesicles in the male and the uterus and vagina in the female are also missing in mice homozygous for these mutations. *Pax-2's* role in kidney formation is dosage dependent, kidneys in heterozygous mice are hypoplasic.

2.8. Pax-5 and the B-Cell Lineage

The B-cell lineage is one of the two cell types that mediate the immune response. Pax-5 is expressed in B cells until terminal differentiation (74) (reviewed in (75)). In *Pax-5* null allele homozygotes, differentiation is arrested at a very early stage prior to the initiation of expression of the early marker, CD19 (27). In fact, the *CD19* gene's promoter contains Pax-5 binding sites (76). However,

the *Pax-5 (-/-)* pre B cells can populate the thymus when injected into *Rag-2 (-/-)* mutants (77), and can be diverted to other fates in vitro (78). Pax-5 is thus required for the generation and maintenance of an immature B-cell population. The finding that Pax-5 represses expression from the *Immunoglobulin Heavy Chain* gene (*IgH*) enhancer (79) suggests that downregulation of Pax-5 expression may be an important part of terminal differentiation.

2.9. Roles of Pax Proteins in Other Tissues

Pax genes have been found, from developmental defects observed in null-mutant homozygote embryos, to participate in the regulation of other developmental processes that are less studied. Nevertheless, the roles *Pax* genes play here are similar to the others described above.

Pax-1 and *Pax-9* are required for full development of tissues derived from the third and fourth pair of pharyngeal pouches such as the thymus, parathyroid gland and the ultimobranchial bodies. These structures are completely missing form Pax-9 null allele homozygotes (55) and mice with no functional Pax-1 have a reduced thymus with 50 to 80% fewer T-cells (80).

Pax-9 plays a crucial role in the generation of teeth at the tooth germ stage. It is expressed at discrete sites in the mesenchyme along the developing mandible due to inductive signaling by FGF-8 and antagonistic signaling by BMP-2 and -4 (81). Only *Pax-9* expressing portions of the mesenchyme can initiate tooth formation (81) in an in vitro assay; its absence in *Pax-9* null mutant homozygotes prevents further development of tooth primordia (55).

The thyroid gland is formed from two cell populations: endodermal cells that express *Pax-8* and pharyngeal-derived mesenchymal cells that form the parathyroid (82). Ablation of functional *Pax-8* prevents the endodermal cells participating in thyroid development resulting in thyroid agenesis (83). Moreover, Pax-8 protein can transactivate the promoters of thyroglobulin and thyroperoxidase (84).

The olfactory bulbs differentiate from the nasal placode, which is induced in a *Pax-6* dependent process. These structures are missing in *Pax-6* null allele homozygotes (7-9, 47).

Finally, satellite cells are missing in the muscle tissue of *Pax-7* null mutant homozygotes (85). However, the muscle stem cell population is unaffected.

3. Pax Genes and Human Disease

3.1. Human Syndromes Resulting from Mutation of Pax Genes

PAX gene mutations have been implicated in a number of syndromes over the last decade. The symptoms of these conditions are broadly consistent with the observations in heterozygous null mutant mice.

Two syndromes are known to result from mutations at the *Pax-6* locus: Aniridia and Peter's anomaly. Aniridia is a syndrome in which the iris fails to develop fully (86-88). This is consistent with the iris malformations in heterozygous Sey mice (7, 8). Significantly, the posterior layer of the iris is derived from the optic cup, which expresses *Pax-6*. Peter's anomaly is a defect in the formation of the cornea that renders it opaque (89). The cornea develops from ectodermal tissue that expresses *Pax-6* and forms over the lens after its formation.

The symptoms of Waardenburg's Syndrome 1 are pigmentation defects and hearing loss, which occurs as a result of *PAX-3* mutation (90, 91). These defects occur as a result of the impaired migration or differentiation of neural crest cells, which give rise to structures of the inner ear and to the melanocytes. Sufferers of this syndrome are deaf, however mice heterozygous for the *Splotch* null mutation of *Pax-3* are not (91).

In humans, disruption of PAX-2 function leads to optic nerve colobomass, renal hypoplasia and vesicouretal reflux (92, 93). This syndrome is consistent with the optic nerve and kidney phenotypes

in mice heterozygous for the targeted Pax-2 null mutation (73).

3.2. Pax Genes and Cancer

Transcription factors that are inappropriately expressed or mutated play a significant role in tumorigenesis. Some studies have identified *PAX* genes as tumor promoters in certain cancers. The potential for *PAX* genes to promote neoplasia was shown in a study where *Pax-1,-2,-3* and *-6* transformed 3T3 cells could form tumors when injected subcutaneously into nude mice (94). Moreover, the cells transformed in focus assays.

Chromosome translocations leading to fused genes that contain some PAX sequences is one way by which *PAX* genes may promote tumorigenesis. Rhabdomyosarcomas are soft-tissue tumors with a muscle morphology found in the young. Characteristic of this sarcoma is a translocation from chromosome 13 to the *PAX-3* locus in chromosome 2 GALILI, (95). This results in a fusion of sequences of a forkhead-class gene to the homeobox of *PAX-3*, which expresses a chimeric protein that can transactivate gene expression via PAX-3 binding sites in their enhancers (96), (97)s. More recently a *PAX-7* to *forkhead* translocation was isolated from a rhabdomyosarcoma (98). The effect of a translocation like this may put expression of the chimeric gene under a different, looser regulation. Alternatively, the resultant fusion proteins may simply have better transactivator potential than their parent proteins. A recent study found that the PAX-3/forkhead fusion protein was unresponsive to the PAX-3 repressor protein, hDaxx (99).

In other cases, the genetic lesion does not change the coding sequences of the PAX gene but only the promoter-enhancer region. An example of this is the translocation of the Em enhancer of the *IgH* gene to the *PAX-5* locus in diffuse large-cell lymphomas (100). PAX-5 has been shown to directly repress the transcription of p53 (101) whose protein is crucial for initiation of apoptosis and cell cycle control. Another is the elevated *PAX-2* and *PAX-8* expression in Wilm's tumor (102-104).

4. Conclusion

Over the last twelve years, the *Pax* genes have been identified, their patterns of expression characterized, and many of their functions analyzed. Functional analyses have been helped by the fortuitous discovery of natural *Pax* rodent and zebrafish mutants, which complemented the targeted mutational studies. All Pax genes display restricted patterns of expression in both neural and nonneural structures. Some Pax genes have very similar functional roles in the development of certain tissues. The best example of this is Pax-2 and Pax-5 in the morphogenesis of the midbrain-hindbrain boundary. Pax protein functions in some morphogenetic processes are sensitive to gene dosage, and the malformations seen in heterozygous mouse mutants and in the corresponding human syndromes resulting from mutation of the correlating PAX gene are strikingly similar. Thus haploinsufficiency is a conserved feature of Pax function in different species.

Pax proteins play important roles in certain morphogenetic processes. One of these is in conferring competence to respond to inductive influences. Examples include the competence of ectodermal tissue to be induced to form lens or nasal placode tissue, metanephric mesenchyme to form kidney epithelial structures, and the competence of dermomyotome cells to form a migratory myogenic cell type. Pax proteins also function in cell specification, examples being the B cells, pancreatic endocrine cells, the neural e developing crest, and certain neuronal cell types. In these cases, Pax proteins also help to mediate the survival of these cell types, since null mutations of Pax genes also lead to the disappearance of the cell types.

Studies in coming years will identify more structures whose genesis requires the actions of *Pax* genes particularly in the developing brain. Studies will also focus on Pax protein interactions with other nuclear proteins in forming transcriptional complexes, which is poorly characterized at present. Yet other studies will investigate the control of the expression of *Pax* genes.

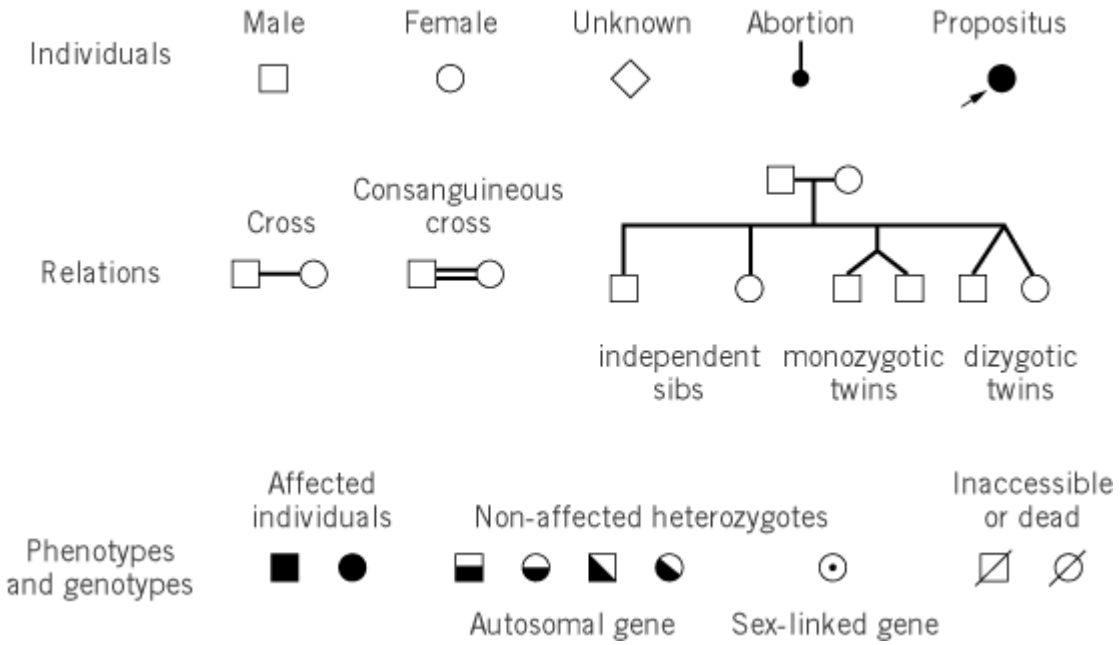
Pedigree

A pedigree is a family tree, a graphical representation of biological descent (Fig. 1). Each generation is represented in a separate row. Males are represented by squares and females are represented by circles; alternative respective symbols are ♂, representing the shield and spear of Mars, and ♀, the mirror of Venus. Horizontal lines join parents and sets of sibs; vertical lines indicate descent. Sibs are ordered according to birth from left to right. Double horizontal lines call attention to parents that are closely related (inbreeding); sometimes they are used to join monozygotic twins as well. Filled, colored, or shaded symbols indicate affected individuals in pedigrees that represent the inheritance of certain traits; partly modified symbols indicate unaffected **heterozygous** carriers. Several sibs can be pooled together by indicating their number within a single symbol. A pedigree may be described in words, but this is usually impractical.

Figure 1. Conventional symbols used in the representation of pedigrees.



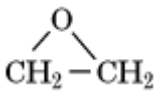
In the analysis of pedigrees, attention must be given to inconstant phenotypes due to effects of the environment or the rest of the genotype of the affected individuals on the expression of the **allele**. Some alleles are unstable and change from one generation to the next (see Trinucleotide Repeats). Because of the small size of human families, linkage has to be deduced from the pooled results of many groups of sibs (see **Lod scores**).

PEG (Polyethylene Glycol)

PEG is a polyether polymer commonly used to induce the precipitation or crystallization of macromolecules and **viruses**. In spite of its name, polyethylene glycol, it has hydroxyl groups only at each end of the polymeric chain:

$$\mathrm{HO-(CH_2CH_2O-)_nH} (n = 5 \text{ to } 500)$$

Except for these ends, the polymer is essentially nonpolar. The ether oxygen atom is only slightly polar and hydrogen bonds with water just sufficiently to make PEG water-soluble. PEG is produced by the simple polymerization of ethylene oxide,



and is available in different lengths, whose molecular weights vary from 200 to 20,000, depending on the polymerization process. The average number of monomers in each molecule may be estimated by dividing the molecular weight of the polymer by 44, the molecular weight of the monomer.

PEG precipitates proteins because it is a large, water-soluble polymer that is excluded from the surfaces of macromolecules simply because of its large physical size, a phenomenon known as steric exclusion (see Excluded Volume). A large polymer cannot penetrate the interior of a folded protein or other macromolecule, so it is effectively excluded from a shell around the macromolecule. The thickness of the shell is defined by the center of the polymer at its point of closest approach to the macromolecule. The presence of the polymer in effect increases the concentration of the macromolecule because the macromolecule is excluded from the volume of the solution occupied by the polymer. When the solubility limit of the macromolecule is reached, it precipitates or crystallizes.

Water molecules are smaller and penetrate within the shell of solvent around the macromolecule from which PEG is excluded. As a result, a zone enriched in water is formed around the protein molecule. The end result is preferential hydration of the macromolecule and preferential exclusion of the polymer (1). Solely on this basis, PEG would be expected to stabilize the folded conformation of the macromolecule (see Stabilization And Destabilization By Co-Solvents). However, PEG is a relatively nonpolar molecule that interacts favorably with the nonpolar surfaces exposed when a macromolecule unfolds, and the net effect is that PEG destabilizes folded proteins (1, 2).

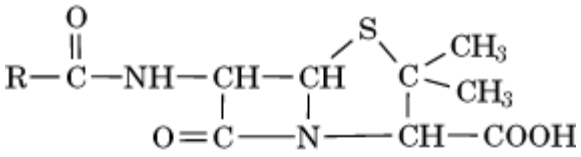
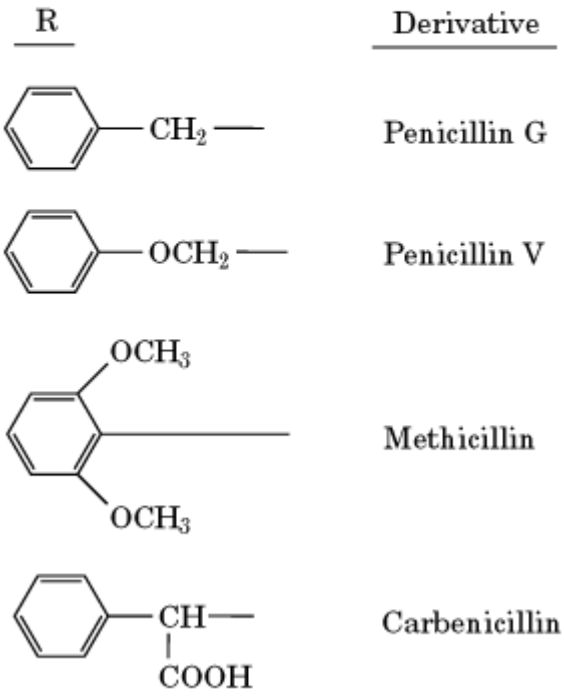
Penicillin

The penicillins are antibacterial agents belonging to the group known as the b-lactam antibiotics. Penicillin was first discovered about 70 years ago by Alexander Fleming as a metabolic by-product of the fungus *Penicillium notatum* (1). Since then, other fungi have been shown to produce several different structural types of penicillins. All penicillins share a common bicyclic nucleus that is composed of fused b-lactam and thiazolidine rings (Fig. 1). This compound, known as 6-aminopenicillanic acid, is a cyclic peptide formed by the condensation of L-cysteine and D-valine. An important structural feature of the penicillins is the acyl side-chain attached to 6-aminopenicillanic acid (represented by R in Fig. 1). The different members of the penicillin family are distinguished by their acyl side chains, some examples of which are shown in Figure 1b. The derivatives known as penicillin G and penicillin V are natural penicillins, namely, fungal metabolites. The medical application of penicillin in the 1940s highlighted the birth of the antibiotic era, and subsequent misuse of this and other antibiotics has led to the current drug resistance crisis (2) (see Antibiotic Resistance).

Figure 1. (**a**) The structure of the penicillin nucleus; R represents a hydrogen atom in the case of 6-aminopenicillanic acid. (**b**) Examples of acyl side chains of natural and semisynthetic pencillins.



(a)



(b)

Comparative studies indicated that the structure of the acyl side chain significantly influenced the antibacterial spectra and physical properties of penicillin. The development of semisynthetic penicillins was an important event in penicillin development. Nayler (3) has presented a historical account of the discovery of semisynthetic penicillins. Semisynthetic antimicrobial agents are derivatives of a natural product that have been deliberately modified chemically. In the case of the semisynthetic penicillins, the natural product is the penicillin nucleus, 6-aminopenicillanic acid. The discovery of methods to produce large amounts of 6-aminopenicillanic acid in the late 1950s was the pivotal event that led to the development of semisynthetic penicillins. The subsequent synthetic chemical acylation of 6-aminopenicillanic acid gave rise to numerous new penicillins with novel properties, and this approach was essential to keep up with the growing demands to solve problems faced by medical applications. For example (see Fig. 1), this technology gave rise to agents that exhibited broad-spectrum antibacterial activity (eg, ampicillin and carbenicillin), agents that could be administered orally (eg, ampicillin), and agents that were resistant to the action of b-lactamase (eg, methicillin).

Penicillin inhibits the synthesis of the bacterial cell wall polymer known as peptidoglycan or murein. This topic has been reviewed recently by Höltje (4, 5). Peptidoglycan is a single large macromolecule that completely envelopes bacterial cells. It represents an exoskeleton that supports the underlying cytoplasmic membrane. In this regard, it serves an absolutely essential function in preventing osmotic lysis of the bacterial cells. The actual targets of penicillin are membrane-bound enzymes, known as penicillin-binding proteins (PBPs), that catalyze the transpeptidation reaction in

the final stage of peptidoglycan polymerization. Transpeptidation creates crosslinkages between adjacent peptide chains in the peptidoglycan polymer. The amide group in the b-lactam ring of penicillin represents a structural analogue of the D-alanyl-D-alanine peptide bond involved in the transpeptidation reaction. Penicillin is a **suicide substrate** for PBPs, and the interaction of penicillin with its PBP target results in the formation of a stable penicilloylated enzyme derivative. For details of the mechanism of action of penicillin, see Penicillin-Binding Proteins (see Fig. 1 of that article).

Penicillin is bactericidal. The lethal effect of penicillin treatment is normally associated with bacterial cell lysis (4, 5). This lysis is catalyzed by one or more bacterial enzymes known as peptidoglycan hydrolases. These enzymes cleave chemical bonds in peptidoglycan. Their normal physiological functions are poorly understood. It is believed that the activities of at least some of these hydrolases create openings in the completely closed peptidoglycan molecule, to permit the insertion of new subunits during the growth of bacterial cells. The terminal stage of peptidoglycan synthesis is consequently proposed to be a coordinated process catalyzed by two classes of enzymes: the PBPs and the peptidoglycan hydrolases. These enzymes are further proposed to form a multienzyme complex. Therefore, bacteria are killed by penicillin in a two-step process. In the first step, penicillin inhibits activities of the PBPs involved in peptidoglycan polymerization. In the second step, the peptidoglycan hydrolases become uncoupled from the peptidoglycan biosynthetic process and cause lysis of the bacteria.

It has long been recognized that penicillin kills only actively growing bacteria (6). More recent studies have confirmed that the bactericidal effect of penicillin is directly dependent on the bacterial growth rate (7). The first application of penicillin in genetics was based on this concept. Lederberg and Zinder (8) and Davis (9) independently developed a technique, known as penicillin selection, for the isolation of auxotrophic mutants of *Escherichia coli*. The procedure involves inoculating a sample of *E. coli* containing rare auxotrophic mutants into a minimal medium lacking the nutritional factor(s) required by the mutants. Only the wild-type cells in the population are capable of growing in this medium, and the majority of these are subsequently killed by the addition of a lethal dose of penicillin. The auxotrophic mutants are tolerant to penicillin and are readily recovered by screening the survivors of the penicillin treatment.

The basis for the pencillin tolerance of amino acid–deprived cells has been investigated. Amino acid deprivation of *E. coli* results in the coordinate inhibition of a variety of metabolic activities in a phenomenon that has been called the “stringent response” (10) (see Stringent Control). The stringent response is probably a strategy to restrict energy consumption in an effort to promote the survival of bacteria during periods of starvation. Amino acid–deprived *E. coli* accumulate a novel nucleotide, guanosine 3′,5′-bispyrophosphate (ppGpp), which is believed to mediate the stringent response. Membrane phospholipid synthesis, cell wall peptidoglycan synthesis, and penicillin-induced lysis are among the many metabolic activities that are inhibited during the stringent response (11, 12). Moreover, the activities of the membrane peptidoglycan polymerases and peptidoglycan hydrolases have been shown to be dependent on ongoing phospholipid synthesis. Therefore, the inhibition of phospholipid synthesis by ppGpp results in the inhibition of the membrane-associated reactions in peptidoglycan metabolism and is the direct cause of the penicillin tolerance of starved *E. coli*.

The concept of penicillin selection can be applied more broadly. It can be used in any situation where it is possible to design culture conditions that do not permit the growth of the cells to be selected. For example, penicillin selection can be used to select cells that have been spontaneously cured of transposon insertions. Therefore, cured cells can be selected from a population of cells that carry the transposon Tn *5* (which encodes kanamycin resistance) by growing the culture in a medium containing both kanamycin and ampicillin. The ampicillin will kill only those cells that carry Tn *5*, and cured cells can be isolated by screening the surviving population.

Genetic elements encoding b-lactamases (see Penicillin-Binding Proteins) are currently widely employed as selective markers in molecular biological applications. Consequently, penicillin derivatives, especially ampicillin, are among the most common chemicals encountered in a

molecular biology laboratory. Penicillin selection is attractive because the antibiotics are relatively inexpensive and are highly effective because of their bactericidal action. In medical applications, penicillin derivatives are considered to be of low toxicity. They are allergenic, however, and the development of either immediate or delayed hypersensitivities are the most frequent and serious problems associated with penicillin therapy. It is notable that anaphylaxis to penicillin has been reported after nontherapeutic exposure (13). It is therefore conceivable that exposure to penicillin in the laboratory could result in hypersensitive reactions in sensitized individuals, and those who are known to be allergic to penicillin should be alerted to this possibility.

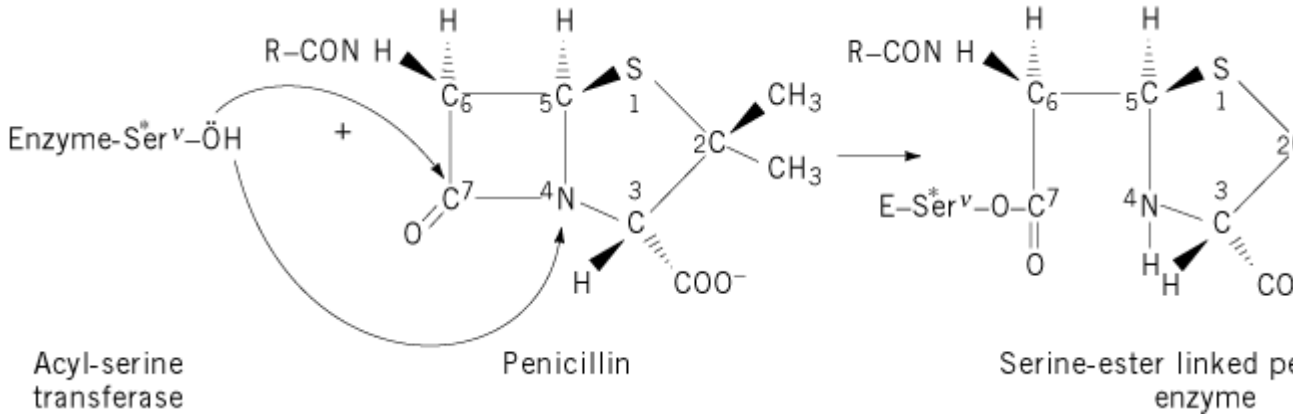
Penicillin-Binding Proteins

The concept of antibiosis originated with Ehrlich and the sulfa drugs. It was firmly established by Fleming, Florey, and Chain, who discovered the uses of penicillin. The chemical structure of penicillin has some remarkable features: its b-lactam amide bond is equivalent to a peptide bond extending between two carbon atoms that have the D configuration (see **Stereochemistry**), in the a position to a free carboxyl group . Penicillin kills bacteria because it inactivates specialized acyl

serine transferases that are involved in the assembly and metabolism of the cell-wall peptidoglycan. It immobilizes the catalytic center in the form of a stable serine ester-linked penicilloyl enzyme derivative (Fig. 1). Variants of penicillin, such as ampicillin, also exist.

Figure 1. The structure of penicillin and its reaction with the active-site serine residue of acyl-serine transferases. The m of the reaction is shown at left, and the resulting penicilloyl enzyme is shown at right. If the penicilloyl enzyme is stable, enzyme is a penicillin-binding protein. Alternatively, if the penicilloyl enzyme is hydrolyzed rapidly, the enzyme is a b-l



The bacterial cell-wall peptidoglycan is a covalently closed, net-like **polymer** (1). Linear glycan strands are made up of alternating b-1,4-linked units of *N*-acetylglucosamine and *N*-acetylmuramic acid. The carboxyl groups of the *N*-acetylmuramic acid residues are amide linked to the amino terminal L-alanine residues of peptide units L-alanyl-g-D-glutamyl-L-diaminoacyl-D-alanine. Neighboring peptide-substituted glycan strands are crosslinked by peptide bridges that extend from the D-alanine at the carboxyl end of one peptide to the side-chain amino group of the diamino acid residue of another peptide. The nature of the diamino acid residue and the composition of the peptide bridge vary according to the bacterial species.

In *Escherichia coli*, the diamino acid residue is *meso*-diaminopimelic acid, and the peptide bridges are direct D-alanyl-(D)-*meso*-diaminopimelic acid bonds. The immediate biosynthetic precursor of the cell-wall peptidoglycan is lipid II (2), in which a disaccharide peptide unit is linked to a $C_{55}H_{89}$ undecaprenyl lipid carrier via a pyrophosphate bridge involving C_1 of *N*-acetylmuramic acid, and the peptide borne by *N*-acetylmuramic acid is a pentapeptide that terminates with a D-alanyl-D-alanine sequence. From this precursor, glycosyl transferases catalyze glycan chain elongation by displacement of the pyrophosphate linked to C1 of *N*-acetylmuramic acid by the 4-hydroxyl group of *N*-acetylglucosamine. Then acyl serine transferases catalyze peptidoglycan crosslinking at the expense of the D-alanyl-D-alanine bond of the pentapeptide units. This reaction proceeds via formation of a peptidyl (~L-alanyl-g- D-glutamyl-L-diaminoacyl- D-alanyl) enzyme intermediate linked as an ester to a serine residue at the active site, with the concomitant release of the carboxy terminal D-alanine residue of the pentapeptide. It is achieved by the transfer of the peptidyl moiety to the side-chain amino group of the diamino acid residue of another peptide. Because the reaction involves breaking a D-alanyl-D-alanine bond, the acyl serine transferases are classified as DD-transpeptidases.

Acyl serine transferases are also involved in the control of the extent of peptidoglycan crosslinking. DD-carboxypeptidases hydrolyze the D-alanyl-D-alanine peptide bonds of pentapeptide units by transferring the peptidyl moiety of the acyl-enzyme intermediate to water. DD-endopeptidases hydrolyze the interpeptide bonds, which in some bacteria extend between two D centers in a position to a free carboxylate, as, for example, the D-alanyl-(D)*meso*-diaminopimelic acid bonds in the *E. coli*

peptidoglycan.

Penicillin has similarities to the above substrates and is a **suicide substrate** of the DD-(trans, carboxy, endo)peptidases. These DD-peptidases react with and rupture the b-lactam amide bond of penicillin but produce a serine ester-linked penicilloyl enzyme that is almost completely inert and inactive. The catalytic center turns over very slowly—one time or less per hour—and the inactivated enzymes are detectable as penicillin-binding proteins (PBPs).

In some cases, proteins acquired the ability to catalyze the hydrolysis of the serine ester-linked penicilloyl enzyme, which resulted in a remarkable defensive mechanism by producing enzymes, (the b-lactamases), with the ability to hydrolyze penicillin and other b-lactam antibiotics. On good b-lactam substrates, the catalytic center of the serine b-lactamases can turn over 1000 times or more per second.

The DD-peptidases and serine b-lactamases form a superfamily of penicilloyl serine transferases (3). They are an exemplary model of molecular evolution. Numerous changes in their amino acid sequences, and gene fusion with the genes for several polypeptides of different origins, resulted in a prolific expansion of groups, classes, and subclasses of these enzymes, with multiple personalities. They share structural motifs. Some have similar enzymatic activity but varying substrate specificities. Others catalyze distinct reactions and fulfill different functions.

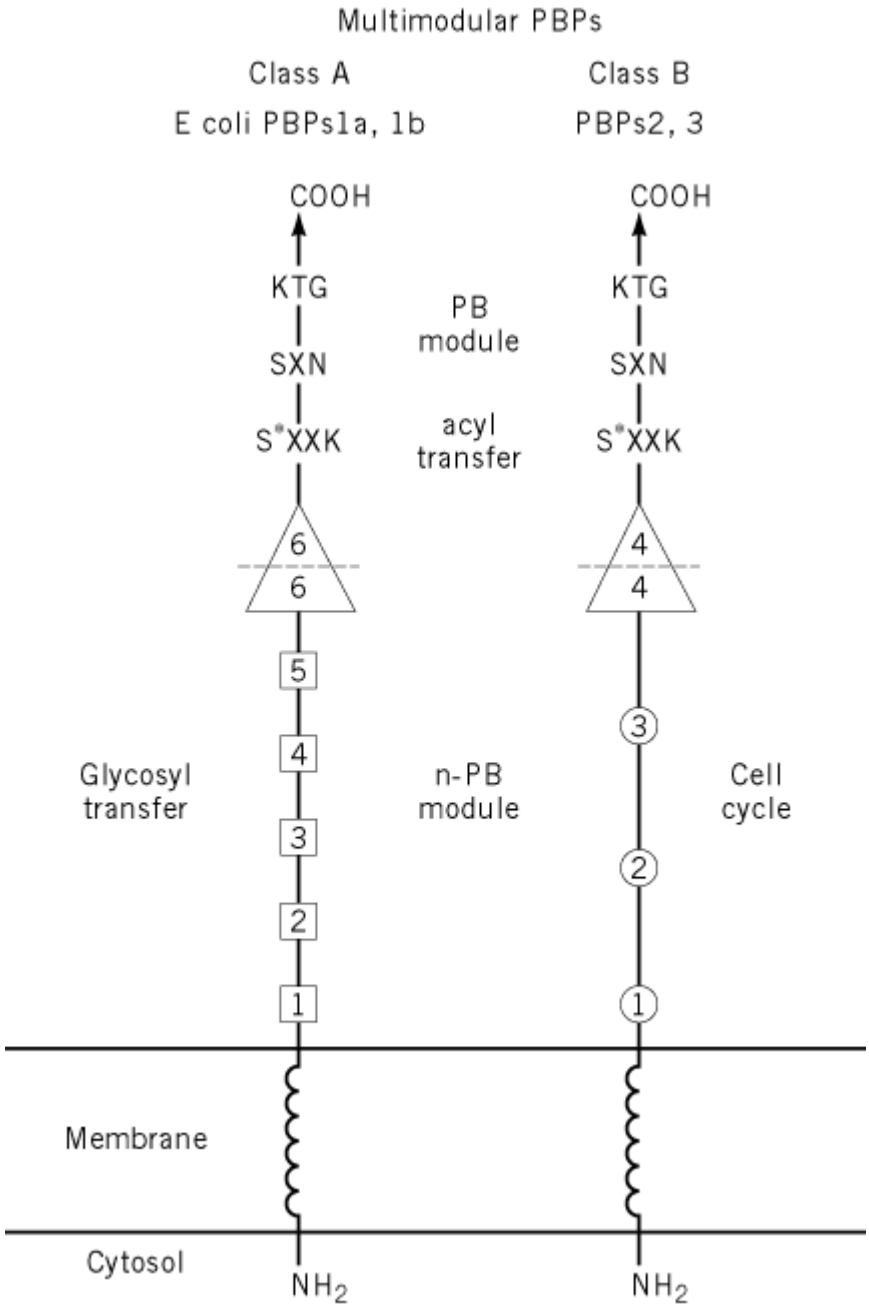
1. Protein Structure

The DD-peptidases and b-lactamases presumably diverged from a common ancestor while retaining the same basic protein structure (4). Similarities in their overall amino acid sequences are almost nonexistent, but folding invariably brings three common motifs of the polypeptide chains close to each other in the tertiary structure, forming the catalytic center at the boundary between an all-a **domain** and an a/b domain, which consists of a five-stranded beta-sheet covered by **alpha-helices** on both faces. With "x" denoting a variable amino acid residue, motif 1 has the sequence -Ser-x-x-Lys- (where Ser is the active-site serine), is at the amino end of an a-helix, and occupies a central position in the cavity. Motif 2 has the **consensus sequence** [Ser/Tyr]-x-[Asn/Asp/Cys] and is on a loop between two a-helices on one side of the cavity. Motif 3 has the sequence [Lys/His]-[Thr/Ser]-Gly and is on the innermost strand of the b-sheet on the other side of the cavity. The relative positions of these three motifs are well conserved in the various proteins.

2. Penicillin targets in *Escherichia coli*

E. coli possesses nine PBPs. PBPs 4, 5, 6, and 7 are monofunctional DD-carboxypeptidases that are not essential for viability. PBPs 1a, 1b, 1c, 2, and 3 are multidomain proteins (3) in which a transmembrane spanner is linked to the amino end of a non-penicillin-binding (n-PB) module that is linked to the amino end of an acyl serine transferase, penicillin-binding (PB) module. The two modules comprise a single polypeptide chain that folds on the exterior of the plasma membrane (Fig. 2). There are two classes: A and B (see text below).

Figure 2. Design and membrane topology of multimodular penicillin-binding proteins (PBPs) of class A and class B. Indicated are the five motifs of the n-PB modules of class A PBPs *f*, the three motifs of the n-PB modules of class B PBPs ○, and the intermodule junction sites D. For more details on the class-specific motifs, see text. The PB modules bear the characteristic motifs of the penicilloyl serine transferase superfamily. Some PBPs have inserts and N- and C-terminal extensions, which are not shown.



PBP1a and PBP1b of class A (850 and 844 amino acid residues, respectively) combine the transglycosylase (n-PB module) and the DD-transpeptidase (PB module) activities that are required for peptidoglycan assembly. Each catalyzes the conversion of lipid II into polymeric peptidoglycan in in vitro assays (5). Loss of either PBP1a or PBP1b is tolerated, but loss of both is fatal (6). Under these extreme conditions, PBP1c (770 amino acid residues) does not rescue *E. coli* from death.

PBP2 and PBP3 of class B (633 and 588 amino acid residues, respectively) are inert on lipid II (7). They combine in a single polypeptide chain a cell cycle (n-PB) module and an acyl serine transferase (PB) module. Both modules are essential, and loss of neither PBP2 nor PBP3 is tolerated. The genes for PBP2, the DD-carboxypeptidase PBP5, and the integral membrane protein RodA cluster at the 14-min region of the chromosome; these proteins prescribe traits as complex as cell-wall expansion and cell-shape maintenance (8). PBP3, MraW, FtsL, FtsQ, FtsA, the cytoskeletal FtsZ, and FtsW (an analog of RodA)—the encoding genes of which cluster at the 2-min region of the chromosome—prescribe traits as complex as septum formation (9).

3. The Multimodular PBP Family

Sixty-three multimodular PBPs of various bacterial species (10) comprise two classes, A and B, with distinct amino acid sequence signatures in their n-PB modules but conserved motifs in their acyl serine transferase-PB modules. Their junction sites between the n-PB and PB modules usually have the carboxy terminal sequence Asp-x-x-x-Gln (Fig. 2). There is a clustering into several subclasses of A and B, corresponding to **Gram-negative** and **Gram-positive** bacteria.

Based on these observations, the cores of the n-PB modules (n-PB cores) of the multimodular PBPs start at the amino end of the first motif and terminate at the intermodule junction site. The cores of the associated PB modules (PB cores) start about 70 residues N-terminal of the Ser-x-x-Lys motif—at the carboxy end of the intermodule junction site (where insertions occasionally occur), and they terminate about 70 residues C-terminal of the Lys-[Thr/Ser]-Gly motif; PBPs also have C-terminal extensions. In *E. coli* PBP1b, motif 3 of the PB core has the sequence Lys-Thr-Gly at residues 698–700, residues 762–780 are essential, but residues 781–844 are dispensable (11). In *Streptococcus pneumoniae* PBP2x (the structure of which is known at low resolution [(12)]), motif 3 of the PB core has the sequence Lys-Ser-Gly at residues 547–549, and residues Ser617–Asp750 form a carboxy terminal module with its own fold.

The multimodular PBPs are fully integrated hybrids. In contrast to the monofunctional PBPs, which are autonomous folding entities, the PB modules of multimodular PBPs have lost the ability to fold by themselves (13-15). They require the assistance of the associated n-PB modules, which implies precise and specific module-module interactions. Correct folding (in terms of penicillin binding) of the associated n-PB and PB modules of *E. coli* PBP3 is independent of the transmembrane spanner (13). In contrast, the cell septation activity of *E. coli* PBP3 is dependent on the membrane-anchor module, indicating that the membrane anchor and its cytosolic tail have more sophisticated functions than that of a simple anchoring device (16).

4. Evolution of Multimodular Class A PBPs

The n-PB cores of the class A PBPs form a continuum of homologous sequences, and they have an extended amino acid sequence signature in the form of five motifs, indicative of conserved transglycosylase activity. In *E. coli* PBP1a, motif 1 starts at residue 86 with the sequence Glu-Asp-Ser-Arg-Phe-x-Glu-His-x-Gly, motif 2 starts at residue 117 with the sequence Gly-Ala-Ser-Thr-Ile-Thr-Gln-Gln, motif 3 starts at residue 139 with the sequence Arg-Lys-x-x-Glu, motif 4 starts at residue 156 with the sequence Lys-x-Glu-Ile-Leu-Glu-x-Tyr-x-Asn, motif 5 starts are residue 221 with the sequence Arg-Arg-x-x-x-Val-Leu-, and Gly284 is at the amino end of the intermodule junction site. Residues Glu86 of motif 1 and Glu143 of motif 3 are almost certainly important components of the transglycosylase catalytic center.

The associated PB cores of the class A PBPs of Gram-negative bacteria cluster into two subclasses: A1 (prototype: *E. coli* PBP1a) and A2 (prototype: *E. coli* PBP1b), which form a supercluster. Those of Gram-positive bacteria cluster into three subclasses: A3 (prototype: *S. pneumoniae* PBP1a), A4 (prototype: *S. pneumoniae* PBP2a), and A5 (prototype: *S. pneumoniae* PBP1b).

Although performing the same transglycosylase-transpeptidase activities, PBPs of subclasses A1 and A2 in Gram-negative bacteria and PBPs of subclasses A3, A4, and A5 in Gram-positive bacteria are almost certainly **paralogous**. They prescribe distinct, subtle traits in peptidoglycan assembly in these two groups of bacteria that sometimes are difficult to detect.

5. Evolution of Multimodular Class B PBP

The class B PBPs evolved differently than did class A PBPs (10). The n-PB and PB cores underwent adaptive evolution in such a concerted manner that, in Gram-negative bacteria, an n-PB core of

subclass B2 (prototype: *E. coli* PBP2) or B3 (prototype: *E. coli* PBP3) is linked to a PB core of subclass B2 or B3, respectively. In Gram-positive bacteria, an n-PB core of subclass B1 (prototype: *Enterococcus faecium* PBP3), B4 (prototype: *S. pneumoniae* PBP2x), or B5 (prototype: *S. pneumoniae* PBP2b) is linked to a PB core of subclass B1, B4, and B5, respectively.

This unique combination of the n-PB and PB cores indicates that they have different functions in cell morphogenesis (n-PB module) and peptidoglycan crosslinking (PB-module). The **Gram-negative** PBPs of subclasses B2 and B3 are paralogous, and the **Gram-positive** PBPs of subclasses B1, B4, and B5 are also paralogous. In contrast, the **Gram-negative** PBPs of subclasses B2 or B3 may be orthologous to the **Gram-positive** PBPs of subclass B5 or B4, respectively.

The **Gram-positive** PBPs of subclass B1 have no equivalent in the **Gram-negative** bacteria. They are endowed with unique properties, and they represent an important mechanism of resistance to penicillin. These PBPs have a very low affinity for the drug. They allow the strains that (over) produce them to grow in the presence of penicillin at concentrations sufficient to inactivate the PB modules of all the other PBPs of class A and class B. To all appearances, they are able to perform the basic functions required for cell-wall peptidoglycan assembly in a cell cycle-dependent fashion in conjunction (presumably) with the transglycosylase-n-PB module of class A PBPs (or with monofunctional transglycosylases).

The question of how the class B PBPs function in cell morphogenesis is still open. Yet the unique amino acid sequences of their n-PB modules (10) and the three-dimensional structure of *S. pneumoniae* PBP2x (12) are worthy of reflection. The n-PB cores of all class B PBPs have three conserved motifs. In *S. pneumoniae* PBP2x, motif 1 starts at residue 76 and has the sequence Arg-Gly-x-x-x-Asp-Arg-Asn-Gly, motif 2 starts at residue 186 and has the sequence Arg-x-Tyr-Pro-x-Gly, motif 3 starts at residue 215 and has the sequence Gly-x-x-Gly-x-Glu-x-x-x-Asn, and Gly258 is the amino end of the intermodule junction site. The n-PB module of PBP2x is shaped like a pair of sugar tongs; motifs 1, 2, 3 and the amino half of the intermodule junction site are located in the head of the sugar tongs (which fits into a noncatalytic groove of the PB module), and the long polypeptide stretch that extends between motifs 1 and 2 is well exposed at the surface of the protein.

Other class B PBPs probably adopt the same basic folded structure but with subclass- and species-specific variations. The acyl serine transferase-PB module of class B PBPs probably prescribes traits related to peptidoglycan crosslinking, and this activity might be regulated by the associated n-PB module itself, in conjunction with other components of the morphogenetic networks.

6. Penicillin-Oriented Evolution

Evolution is occurring before our eyes. The massive use of b-lactam antibiotics functions to fuel the emergence of b-lactamases of widely varying specificities by the alteration of a limited number of amino acid residues in the wild-type enzymes (17). Oriented evolution also results in the spread of low-affinity PBPs of subclass B1 among enterococcal and staphylococcal pathogens (18, 19). Strains close to the squirrel *Staphylococcus sciuri* might be the source of the PBPqa-encoding gene in human MRSA (methicillin-resistant *S. aureus*) strains (20). Multimodular PBPs also evolve into variants having a decreased affinity for the drug. Penicillin-resistant *S. pneumoniae* strains possess PBPs that are reduced-affinity variants of PBP1a of subclass A3, PBP2x of subclass B4, and PBP2b of subclass B5 (21). These altered PBPs are the products of **mosaic genes** in which **sensitive** sequence blocks are replaced by homologous, **resistant** blocks from related, naturally penicillin-resistant species by transformation and recombination events (22). The origin of the **foreign** DNA sequences is unknown, but several sources are probably involved.

7. Penicillin Sensory Transducers

BlaR is a bipartite protein involved in the inducibility of b-lactamase synthesis in *Bacillus licheniformis* (23). An amino terminal module is embedded in the plasma membrane via a **four-helix**

bundle. Loops connecting the transmembrane segments are exposed on the outer and inner faces of the membrane, respectively; the carboxy end of the fourth transmembrane segment is fused to an extracellular penicilloyl serine transferase module. This module possesses the three typical motifs described earlier (Ser402-x-x-Lys, Tyr476-x-Asn, and Lys539-Thr-Gly), and it shares 32% identity with the Oxa-2 class D b-lactamase.

As an independent entity, the penicilloyl serine transferase module of BlaR is a high-affinity PBP. As a component of the full-size BlaR, it adopts a different conformation, and reception of the penicillin-induced signal does not involve penicilloylation of the active-site Ser402. These properties suggest that a class D b-lactamase acquired a new property—penicillin binding—via local structural changes. Fusion of this PBP to another polypeptide then resulted in a hybrid that performs another function: gene regulation.

Signal emission in the cytosol is probably mediated by the intracellular loop that connects transmembrane segments 3 and 4. This loop has no recognizable site of **methylation**/demethylation and no recognizable site that could be associated with a histidine kinase, but it possesses the His-Glu-Leu-Tyr-His **consensus sequence** of a neutral zinc peptidase (see Metalloproteinases). This putative peptidase might adopt an active conformation in response to the signal transmitted via the four a-helix bundle. Following this hypothesis, BlaR would be another example of control of gene activity via proteolytic degradation of key regulatory proteins.

Penicillin receptors similar to the *B. licheniformis* BlaR are involved in the inducibility of the synthesis of b-lactamase and low-affinity PBP2a of subclass B1 in *S. aureus* (24). Gram-negative bacteria have developed a different mechanism. b-Lactamase synthesis is the result of the b-lactam-induced, peptidoglycan hydrolase-mediated deregulation of the peptidoglycan recycling process (25).

Pepsin, Pepsinogen

Pepsin is a carboxyl proteinase that is secreted from the chief (or peptic) cells that are part of the oxyntic glands, located on the lining of the stomach (1). It is synthesized as a 42.5-kDa zymogen precursor, *pepsinogen*, which is stored in the chief cells and released in response to neural and hormonal signals activated by eating. Once pepsinogen enters the acidic environment of the stomach, it undergoes a change in conformation that exposes its active site. This allows pepsinogen to catalyze the hydrolysis of the peptide bond between residues 16 and 17 of its own polypeptide chain. Subsequently, residues 17 to 44 are also removed proteolytically, and the resultant 35-kDa protein is pepsin. It is active at acidic pH and has broad specificity, with preference for hydrolysis of peptide bonds involving tryptophan, phenylalanine, leucine, and methionine residues, especially when they are adjacent to other **hydrophobic** amino acids. It is often used to digest proteins under acidic conditions in order to obtain peptides linked by disulfide bonds. Disulfide rearrangement, which can sometimes occur at neutral or alkaline pH, is minimized at acidic pH. Pepsinogen is stable at neutral pH and becomes activated at acidic pH, whereas pepsin is stable at acid pH but becomes inactivated at neutral pH.

Pepsin is inhibited by pepstatin, *p*-bromophenacyl bromide, diazoketones, and various epoxides. It has been reported that pepsin can catalyze transpeptidation reactions, which could, in principle, cause confusion when trying to sequence proteins. This has not been a major problem in practice, however.

Pepstatin

This naturally occurring peptide analogue was discovered by screening culture filtrates of the mold actinomyces for inhibitors of the **proteolytic** enzyme **pepsin** (1). It also inhibits other carboxyl proteinases, but not serine, **thiol**, or metalloproteinases. Its chemical structure is: isovaleryl-valyl-valyl-statine-alanyl-statine [where statine is the unusual residue (3*S*, 4*S*)-4-amino-3-hydroxy-6-methylheptanoic acid] (Fig. 1, see top of next page). Analogues of pepstatin (also called pepstatin A) have been obtained from ***Streptomyces*** strains with variable inhibitory properties toward different carboxyl proteinases, and a range of synthetic pepstatins have been prepared that have quite remarkable affinities for specific carboxyl proteinases (2). Pepstatin is often used to prevent unwanted proteolysis when isolating proteins under acidic conditions. It is effective at a concentration of about 1 mg/mL.

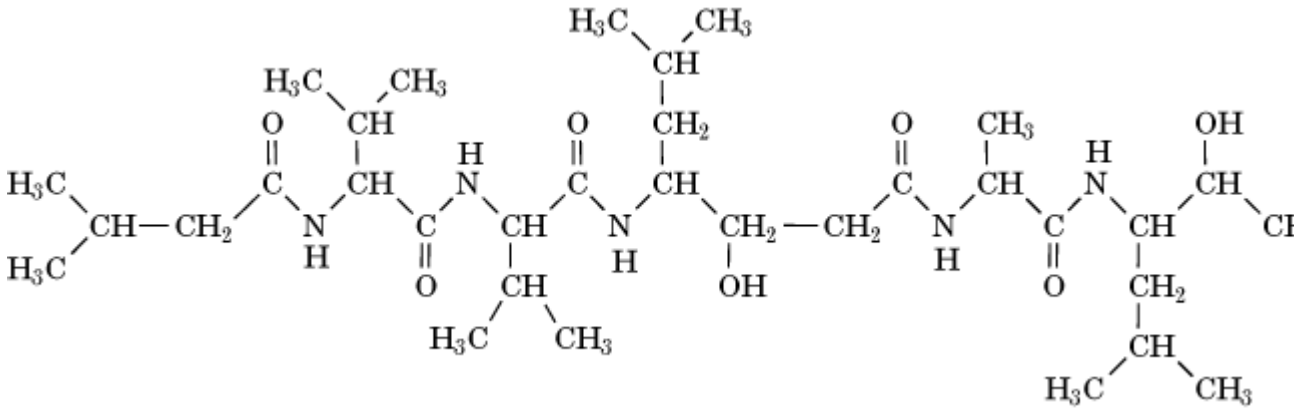
Peptidases

Peptidases are enzymes that catalyze the hydrolysis of peptide bonds—that is, the -CONH- bonds that link amino acids in peptides, **polypeptides**, and proteins. According to the Enzyme Commission of the International Union of Biochemistry and Molecular Biology, they are Class 3, subgroup 4 (peptide hydrolase) enzymes (E.C. 3.4). Some peptidases only act on small substrates—di-, tri-, or oligopeptides—while others act preferentially on protein substrates. The latter are more properly referred to as proteinases (also known as proteases, proteolytic enzymes). Some peptidases cleave peptide bonds involving the amino acids at either the beginning or end, i.e., the amino terminal (N-terminal) or carboxy terminal (C-terminal)—of a peptide chain. They are therefore called *exopeptidases* and, depending on their particular specificity, are either aminopeptidases or carboxypeptidases. Other peptidases cleave internal bonds in a polypeptide chain and are called endopeptidases. Most peptidases are relatively specific and will only act at peptide bonds in which a particular amino acid or type of amino acid (acidic, basic, neutral, **hydrophobic**, etc.) contributes either the -CO or -NH group. Some have broad specificity, especially when acting on unfolded, **denatured** proteins, but they can be highly specific or not active at all with folded, native proteins.

Figure 1. Chemical structure of pepstatin [isovaleryl-valyl-valyl-(3*S*, 4*S*)4-amino-3-hydroxy-6-methylheptanoyl-alanyl-(amino-3-hydroxy-6-methylheptanoic acid], a transition-state analogue inhibitor of certain carboxyl proteinases, such as p cathepsin D, and many microbial carboxyl proteinases. Because its structure resembles the tetrahedral intermediate that f substrate hydrolysis, it forms a tightly bound complex with the active site of each of these enzymes. See Pepstatin, previ



Peptidases have myriad functions. They activate or inactivate peptide hormones; they degrade dietary proteins and peptides; they participate in structural growth and remodeling by degrading collagen and other structural proteins; they protect against infectious agents; and they induce blood clotting. They regulate blood pressure, play an important role in fertilization, and control the cell cycle. They are ubiquitous and enormously diverse. As might be expected, inappropriate peptidase activity could have devastating consequences, so there are numerous peptidase inhibitors and other biological means of curtailing peptidase activity (see Proteinase Inhibitors).

While all peptidases catalyze peptide bond hydrolysis, they do not all do this the same way. In order to act under various conditions, four different mechanisms have evolved, and peptidases are classified as carboxyl proteinase, thiol proteinase, serine proteinase, and metalloproteinase, depending on the particular mechanism they employ. Even within these classes, there are many thematic variations such that it seems that there are almost as many peptidases as there are peptides.

Peptidases have a host of commercially significant uses ranging from “clot busters” (both in blood vessels and in drain pipes) to meat tenderizers. Peptidase inhibitors represent a multibillion dollar pharmaceutical market where they are important for controlling high blood pressure, as well as preventing the progress of acquired immune deficiency syndrome (AIDS).

Peptide

Peptides, sometimes referred to as oligopeptides, are oligomers in which the repeating units are amino acids. Peptides have a defined sequence of amino acids that are linked together by formation of peptide bonds. In contrast to **polypeptides** and proteins, peptides consist of a small number of amino acids. The distinction between a peptide and a polypeptide is somewhat arbitrary, but generally a peptide has between 2 and 50 amino acid residues. A peptide of two amino acids may be more specifically referred to as a *dipeptide*, three repeating units as a *tripeptide*, four repeating units as a *tetrapeptide*, and so on.

Most peptides are unstructured, described as having a **random coil conformation**, but others have highly ordered **secondary** and tertiary structure similar to that observed in larger proteins. The more structured peptides often incorporate disulfide bonds. Many peptides have important biological functions. For example, the pentapeptide leucine-enkephalin (Fig. 1) is a neurotransmitter with opiate-like activity; the hormone insulin is formed from two disulfide cross-linked peptide chains;

and the major toxins from venomous spiders and cone shells are disulfide-rich peptides (Fig. 2). Naturally occurring peptides are usually produced by hydrolysis or cleavage of precursor proteins, through the action of peptidases or proteinases.

Figure 1. Chemical structure of the pentapeptide Leu-enkephalin, which has the sequence Tyr–Gly–Gly–Phe–Leu.

Peptide Antibiotic Biosynthesis

Peptide antibiotics include a variety of peptide structures with diverse biological properties (1). Historically, the first antibacterial compounds identified were peptides (penicillin, **gramicidin**, tyrocidine). New such peptides have been characterized steadily, including **actinomycin** (antitumor); cyclosporin (immunosuppressant); destruxin (insecticide); ferrichrome (siderophore); pepstatin, antipain, and bestatin (proteinase inhibitors); microcystin (**phosphatase** inhibitor); and defensin and magainin (anti-infectives).

Their biosynthesis may occur either (i) on ribosomes by direct transcription, translation, and **post-translational processing** of peptide antibiotic **genes** (see **Protein biosynthesis**)—for example, nisin—or (ii) without ribosomes but on a multienzyme system, using the **thiotemplate mechanism**. The structural complexity of peptide antibiotics ranges from modified amino acids to **polypeptide** chains of up to 50 amino acid residues (2). Ribosomal systems can incorporate only the L isomer of the 20 normal amino acids, plus selenocysteine, while there are no such limitations to the nonribosomal systems, which can use hydroxy acids, fatty acids, and amines. Nevertheless, peptides of ribosomal origin are known to include D amino acid residues, cyclic side chains, and disulfide bonds. All nonribosomal peptides also originate from linear precursors, but a variety of types of cyclization are known. Identification of the biosynthetic origin is crucial for subsequent genetic analysis, and the structural properties of compounds arising from the two types of pathway are compared in Table 1.

Table 1. Structural Features of Peptide Antibiotics of Ribosomal and Nonribosomal Origin

Feature	Ribosomal Path	Nonribosomal Path
Size (amino acids)	No size limitation	2 to about 50, 4 to 10 dominating
amino acid constituents	21 protein amino acids and modified amino acids	Various types of amino acids modified amino acidsincluding 2-, 3-, and 4-amino compounds (more than 300 known)
D-Amino acids	Not more than one, epimerized post-translationally	Often several, either incorporated directly,or epimerized during synthesis
Non-amino acid constituents	Acyl residues, amines originating from decarboxylation	Various acyl residues, including aromatic acids,hydroxy acids
Cyclic structures	Rare; frequent disulfide cycles, thioether cycles	More frequent than linear structures, variouspeptide bond cyclizations, but also lactones
Modifications	Hydroxylation,	*N*-Methylation,

	dehydration (Ser, Thr), side-chaincyclization (Cys to thiazoles, Thr to oxazoles, Glu to pyroGlu)	hydroxylation,side-chain cyclization (Cys to thiazole), glycosylation, side-chain crosslinking(aromatic rings)
Unusual constituents	Not known	Urea type of peptide bond, phospho-amino acids,amino-modified fatty-acid-derived components (lipopeptides), mixed polyketidestructures
Biosynthesis	Gene can be identified; consider splicing, processing,and posttranslational modification; often prepropeptides detected	Nonribosomal enzyme systems present; peptidesfamilies are frequent in the same or related organisms, biosynthesis of rareprecursors needed
Sources	Various animals and plants, sometimes bacteria	Mainly bacteria and lower fungi, occasionallyplants and insects

1. Ribosomal Biosynthesis

Peptide antibiotics that are synthesized initially on ribosomes comprise a rapidly expanding field of research (3, 4). The compounds synthesized in this way range from linear polypeptide chains to compact multicyclic peptides with several disulfide bonds or thioether linkages (lantibiotics). Their genes are usually isolated by **reverse genetics**, and they usually reside within gene clusters, together with genetic information for their post-translational modification and export, and for resistance of the host to their actions. Genes for typical animal peptides, like defensins, are present in multiple copies with minor differences in sequence (5). The signals for their targeting and processing are critical for their functions in innate immunity. A peptide from the venom from the spider *Angelopsis aperta* is activated by **epimerization** of a specific residue (6).

Internal cyclizations other than disulfide bond formation have been restricted to bacterial sources, and the enzymes involved in formation of thiazolidines (microcin B) and lantibiotic ethers (dehydration of serine and threonine residues to dehydroalanine and dihydrobutryine, respectively, followed by addition of the thiol group of cysteine) are being characterized (7). The post-translational modification of these antibiotics takes place on a membrane-attached multienzyme complex, which also facilitates their export and their role in intercellular communication.

2. Synthesis by Peptide Synthetases

The biosynthesis of peptide antibiotics by nonribosomal systems, on peptide synthetases, requires a considerable amount of information, and these multienzyme complexes are among the largest protein structures known, with masses up to 1700 kDa, corresponding to a 45.5 kbp open reading frame, to synthesize cyclosporin (see Gene Structure). Synthesis of each amino acid residue of such a peptide antibiotic requires a minimum of three catalytic **domains**: (i) the activating adenylate domain, (ii) the carrier protein, and (iii) the condensing domain, which collectively are referred to as a module (see Thiotemplate Mechanism Of Peptide Antibiotic Synthesis). The nonribosomal code for the amino acid sequence of the peptide is determined by the substrate specificity of the activating domain. Selection and activation of the appropriate amino acid is followed by its attachment as a thioester to the 4′-phosphopantetheine prosthetic group attached to the adjacent carrier domain (8); it is then linked covalently to the next amino acid, on the adjacent module. The thioester intermediates

may be subjected to various modifications, such as epimerization, *N*-methylation, and hydroxylation, catalyzed by additional domains introduced into the module structure. The intermediates in the reaction are covalently attached to the peptide synthetase, and only the final product is released. Examples of known peptide synthetases are compiled in Table 2.

[a] The abbreviations used are: P, peptide; C, cyclopeptide; L, lactone; E, ester; R, acyl; M, modified. The structural types are defined by the number of amino-, imino-, or hydroxy acids in the precursor chain. The ring sizes of cyclic structures are indicated in the number following C, L, or E, defining the type of ring closure. The abbreviations used for unusual amino acids and other compounds are listed in the abbreviations footnote on the first page.

Current applications of such enzyme systems are the enzymatic synthesis of peptide analogues, taking advantage of the relatively low stringency of the nonribosomal code—that is, the specificities of the peptide synthetases (9). Efforts are being made to alter the modular construction of peptide synthetases so as to generate new enzyme systems capable of synthesizing novel peptides.

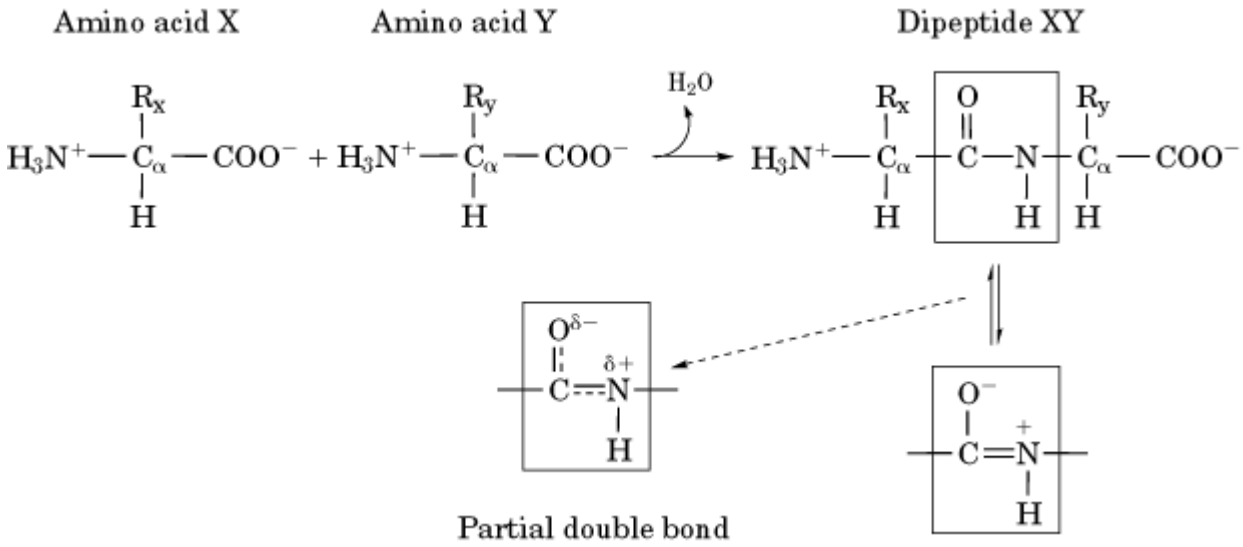
Peptide Bond

The peptide bond is the chemical link that connects amino acids to form the polypeptide chains of peptides and proteins. The repeating units of these linear polymers, the 20 amino acids, are naturally occurring chemical entities comprising an amino group, a carboxyl group, a hydrogen, and a side chain of variable chemistry. These four groups are connected to a central carbon atom, denoted C_a; (or C_{alpha}) (Fig. 1). Peptide bonds are formed by condensation of the carboxyl group of one amino acid with the amino group of another amino acid, giving rise to a dipeptide. Repeated condensation of amino acids produces tripeptides, tetrapeptides, and so on. Proteins can incorporate many thousands of peptide-linked amino acids.

Figure 1. General scheme for formation of a dipeptide XY from two amino acids, X and Y, by reaction of the carboxyl group of amino acid X with the amino group of amino acid Y. The R group attached to C_a; is variable, depending on the type of amino acid (R_x and R_y). The peptide bond of the dipeptide product is boxed, and its partial double bond character is depicted.

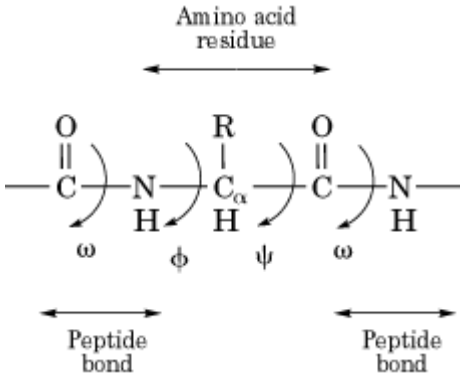


In vivo, peptide bond condensation occurs at the C-terminus of the growing polypeptide chain to produce proteins having specific sequences defined in the genetic code. This reaction is catalyzed in a process called translation, by enzymes of the cell's **protein biosynthesis** machinery. Synthetic peptides and proteins can also be produced by chemical peptide synthesis. In contrast to *in vivo* protein biosynthesis, **solid-phase synthesis** usually occurs by condensation of amino acids to the N-terminus of the growing polypeptide chain. Peptide bonds can be broken down, or hydrolyzed, by enzymes such as peptidases and proteinases.

Each peptide unit in a polypeptide chain has three chemical bonds. The central peptide bond is not

freely rotatable, because it has partial double bond character (Fig. 1). This imposes planarity on the peptide bond, so that only two discrete conformations are available. These two conformations, defined by the angle w (Fig. 2), are called the cis and trans configurations. Of these two, the *trans* configuration is energetically preferred, and is much more commonly observed, unless the following residue is proline (see Cis/Trans Isomerization).

Figure 2. Section of a polypeptide structure showing two peptide bonds (–CONH–) and one amino acid residue (–NH–C_a;(R)(H)–CO–). The dihedral angles w, f, and y of the peptide backbone are labeled.



The single bonds on either side of the peptide bond are rotatable. The angle around the N–C_a; bond of a peptide is called phi (f), and the angle of the C_a;–C bond is called psi (y). Certain combinations of f and y, defined as the "allowed" regions of a f/y or Ramachandran Plot, are preferred and energetically favored over others. The allowed f/y angles define the conformations of regular **secondary structure** such as a-helix or b-strand that are stabilized by backbone hydrogen bonds between peptide bond units.

Peptide Hormones

The first identified peptide hormone, secretin, was found in 1902 by Baylis and Starling. They discovered that the bioactive compound stimulated the secretion of saliva, and thus they named the factor secretin. Because the compound was produced by one tissue and transported by the blood to a distant organ, where it stimulated the saliva secretion, it was called a hormone based on the Greek word *hormao*, which means "to stimulate". Since then it has been found that many physiological functions in the body are controlled by such communication with the endocrine and neural systems (1). That is, the regulation, integration, or coordination of various metabolic activities and bodily functions of tissues and organs involve the synthesis of low concentrations (micromolar to

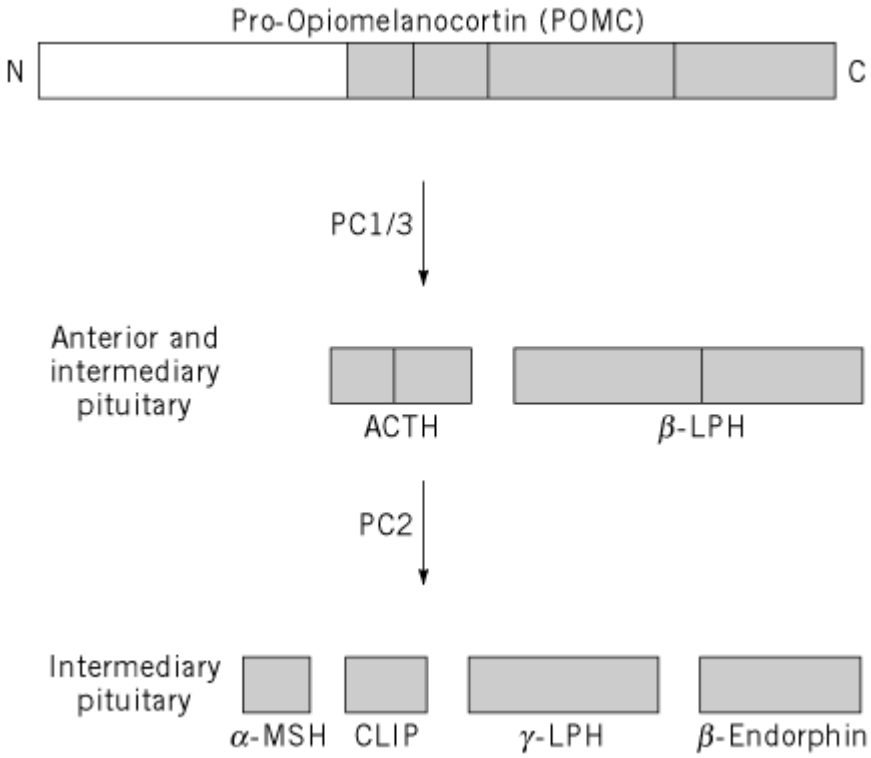
picomolar) of biochemical signals or messengers that can be disseminated and transported throughout the organism, to effect the required changes through **receptors** at distant target cells. Such regulation of function also requires that the production of the hormone be self-limiting; consequently, it requires both negative and positive feedback loops and interactive modulation of G-coupled systems (see GTP-Binding Proteins) of neurotransmitter (see Neuropeptides) systems to affect functional balance, or homeostasis. Through modulation, downregulation, desensitization, upregulation, and receptor cross talk, hormones in some cases interact with the central nervous system (CNS) to influence neuronal function, to alter behavior, and to control other hormones. In other cases, one function can be influenced by several different hormones. All operate primarily under the hierarchical control of the central nervous, endocrine, and **immune systems**. Although hormones were originally defined as material that is secreted by endocrine glands, the term is now often applied to hormones that are expressed in other tissues or are formed from precursors located in other tissues. For example, angiotensin, which maintains the water and electrolyte balance and controls blood pressure, is produced by converting angiotensinogen in the blood with renin secreted by the juxtaglomerular cells in the kidney.

1. Biosynthesis, Secretion, and Interaction with Receptors

A peptide hormone is first synthesized on the ribosome as a pre-pro-hormone following transcription and translation of the genetic information (2) of the messenger RNA. This precursor of high molecular weight contains an *N*-terminal signal peptide, which guides the protein to the rough endoplasmic reticulum (ER), where the signal peptide is removed proteolytically by a signal peptidase, in a form of co-translational processing. The pro-hormone, or hormone precursor (see Polyproteins), that is produced usually does not possess much biological activity. Most pro-hormones and pro-neuropeptides contain within their polypeptide chains several smaller peptides with various biological activities. These pro-hormones normally undergo **posttranslational processing**, **protein folding**, disulfide bond formation, or chemical modification, such as N-glycosylation, O-glycosylation, **acetylation**, or amidination, when they are processed through the Golgi apparatus. The pro-hormones undergo specific proteolytic cleavage by endoproteinases or processing enzymes and then are sorted (3) into **secretory granules**. The polypeptide hormone is stored in the secretory vesicles and, in some cases, may undergo further processing by enzymes.

Almost all of the cleavage sites in the precursor protein contain a dibasic sequence, Lys–Arg or Arg–Arg, that is recognized by the processing enzymes. The **kex-2** proteinase of yeast, kexin, was the first enzyme found to cleave at Lys–Arg and Arg–Arg sequences. Subsequent use of the *kex-2* gene as a probe (see Probe Hybridization) led to the cloning of similar gene products from mammalian cells (4). Investigations demonstrated that these convertases, which cleave at the *C*-terminal side of Lys–Arg and Arg–Arg sequences, play an important physiological role. Differential processing of a single precursor protein in two different tissues can now be explained by the presence or relative concentrations of different posttranslational enzymes in tissues. For example, pro-opiomelanocortin (POMC) is differentially processed in the anterior and intermediary pituitaries (5). In the anterior and intermediary pituitary, ACTH and b-LPH are the predominant products because PC-1/3(pro-protein convertase) is most prevalent. In the intermediary pituitary, however, alpha-melanocyte-stimulating hormone (a-MSH), corticotropin-like intermediary peptide (CLIP), and b-endorphin are secreted because PC-2 is more prevalent there (see Fig. 1).

Figure 1. Processing of the pro-opiomelanocortin (POMC), to produce ACTH (adrenocorticotropic hormone), B-LPH (b-lipotropin), A-MSH (a-melanocyte stimulating hormone), CLIP (corticotropin-like intermediary peptide), g-LPH, and b-endorphin. The pro-protein convertase PC-1 / 3 carries out the initial cleavages in the anterior and intermediary pituitary, whereas convertase PC-2 is present primarily in the intermediary pituitary.



The hormone within the secretory vesicles is released from the vesicles by exocytosis upon stimulation by extracellular signals provided by neurotransmitters or other hormones, wherupon the hormone is transported by the blood or extracellular fluid to the target cells. Once a hormone is secreted, it usually binds to a specific plasma protein carrier, which **prolongs** its half-life because the complex reduces the rate of hormone destruction by plasma proteinases.

The release of the peptide is normally controlled by a feedback mechanism. In the case of ACTH, for example, the secretion of corticoid is stimulated by ACTH, but on the other hand, corticoid suppresses CRF and ACTH secretion from the hypothalamus. In turn, ACTH suppresses CRF secretion.

The type of endocrine hormone secretion is classified by the distance between the cells that secrete the peptide and its target cells. Classically, endocrine hormones act at a distant target, while paracrines act upon nearby cells, and an autocrine acts upon the cell that secreted it. Many hormones often function in all three ways, however, making such distinctions difficult. Hormones secreted by neural cells and neurons are called neuroendocrines.

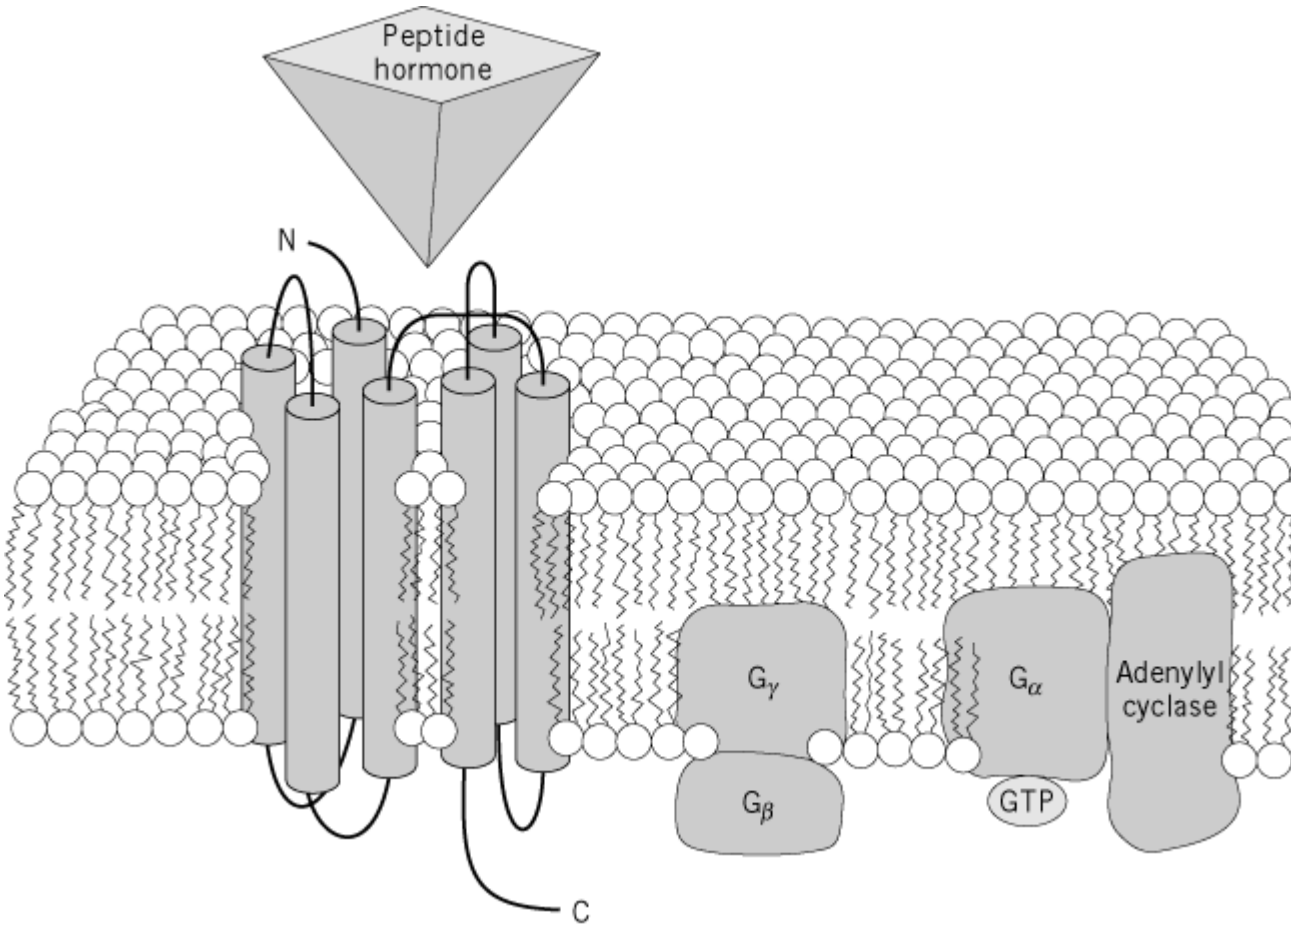
When the hormone reaches its target cell, it binds to its specific receptor in the cell membrane. Each receptor is a membrane protein or complex and consists of three domains, (*1*) extracellular, (*2*) transmembrane, and (*3*) intracellular domains. The tertiary structure of the receptor is essential for specific binding of the ligand. This interaction induces structural changes in the receptor that result in activation of an intracellular enzyme that generates a transient increase in concentration of a signaling compound (see Signal Transduction), such as cyclic AMP (cAMP), cyclic GMP (cGMP), **diacylglycerol** (DAG), or inositol triphosphate, IP3. The elevated concentration of these second messengers and of the **phosphorylated** forms of proteins triggers the appropriate metabolic response. Proteins are phosphorylated on serine, threonine, or tyrosine residues by cAMP-dependent protein kinase (PKA), DAG-activated protein kinase C (PKC), or **tyrosine kinases**.

Many hormone receptors have a common structure in which the single polypeptide chain passes back and forth through the membrane seven times, forming seven transmembrane alpha-helices. For these

receptors, the hormone-binding signal is transmitted or transduced to the interior of the cell by binding the receptor-ligand complex to a series of G-proteins (see Heterotrimeric G Proteins). G-proteins bind GDP or GTP. When G-proteins bind to their receptors, GTP exchanges with GDP bound to the a-subunit of the G-protein. The Ga–GTP complex binds adenylate cyclase, activating the enzyme. The activation of adenylate cyclase produces cAMP in the cytosol and leads to the activation of PKA and the phosphorylation of enzymes. Many classes of G-proteins exist, such as G_s and G_i, stimulatory and inhibitory G-proteins, respectively. A second class of G-protein coupled-receptor synthesizes DAG and IP3 as second messengers. The hormone-receptor complex interacts with G-proteins, and this is followed by the G-protein activation of phospholipase C-g (PLCg). PLCg hydrolyzes phosphatidylinositol bisphosphate to IP3 and DAG. IP3 binds to the endoplasmic reticulum and opens the calcium channels so that stored calcium flows into the cytosol and activates enzymes. On the other hand, the DAG binds and activates PKC and also opens **calcium channels**. PKC phosphorylates serine and threonine residues, thereby modulating the catalytic effect of the corresponding enzymes.

One receptor, that of ANF (atrial natriuretic factor), is coupled to the production of cGMP by guanylate cyclase. Another ANF receptor lacks guanylate cyclase activity and is thought to play a role in the clearance of ANF. Yet another type of receptor is the heterotetrameric insulin receptor. It is composed of two a- and two b-subunits. The a-subunits protrude outside the membrane and contain the binding sites, while the b-subunits penetrate through the membrane in a single transmembrane a-helix and contain the tyrosine-kinase activity. When insulin binds to the receptor, intramolecular phosphorylations are triggered, and this autophosphorylation enhances its ability to phosphorylate enzymes that induce the physiological response (Fig. 2) (see also Heterotrimeric G Proteins).

Figure 2. General mechanism of action of peptide hormones that bind to receptors and thereby alter the activity of adeny cyclase through heterotrimeric G-proteins. The peptide hormone binds to the extracellular part of the receptor embedded plasma membrane. This is transmitted to the abg heterotrimeric G-protein, which dissociates in the Gbg-dimer and the G subunit, which binds to adenylate cyclase and alters its activity accordingly.



2. Methods of Isolation and Structure Determination

The structure of a peptide hormone was first demonstrated by de Vigneaud in 1953, when he determined the structure of oxytocin and confirmed it by total chemical synthesis. In 1954, the structure of insulin was determined by Sanger. The chemical structure of secretin was not determined until 1966, 60 years after its initial discovery. Because peptide hormones exist in such small concentrations, it was difficult then to isolate, purify, and analyze them. Subsequent development of better detection methods with higher sensitivities, such as radioimmunoassay (RIA), made possible the rapid isolation and structure determination of a large number of peptide hormones and neuropeptides. Later gene cloning provided the sequence of the complementary DNA of hormone precursors by using a DNA probe (see Probe Hybridization) based on the known peptide sequence. This also provides the structure of previously undetected protein **isoforms**. For example, in the case of endothelin-1 (ET-1), which had been isolated from cultured endothelium cells of blood vessels, screening of the human chromosomal DNA library revealed the existence of genes for three isoforms: ET-1, ET-2, and ET-3. Each isoform consists of 21 amino acid residues, and they have high sequence homology. Another method of detecting new peptide hormones is by screening the DNA sequence of the precursor protein. In this case, another new peptide hormone that is linked in the precursor molecule can be detected. In the precursor of glucagon, two amino acid sequences that resemble glucagon were found, GLP-1 and GLP-2. Another example is the case of calcitonin gene-related peptide (CGRP), which stimulates the formation of cAMP. Analysis of the gene of the precursor protein of calcitonin (CT), which modulates serum calcium concentrations, revealed that the CT gene consists of five **introns** and six exons. As a consequence of alternative splicing of the RNA transcripts (see Transcription), the mRNA for the CT precursor is found in the thyroid but the mRNA for CGRP is formed in the nervous system.

As a result of the progress in gene technology, the chemical structures of a large number of hormone receptors have now been determined. Most of their intrinsic ligands also have been identified. However, there are still receptors for which no ligands are known. New techniques are being developed to search for new bioactive peptides that serve as ligands for such orphan receptors. In 1998 (6), a prolactin-releasing factor or peptide was found in the search for the ligand for one such orphan receptor that is expressed in the human pituitary. The 31-residue peptide stimulates the pituitary to release prolactin.

3. Synthesis and Conformational Analysis

After the isolation and structure determination of a peptide hormone has been achieved, the peptide is often chemically synthesized to confirm the structure. With the synthesized material, structure-activity relationships can be explored to design drugs for treating individuals with peptide-hormone deficiencies or with malfunctioning peptides. The technique of **combinatorial chemistry** has recently made it possible to synthesize millions of compounds and to screen them for activity rapidly and efficiently (7). In addition, gene technology has provided a means of producing human peptide sequences, such as insulin, in *Escherichia coli*, yeast, or other expression systems. This has afforded the opportunity to produce peptide hormones and receptors that are uniformly labeled with ^{13}C and ^{15}N isotopes for nuclear magnetic resonance (NMR) analysis. These labeled compounds can then be used to investigate the interaction between ligand and receptor, as well as to study the conformational changes that occur upon binding. Consequently, the ongoing study of the tertiary structures by NMR and X-ray crystallography is now providing more details regarding the mechanisms of hormonal action.

Peptide Libraries

Peptide libraries were first introduced during the mid-1980s as a means to elucidate the details of **antibody–antigen** recognition (1, 2). Prior to that time, epitope mapping required fragmentation analysis, either at the protein or DNA level, which was a laborious and time-consuming process. Geysen et al. (1) demonstrated that synthetic peptide libraries could be prepared and screened by enzyme-linked immunosorbent assay (ELISA) to elucidate antibody–epitope recognition to the resolution of a single amino acid residue. This was the first case in which a problem in molecular recognition was elucidated using a synthetic library and is often cited as a critical development in the emergence of combinatorial libraries.

The first generation of synthetic peptide libraries was limited in size to a few hundred peptides, due to the need for each library member to be prepared as a discrete compound. However, the combination of mixture-synthesis techniques (14), reliable strategies for identifying active species from complex mixtures (3, 4), and advances in peptide sequencing methods quickly led to the routine preparation and screening of libraries containing millions of distinct peptide sequences. Several reports of ten-residue peptide libraries containing more than 10^{12} peptides have even appeared (5, 6). When coupled with an increasing availability of unnatural amino acid building blocks, peptide libraries of this scale and complexity became valuable tools for identifying novel peptide agents for a wide range of applications (eg, see Refs. 7 and 8). Soluble and solid-phase peptide libraries continue to find applications in the identification of **antigenic** determinants. In addition, they have been used to identify receptor ligands (5, 9-14), inhibitors of enzymatic activity (15), and novel antibacterial agents (3, 7, 14). Many of these applications have employed standard assay formats (eg, soluble activity or binding assays), requiring complex deconvolution or iterative synthesis and screening cycles to identify the active species from complex synthetic pools (see Combinatorial Synthesis).

Split synthesis methods for preparing one-bead, one-compound (OBOC) peptide libraries have overcome many of the limitations of standard assay formats and pooling strategies. Because each bead carries a single compound in amounts approaching several nanomoles, assays can be performed directly on the resin beads that detect interactions of bead-linked compound with a soluble target. A typical assay utilizes ELISA methodologies to indicate beads bearing compounds that interact with the target (16). Positive beads may be selected manually, or more sophisticated instrumentation may be employed to detect and isolate active beads (17). Alternatively, the OBOC format is amenable to off-bead assays through the use of cleavable linkers inserted between the peptide and the solid-phase support (18, 19). In an off-bead assay, the peptide is released from the resin bead, but proximity to the bead is maintained through use of a diffusion-limiting matrix or a positional array. For example, distribution of the library and a test cell line within a soft agar matrix, followed by partial peptide release, leads to the formation of locally high concentrations of peptide in the agar surrounding each bead. Zones of reduced cell growth (or any other reporting mechanism such as color change) surrounding single beads are used to identify peptides having the desired activity. Beads producing a zone of activity are removed and analyzed by standard Edman Degradation or **mass spectrometric** analysis to determine the sequences of the active peptides. This approach has been used for identifying peptide ligands for G-protein-coupled receptors (20), as well as cytotoxic peptides that may have application as anticancer agents (19). This represents but a few examples of the unique screening methods that have been developed using peptide chemistry coupled with the OBOC library format. Other notable examples include the use of a fluorescence-activated cell sorter (FACS) (17) (see Flow Cytometry) to identify active beads, as well as direct visualization of cancer cells binding to peptides on beads (21).

The initial excitement surrounding synthetic peptide libraries has been tempered in recent years. Peptides are linear, highly flexible polymers with fixed side-chain spacing. In contrast, most proteins adopt complex three-dimensional **structure** that place active chemical groups in positions that cannot be approximated by linear peptides. As a result, many targets fail to yield hits from short peptide libraries. The introduction of constraints into the peptide chain, including cyclization or use of domain scaffolds with defined structural propensities (Fig. 1**a**), may increase the success rate for some targets. In addition, altering the polymeric backbone can change the spacing of the side chains (22-25). Although unnatural amino acids can be used to shift the side-chain spacing (eg, b-amino acids), the problems enumerated above associated with a linear and flexible polymer remain. A wide range of peptidomimetics that employ novel backbones have emerged to address this issue (Fig. 1**b**) (26-28). Such compounds also address a second major criticism of peptides: They are ill-suited for *in vivo* applications due to poor pharmacokinetic properties. By utilizing building blocks with physicochemical properties compatible with uptake and adsorption, peptidomimetics have moved a step closer to lead compounds for drug discovery. The true utility of peptidomimetics for drug

discovery remains unknown, but their potential for use as research tools is high.

Peptide Mapping

Peptide mapping allows rapid overall evaluation of a **protein**'s primary structure from limited analysis of the **peptides** produced by **proteolysis** . Only a single amino acid difference between two peptides caused by mutation or **posttranslational modification** alters the physical properties of the peptide in which that difference occurs. So peptide mapping is a very sensitive way of detecting differences between closely related proteins. The peptides produced by a specific proteinase are separated into a pattern ("peptide map"), and the maps of related proteins are compared. Single differences, such as the Glu/Val difference between normal/**sickle cell hemoglobins** that was early recognized by peptide mapping (1) or the relationships between **isozymes** are found rapidly (2). Subsequent refinements in the methods and resolution of mapping produced excellent one- and two-dimensional (2-D) techniques that have been reviewed (3) and much used. The classical peptide mapping methods of two-dimensional **fingerprinting** and Cleveland maps are described in those articles. These classical approaches are still practical when the amounts of protein are sufficient, but molecular biology now centers on different approaches.

One extension increases the sensitivity, as required by present-day and future needs, to evaluate proteins available only in very small amounts. This has become possible by modern separation techniques, such as capillary **HPLC** (4), **capillary electrophoresis** (5), and high-resolution two-dimensional gel electrophoresis (6, 7). A further extension is to rely on mass spectrometry, using laser desorption instruments, triple quadrupoles, ion-trap devices, or other techniques, and perform the mapping, detection, and analysis in one step. In this manner, using entire peptide mixtures or preselected fragments, direct determination of the total masses of peptide fragments from a protein gives a unique "fingerprint" and is expected soon to be the mapping method of general choice. Combined with databases of peptides from all known proteins, it allows direct identification of any protein that has been characterized from the same or a closely related source (8-10). Then, mass spectrometric peptide mapping and simultaneous data bank screening will constitute a powerful technique as a descendant of the classical peptide mapping idea. In the near future, when crucial **genomes** are completely sequenced, the work remaining will center on identifying of each gene product and on proteome analysis to correlate **gene expression** with predicted protein structures stored in data banks.

1. Liquid chromatography

When reverse-phase HPLC was introduced in the mid-1970s, column **chromatographic** methods largely replaced paper and **thin-layer** plate separations. Further miniaturization and additional separation techniques have since continuously altered the separation methods (4), but the principle of peptide mapping by comparing efficient separations of peptides remains. In many cases, the resolution now is so high that complex peptide mixtures are separated completely by single-column chromatographic steps, thereby reintroducing one-step mapping methods. Instruments are also so

reproducible that repeated runs, even at different times, are virtually identical, thereby introducing mapping comparisons on the same instrument on different occasions. The principle of peptide mapping has gained further momentum which is expected to continue in present and future stages of proteome research with all of its gene product characterizations.

The principle is still to compare two or more expressed proteins by suitable proteolytic digests, followed by identical instrument runs, and subsequently evaluating all peak positions and heights of the resulting patterns. The era of peptide mapping has moved from spots or bands on solid supports and multiple but simultaneous separations to peaks and positions on microcolumns after successive separations. In addition to detecting structural differences, many other applications of this technique are now in use, for example, epitope mapping, determination of **glycosylation**, **phosphorylation**, or oxidation sites, and assignment of disulfide bonds. Peptide mapping is used extensively for quality control and characterization of **recombinant DNA** -derived products.

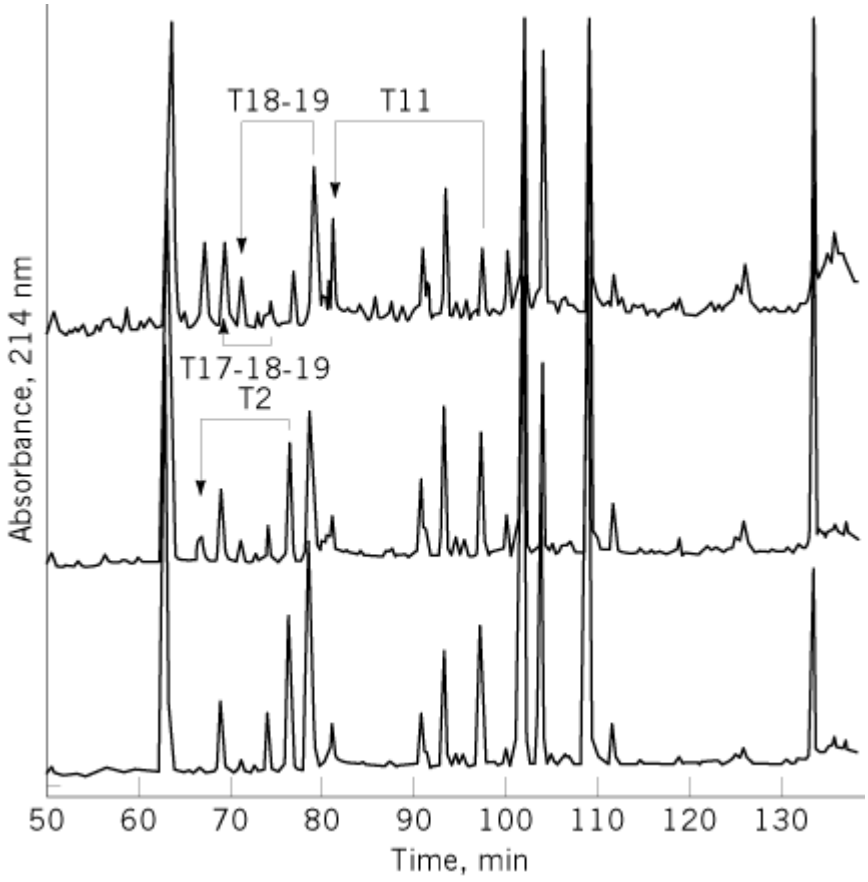
The major advantages in using microcolumn methods for peptide mapping are speed (often minutes), sensitivity (femtomole amounts, even with detection by **UV absorbance**), and ease of recovery for further characterization by amino acid analysis, Edman Degradation, and mass spectrometry. Several high-performance separation media have been developed that allow rapid HPLC resolution of peptides and proteins. The classical silica-based stationary phase HPLC column has been used extensively for nearly twenty years in numerous applications, and alternative materials, such as divinylbenzene cross-linked polystyrene (11), have since emerged. Frequently, the stationary phase is packed in microbore columns with a narrow inner diameter (on the order of 1 to 2 mm), with low flow rates (down to 40 µL/min), small elution volumes (40 to 60 µL), better detector response (5- to 20-fold higher) than conventional HPLC columns, and requiring only picomole quantities of protein. However, the current trend is toward further miniaturization and smaller inner diameters, leading to still lower detection limits, but also toward implementation of powerful detection techniques, such as Z-shaped flow cells for efficient UV absorbance, laser-induced **fluorescence**, electrochemical detection, and mass spectrometry.

Capillary reverse-phase HPLC is conducted with column inner diameters of between 350 and 75 µm and at flow rates of 4 to 0.2 µL/min. The low flow rates necessitate special technical solutions for recovering separated peptides. Such a system has recently been developed [MicroBlotter (12, 13)] for subpicomole peptide mapping after digestion of proteins in gels (14, 15) or on membranes after blotting (16) and for isolating peptides for microsequence analysis. The capillary outlet intermittently touches a strip of poly(vinylidene difluoride) (PVDF) membrane while moving along the strip. After sample collection, the PVDF strip is aligned with the chromatogram to excise spots that correspond to peptide candidates for structural analysis.

The protein to be analyzed is still digested with **trypsin**, Lys-C proteinase, or another suitable proteolytic enzyme. Protocols for microdigestion in small volumes (1 to 10 µL) and for recovering peptides from small samples (a few picomoles or less) have been developed (17). After digestion, the proteolytic peptides are derivatized with fluorescent tags (18) for detection. Generally, however, separation problems may arise from precolumn derivatization, and the digest is often injected directly onto the column after adjusting the pH to that of the mobile phase at the start of chromatographing. The most widely used solvent systems still consist of gradients of acetonitrile (often 0 to 60%, v/v) in aqueous trifluoroacetic acid (TFA) (often 0.1% v/v), but several other chromatographic solvents have also been suggested, for example, heptafluorobutyric acid instead of TFA, hydrochloric acid, sodium phosphate buffer at acidic or neutral pH, and ammonium bicarbonate, ammonium acetate, triethylammonium phosphate, or 1.0% sodium chloride at neutral pH. The most common detection technique is still UV absorbance, normally at both 214 and 280 nm, the latter for identification of peptides that contain tryptophan and tyrosine residues. Alkylation of cysteine with [^{14}C]- **iodoacetic acid** or 4-vinylpyridine is common to prevent disulfide formation and peptide aggregation and to promote convenient detection of cysteine-containing peptides in the resulting map. A practical example of capillary HPLC peptide mapping (Fig. 1) illustrates how *in*

vivo oxidation of a recombinant protein hormone after intravenous administration is detected (17).

Figure 1. Capillary HPLC tryptic peptide maps of recombinant human growth hormone (lower profile) and of the same protein recovered from rat serum taken 15 (middle profile) and 45 (upper profile) min after an intravenous dose of the preparation. Arrows link methionine-containing peptides (right in each pair) with their corresponding oxidized forms (left in each pair), showing the increase in oxidized form with time *in vivo*. The peptides were separated with a 320 µm×15cm reverse-phase (C_{18}) column. From Ref. 17 with permission.

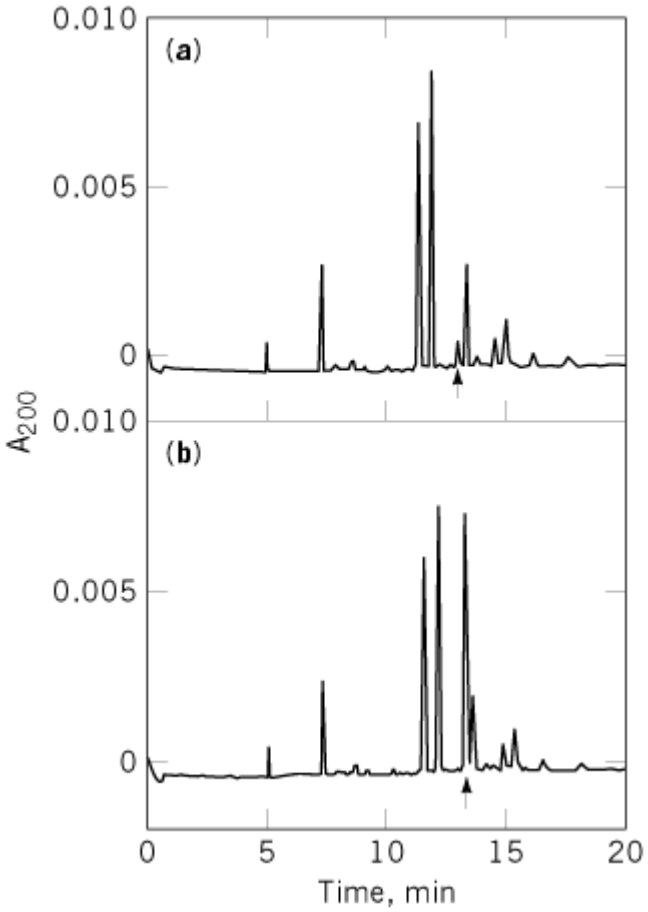


2. Capillary electrophoresis

Capillary electrophoresis in different separation modes, often capillary zone electrophoresis (CZE), provides a further powerful approach to peptide mapping (19), that has high sensitivity (low femtomole level) and short separation time (minutes). More than 10^6 theoretical plates are achieved and used to generate reproducible peptide patterns suitable for mapping experiments (Fig. 2). Capillary electrophoresis is also a suitable complement to reverse-phase HPLC for identifying peptides because the separation mechanisms are different, based on mass-to-charge ratio and **hydrophobic** interaction, respectively. Consequently, peptide fragments not resolved by reverse-phase HPLC are often completely resolved by CZE. Similarly, reverse-phase HPLC may resolve peptides not separable by CZE (21).

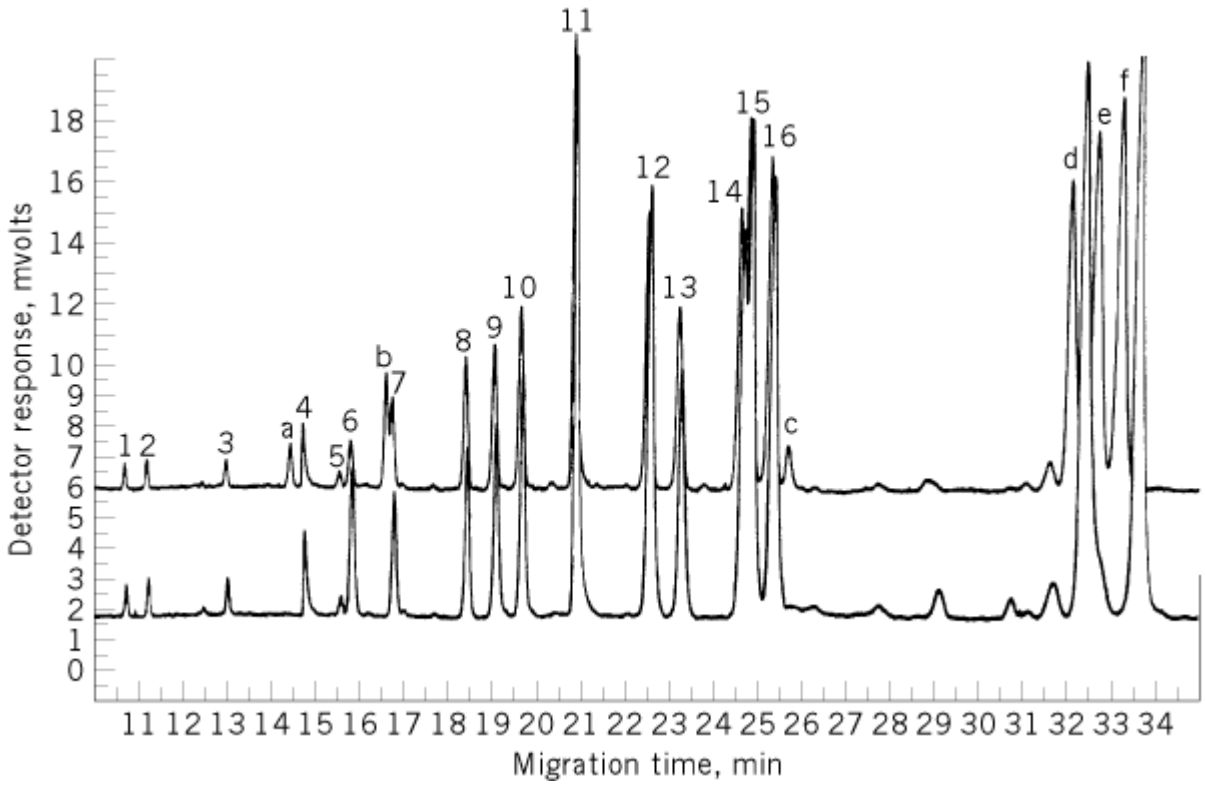
Figure 2. Peptide mapping of a fraction from a brain extract by capillary electrophoresis, to illustrate reproducibility with time and use of mapping for peptide identification. The separation in (**a**) reveals that the fraction contains a mixture of short peptides, the one at the arrow is suspected to be a neuroactive tripeptide, Gly-Pro-Glu. After adding of the corresponding synthetic peptide, reanalysis in (**b**) reveals that the synthetic peptide (arrow) comigrates with the

biological peptide component. Considering that the time between separations (**a** and **b**) is >2 weeks, the repetitive pattern confirms the reproducibility of the system on a sensitive scale (0.1 to 2 pmol analyzed). From Ref. 20 with permission.



Fused silica capillaries that have charged surfaces in which electroendosmosis takes place are commonly employed, typically with inner diameters of 20 to 200 µm and lengths of 20 to 100 cm. Small inner diameters are best suited for peptide mapping because the more narrow the capillary, the better the resolution. For peptide separations, sodium phosphate buffer, pH 2.5, is a good electrolyte that allows sensitive detection at short wavelengths (190 to 200 nm) because of its high UV transparency. Including short-chain, ion-pairing reagents (hexanesulfonic or heptanesulfonic acid) in the buffer improves resolution, in particular of hydrophobic peptides, and has been tested in peptide mapping (Fig. 3). The voltages applied range from 5 to 30 kV, and electric field strengths range from 200 to 500 V/cm. Separations are influenced by a combination of electrophoretic mobility and electroendosmosis. CZE can be used preparatively, and the components separated in the peptide map can be further characterized by amino acid analysis, Edman degradation, or mass spectrometry (5, 23). In particular, electrospray mass spectrometry has gained recent popularity as an on-line detection technique with simultaneous tandem mass spectrometric capability for peptide structure information at the low femtomole level (24-26).

Figure 3. Tryptic peptide mapping of recombinant human erythropoietin in phosphate buffer, pH 2.5, with 100 m*M* heptanesulfonic acid by capillary electrophoresis. The maps from two different expression systems are shown, the upper without glycosylation (*E. coli*), the lower with (Chinese Hamster Ovary cells) but subsequently treated with N-glycanase. Although 16 peaks have identical migrations, indicating identical primary gene products, peaks a–f differ and can be attributed to differences at specific sites in the eukaryotic form. From Ref. 22 with permission.



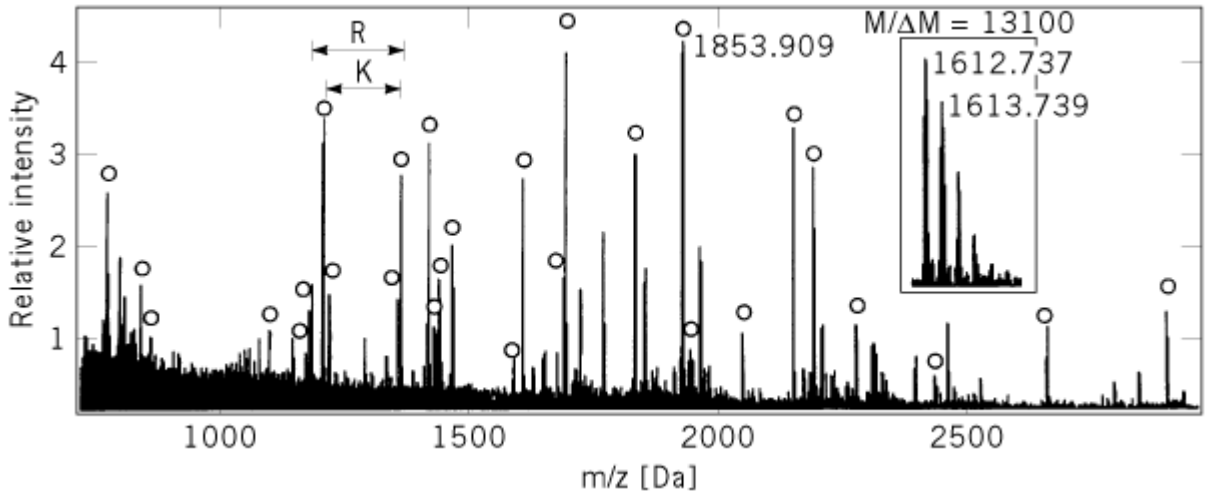
3. Mass spectrometry

Protein fingerprinting by determining the masses of all the peptides generated by proteolysis of polypeptide chains separated by gel electrophoresis has recently emerged as an extremely powerful tool for protein identification. It combines sensitivity and high throughput (8). Complex protein mixtures of crude cell lysates can be separated with 2-D gel electrophoresis systems (27). For identification, the amount of protein in many 2-D gel spots is well below 1 picomole and thus too small for the commonly used sequencer technology, but it is accessible to recently developed sequencer instruments (down to 100 femtomole by cartridge miniaturization and capillary HPLC for phenylthiohydantoin detection; see Edman Degradation) using matrix-assisted laser desorption/ionization (MALDI) (28) or electrospray (29) mass spectrometry, recently extended by nanoelectrospray ionization (30, 31). As a consequence, a novel type of "peptide mapping" of proteins has emerged, using their fragment masses and efficient algorithms to search peptide-mass databases, which permits structural assignment, protein identification, and determination of minor differences (32-34).

As in traditional peptide mapping, the first step in this procedure is proteolytic cleavage of the protein (commonly, still with trypsin), either in solution, in a gel (14, 15), or on a membrane after blotting on nitrocellulose or PVDF membranes (16). The MALDI mass analysis and the database search are highly automated (35), which increases the throughput and makes multiple protein identifications efficient (Fig. 4). If the protein is still unknown after the database search, the peptides are further analyzed by tandem mass spectrometry (36, 37). Using the nanoelectrospray ion source, sequence stretches up to 16 residues obtained from as little as 5 ng of protein digested with trypsin in a gel have been reported (10).

Figure 4. Peptide mapping by automated MALDI mass spectrometry and database searching after in-gel digestion with trypsin of a yeast protein recovered from a 2-D gel system. Ion signals whose measured masses match the

calculated masses of protonated tryptic peptides are indicated with circles. Sequence coverage is greater than 70%. Terminal Arg (R) and Lys (K) sequence tags are marked by arrows. Also shown is a magnification of one of the tryptic peptide peaks that reveals the resolution of molecules containing different natural isotopes. From Ref. 35 with permission.)



4. Conclusion

Peptide mapping, complemented with Edman degradation and mass spectrometry, involves principles from the 1950s and earlier. But they have survived in the newest phases of modern molecular biology and now position themselves at the forefront of developments by providing rapid and sensitive identification of minor differences among related, alternatively synthesized, and posttranslationally modified gene products at femtomole and soon attomole levels.

Peptide Nucleic Acids

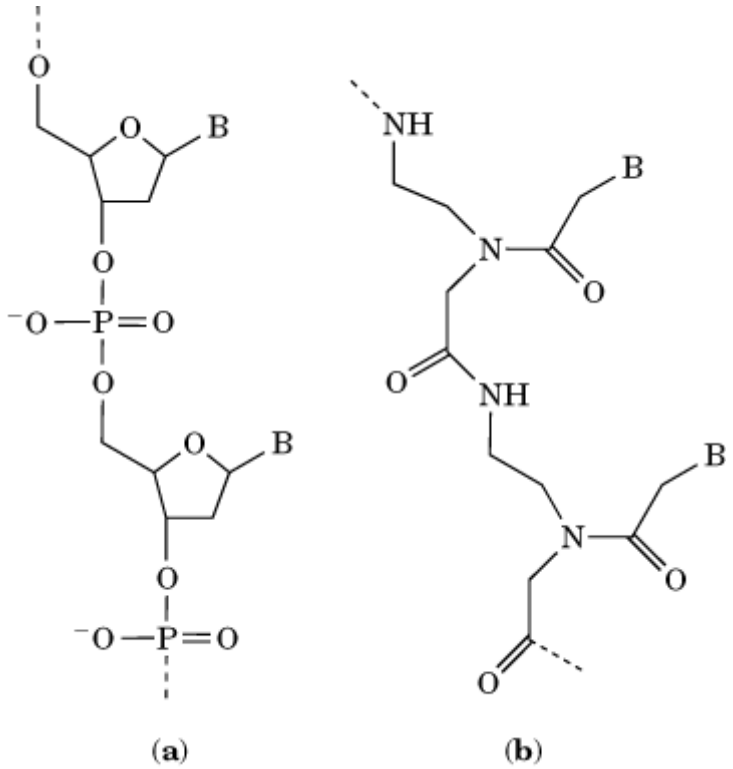
Peptide nucleic acids (PNA) are DNA mimics in which the phosphoribose backbone of DNA has been substituted by a pseudopeptide backbone to which the normal nucleobases are tethered. An 8-mer thymine oligoamide was first described in 1991. The name PNA was coined when it was demonstrated that this molecule forms a rigid **triple helix** with a polyadenine DNA strand and that a PNA of mixed sequence that contains all four DNA bases forms duplexes with DNA and RNA that obey the Watson–Crick base-pair rules. In 1994, it was reported that two PNAs that have complementary base sequences hybridize into a double-helical structure. PNA has attracted great attention within medicinal chemistry and molecular biology, and also in fields, such as organic and physical chemistry because of its interesting chemical and physical properties. Because it binds efficiently and sequence-specifically to single-stranded RNA and DNA and, under certain conditions, also to double-stranded DNA, PNA has great potential for diagnostic and pharmaceutical

applications.

1. Chemistry and Synthesis

The backbone of PNA is based on 2-aminoethyl glycine linkages that mimic the normal phosphodiester backbone of DNA (1). A methylene carbonyl linker connects the standard nucleotide bases to this backbone at the amino nitrogens (Fig. 1). This chemistry has some interesting consequences. In contrast to DNA or phosphorothioate oligonucleotides, PNA is a nonionic molecule. In addition, it is achiral, which avoids diastereomeric structures and the need to develop stereoselective synthesis reactions. Schemes for protecting reactive groups on the PNA monomers are based on either Boc or Fmoc chemistry (see Peptide Synthesis). In both cases, oligomers can be assembled using established, **solid-phase** peptide synthesis procedures and a (methylbenzhydryl) amine polystyrene resin as solid support (2). PNA oligomers are cleaved from the support by treatment with either anhydrous hydrogen fluoride or trifluoromethanesulfonic acid, as in traditional peptide chemistry, followed by purification using **HPLC**. Modifications of PNA are obtained by coupling amino acids during solid-phase synthesis or by attaching other compounds that contain a carboxylic acid group to the exposed N-terminal amino group. The ease with which PNAs are modified should facilitate optimization of specific functional requirements.

Figure 1. Comparison of the chemical structures of (**a**) DNA and (**b**) PNA. B = nucleobase.



2. Physical-Chemical Properties

PNA has proven very potent as a DNA mimic capable of participating in both duplex and triplex formation. Moreover, it displays various interesting properties beyond those of natural DNA.

2.1. PNA-DNA/RNA Duplexes

The properties of PNA-DNA duplexes have been extensively investigated using the mixed-sequence

pentadecamer H-TGTACGTCACAACTA-NH_2 (3). This PNA oligomer forms a duplex with complementary DNA that is antiparallel, has the amino-terminus of PNA facing the 3′ end of DNA, and has a T_m (melting temperature) of 70°C. The corresponding DNA-DNA complex has a T_m of only 53°C. PNA also binds to the parallel, complementary, DNA target, although it has lower affinity (T_m = 56°C). The preference for antiparallel orientation is a general feature of mixed-sequence PNA-DNA duplexes. Kinetic binding studies have shown that antiparallel PNA-DNA duplex formation is very fast, faster than formation of a corresponding DNA-DNA duplex, whereas considerably slower kinetics were observed for formation of parallel PNA-DNA complexes (4). The thermal stability of PNA-RNA duplexes is generally higher than that of PNA-DNA duplexes, and the rate of association between PNA and RNA is somewhat faster than that between PNA and DNA.

The greater thermal stability of PNA-DNA/RNA duplexes compared to the corresponding DNA-DNA duplexes is predominantly ascribed to the lack of electrostatic repulsions between the two strands. This hypothesis is based on the observation that PNA-DNA and DNA-DNA duplexes have equal thermal stability (melting temperatures) at ionic strengths above 1 M Na^+. As expected, the stability of PNA-DNA hybrids is little affected by changes in ionic strength, except in the limit of low ionic strength, where the stability increases. The higher stability of PNA-DNA compared with DNA-DNA duplexes at low ionic strength is due to a more favorable **entropy** change linked to duplex formation, which is attributed to a release of counterions from the DNA polyanion as PNA binds (5).

The sequence-specificity of PNA binding to nucleic acids is manifested in the considerably lower stabilities of heteroduplexes that contain mismatches. The effect of base-pair mismatches in the middle of a pentadecamer PNA-DNA duplex revealed decreases in T_m of 8 to 20°C for single mismatches (3). Similar decreases in T_m were observed in PNA-RNA for the corresponding mismatches. Thus, the sequence discrimination of a PNA oligomer is equal to, or even better than, that of a DNA oligomer.

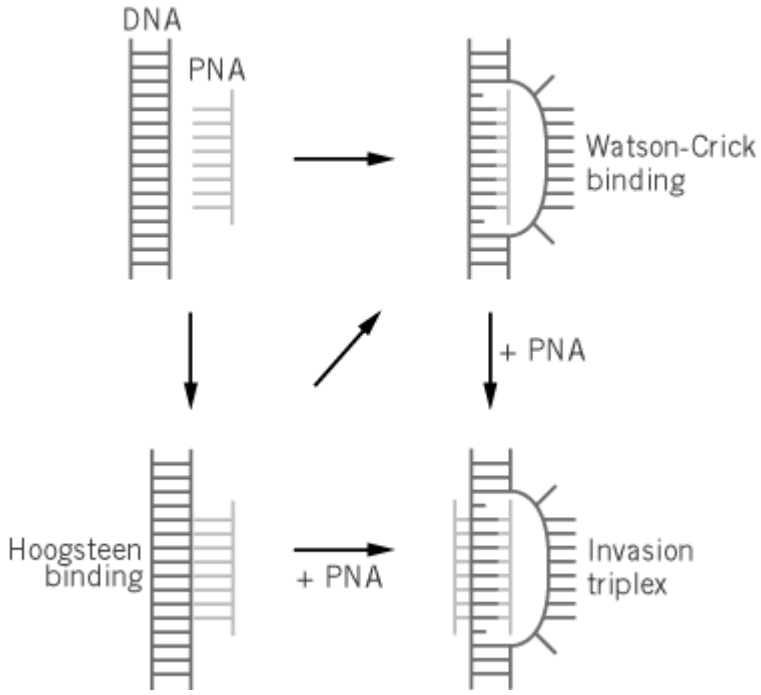
2.2. $(PNA)_2$-DNA Triplexes

Homopyrimidine PNA or PNA oligomers that have a high pyrimidine content bind complementary purine DNA by forming $(PNA)_2$-DNA triplexes (6), virtually without forming of any duplex. Monophasic, well-defined melting curves are obtained for these very stable complexes (T_m>70°C for decamer PNAs), where the binding is most probably governed by standard Watson–Crick and Hoogsteen base pairing. Triplex formation involving cytosine in the homopyrimidine PNA is pH-dependent (lower pH increases hybrid stability), as expected if C^+GC triplets with one cytosine protonated are being formed. It is interesting to note that experiments still indicate a $(PNA)_2$-DNA stoichiometry even at pH 9, where cytosine is not expected to be protonated. This suggests that only a single hydrogen bond of cytosine is sufficient or that its pK_a is drastically changed.

2.3. Binding to Double-Stranded DNA: Strand Invasion

The high stability of $(PNA)_2$-DNA triplexes enables the PNA to dissociate double-stranded DNA (dsDNA). For example, homopyrimidine PNA oligomers displace the pyrimidine strand of dsDNA at the target site and form a $(PNA)_2$-DNA triplex with the DNA homopurine target. The expelled DNA pyrimidine strand forms a single-stranded loop (Fig. 2). PNA-DNA complexes formed by strand invasion are characterized by high thermodynamic stability and high specificity, which seems contradictory. The strand invasion reaction, however, is kinetically controlled, which allows screening by the PNA for the target sequence, without becoming trapped in thermodynamically stable but incorrectly matched complexes. Although restricted to low ionic strength, this is an interesting binding property of PNA that is being pursued extensively, and several applications have been demonstrated.

Figure 2. Schematic general model of the possible mechanisms of PNA_2-DNA triplex formation by strand invasion of a DNA duplex.



The mechanism of formation of a strand-displacement complex involving a PNA(pyrimidine)$_2$-DNA (purine) triplex has been investigated by gel retardation assay using DNA restriction fragments that contain single PNA targets (7). The reaction obeys pseudo-first-order kinetics, and a single mismatch in a 10mer PNA reduces the binding rate constant by more than a factor of 100. For the polynucleotide system poly(dA):poly(dT) and PNA-thymine oligomers, the PNA binding reaction was studied in real time by **circular dichroic** (CD) spectroscopy (8). This revealed somewhat complex reaction kinetics and also demonstrated the presence of at least one intermediate species. The rate-limiting step is a transient opening of a few base pairs in the DNA duplex (as reflected by the size of the activation barrier). Quite remarkably, the reaction is second-order in PNA concentration, indicating that both PNA strands are involved in the precursor complex. Possibly, the two PNAs are associated loosely with the DNA duplex before the base-pair opening step. Interestingly, intercalators bound to the starting duplex DNA increase the PNA binding rate, even at higher salt concentration, presumably by facilitating initiation of PNA invasion at the intercalation site. Even if the formation of strand-displacement complexes is highly dependent on the ionic strength, complexes formed at low ionic strength are generally stable kinetically at salt concentrations up to 0.5 *M* NaCl.

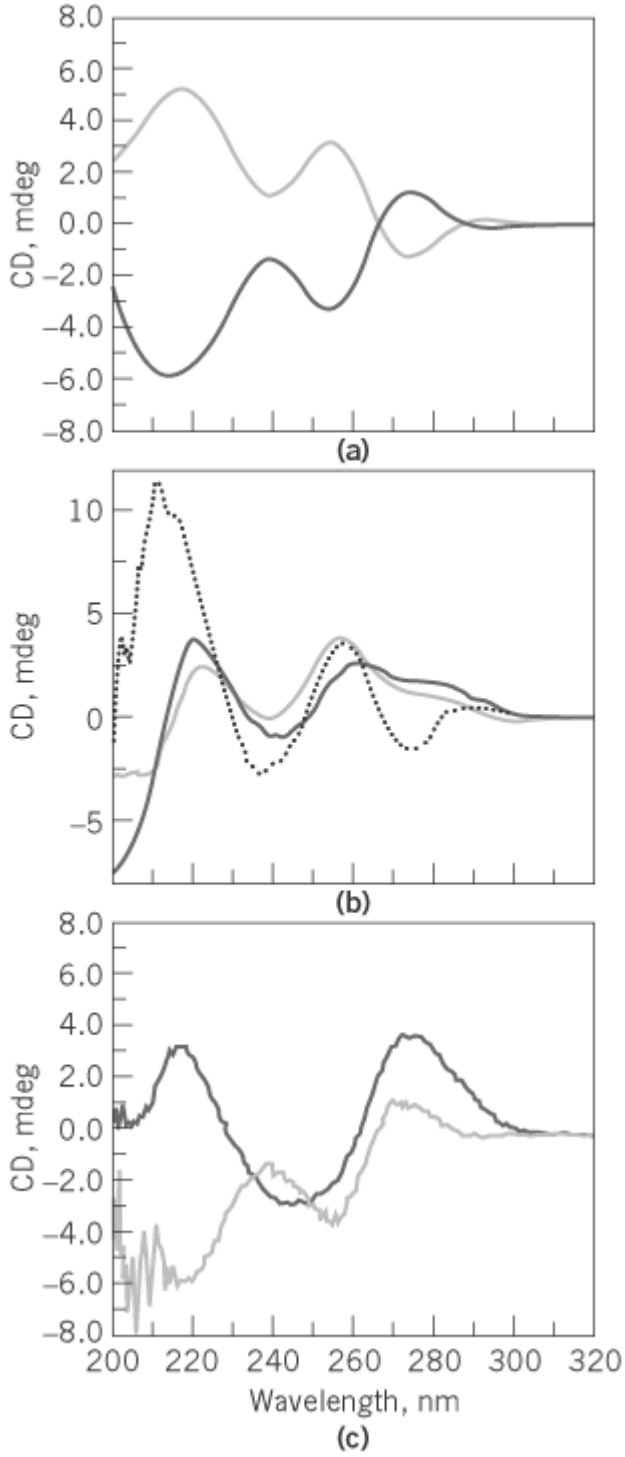
PNA targeted to dsDNA sequences other than purine-rich stretches was recently investigated, but such complexes have reduced stability (9). With purine-rich PNA sequences, duplexes formed by the invasion into dsDNA at a complementary pyrimidine target (making a PNA-DNA duplex) have been detected by CD spectroscopy, and by a gel electrophoresis **mobility-shift assay**. Somewhat surprisingly, cytosine-rich and alternating thymine-cytosine PNA oligomers bind to their corresponding duplex DNA sequence of intact dsDNA by forming PNA-$(DNA)_2$ triplexes. The pH-dependence indicates that this probably involves Hoogsteen base pairing. These recent findings suggest that there are vast possibilities for using PNA to target a variety of base sequences of dsDNA, although more studies are necessary to assess the details of the various binding mechanisms.

2.4. PNA-PNA Duplexes and PNA-PNA-PNA Triplexes

Complementary PNA decamers that contain all four nucleobases form stable antiparallel duplexes very high in thermal stability (PNA–PNA T_m = 67°C; PNA–DNA T_m = 51°C, DNA–DNA T_m = 33.5°C for identical decamer sequences) that have a high sequence specificity that demonstrates Watson–Crick base pairing (10). As observed for PNA-DNA duplexes, the antiparallel PNA-PNA orientation is preferred, although the parallel PNA-PNA complex is still considerably stable (T_m = 47°C. Moreover, a PNA_3 triplex that has two pyrimidine decamers and one purine decamer was detected by optical spectroscopy and mass spectrometry, and the CD spectrum indicates a helical structure similar to $(DNA)_3$ and $(PNA)_2$-DNA triplexes (11).

The base pairing in PNA-PNA duplex formation occurs rapidly on a subsecond timescale. Once formed, some PNA-PNA duplexes undergo a conformational transition (10). Although PNA in complexes with DNA or RNA adopts right-handed helical structures as a result of the hybridization, PNA-PNA duplexes, which are devoid of intrinsic chiral constituents, are believed to exist as a racemic mixture of right- and left-handed helices. However, the attachment of a chiral amino acid to the C-terminus of one strand can induce inversion into one predominating helical sense among the PNA-PNA duplexes, which was detectable as a slowly growing CD signal upon mixing. Such a chiral bias depends on the PNA sequence at the C-terminus (a G-C base pair is preferred) and on the nature of the terminal chiral amino acid. The D and L forms of amino acids give rise to mirror image CD spectra of PNA (Fig. 3**a**), indicating that helices of opposite handedness are formed, The nature of the side chain (**hydrophobic** or hydrophilic) also decides the preferred helical sense. Helix reorganization occurs on a timescale of minutes at room temperature and exhibits first-order kinetics. The reaction shows a high entropic activation barrier, as would be expected for a transition from one helical sense to another. PNA-PNA duplex helicity that originates from a chiral amino acid at the PNA terminus can propagate about 10 base pairs (chiral persistence length), or approximately one helical turn.

Figure 3. CD-spectra of GTAGATCACT·AGTGATCTAC duplexes. (**a**) PNA-PNA duplex with terminal D-lysine (light gray) and L-lysine (dark gray). (**b**) PNA-DNA antiparallel (light gray), PNA-RNA antiparallel (dark gray), and PNA-DNA parallel ( ). (**c**) PNA-PNA (light gray) and DNA-DNA (dark gray).



3. Structure of PNA Complexes

The unique chemical and physical properties of PNA have inspired investigations of structural details of PNA-nucleic acid hybrids by various techniques, including NMR, X-ray crystallography, CD, and linear dichroic (LD) spectroscopy.

3.1. Dichroic Spectroscopy of PNA-DNA Hybrids

The CD of PNA-DNA and PNA-RNA duplexes provided the first indications of the overall base-pair geometry in these complexes (3). The CD spectra of DNA-DNA, antiparallel PNA-DNA, and antiparallel PNA-RNA duplexes are all similar, suggesting that PNA participates in forming right-

handed helices that have base-pair geometry not much different from that found in B-DNA or A-DNA helices (Fig. 3**b**). In contrast, the spectra of parallel PNA-DNA and PNA-RNA complexes deviate more from the DNA-DNA spectrum, suggesting different base stacking (Fig. 3**b**).

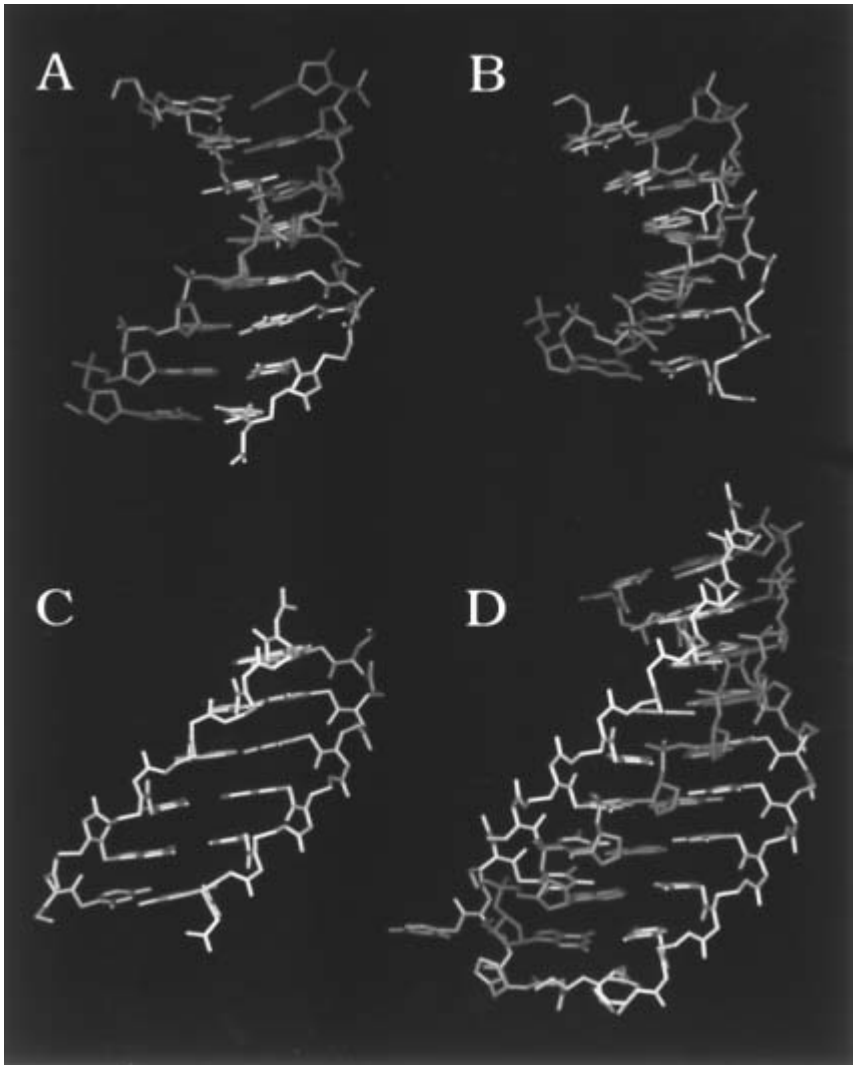
Earlier, LD and CD showed that PNA-T_8 with poly(dA) forms a right-handed PNA_2-DNA triplex, in which the base triplets are arranged with their planes approximately perpendicular to the helix axis, similar to the standard poly(dT) $_2$-poly(dA) triplex (6). Further, the PNA_2-DNA triplex has a remarkably rigid structure, indicating efficient stacking interactions. The high thermal stability of $(PNA)_2$-DNA triplexes is expected because of the absence of interstrand repulsions, and it is assisted by hydrophobic and dipolar interactions, and possibly also by intrabackbone hydrogen bonds (see later). Titration experiments with PNA-T $_8$ added to poly(dA) show by LD and CD that no duplex stretches are present at subsaturation ratios but that segments of (PNA) $_2$-DNA triplexes are distributed evenly on the poly(dA) strand separated by flexible single-stranded regions. Only close to the saturation point, 2:1 PNA to DNA bases, does the complex become rigid due to complete formation of triplex and stacking between each PNA triplex segment.

A helical structure of PNA-PNA complexes has also been suggested. The CD spectrum of PNA-PNA resembles that of the corresponding DNA-DNA duplex (Fig. 3**c**) in shape and amplitude, so it is inferred that the structures similar in their base-stacking interactions and degree of organization (10).

3.2. NMR and X-Ray Crystal Structures of PNA-Containing Complexes

Three-dimensional molecular structures have recently been reported for several PNA complexes (Fig. 4). The structures of PNA-RNA hexamer (12) and PNA-DNA octamer (13) duplexes have been determined by NMR. The structures of a nonamer (PNA) $_2$-DNA (14) triplex and a hexamer PNA-PNA (15) duplex were determined by X-ray crystallography. Some general conclusions can be drawn from these structures. It is clear from the heteroduplexes, that binding of PNA still allows the backbone of the nucleic acid partner to retain a nearly “normal” conformation. The RNA strand in the RNA-PNA duplex, has approximately an A-conformation with C3-*endo* sugar puckering, whereas the DNA in the PNA-DNA duplex is closer to B-form with C2-*endo* sugar puckering (see DNA Structure). It is striking, however, that the base-pair positions in both duplexes are more A-like in their helical displacement, but, in contrast to a canonical A-form helix, are more perpendicular to the helical axis. The two duplexes also show a larger pitch—about 13 base-pairs for the PNA-DNA duplex—than the usual 10 to 11 base pairs observed in nucleic acid duplexes.

Figure 4. Structures of PNA duplexes and triplexes. (A) and (B). Solution structures of PNA-DNA octamer duplex (A) and PNA-RNA hexamer duplex (B). (C) and (D). X-ray crystallographic structures of a PNA-PNA duplex (C) and of PNA_2-DNA nonamer triplex (D). Figure kindly provided by Dr. Scott Carter.



The crystal structure of the $(PNA)_2$-DNA triplex reveals hydrogen bonds between phosphate groups of the DNA backbone and amide protons in the PNA backbone of the Hoogsteen strand. These contacts could be important for the ability of homopyrimidine PNA oligomers to form very stable triplexes with complementary oligonucleotides. Moreover, the two PNA strands in the triplex structure are nearly identical and resemble the PNA strand in the PNA-DNA duplex. Both the $(PNA)_2$-DNA triplex and especially the PNA-PNA duplex show very wide (26 Å and 28 Å, respectively) helices with a large pitch (16 and 18 bases per turn for the triplex and duplex, respectively), strongly suggesting that this latter type of helix is the natural conformation of helices that have PNA backbones. It is further notable that the base pairs in the PNA-PNA duplex exhibits interbase-pair stacking overlaps close to A-form. Thus, it is clear that PNA helices have a structure of their own that resembles, but is also distinctly different from, known nucleic acid helices.

4. Structure–Activity Studies

Because PNA has demonstrated unique hybridization properties toward complementary oligonucleotides, it has been of the utmost interest to understand what structural elements are responsible for its behavior. Furthermore, it is important to know what kind of chemical modifications can be accomplished and accommodated while retaining binding to DNA and RNA.

A large number of studies on backbone-modified PNAs show that only minor deviations from the

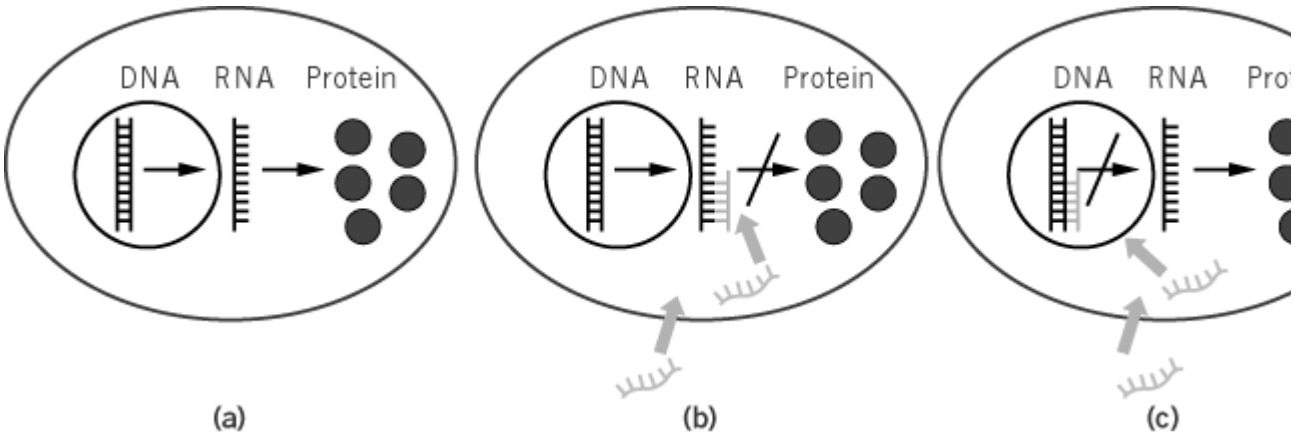
original aminoethylglycine backbone can be tolerated. Extensions in any of the three possible linking directions impair stability of its complexes, and the restricted flexibility imposed by the secondary amido group in the nucleobase linker is also necessary because reducting this to a tertiary amine is deleterious to the hybridization potency (16). Isomerization to the retroinverse structure, which essentially moves a methylene group from the ethyl to the glycine moiety, also results in PNAs of low hybridization efficiency. However, there is much freedom in the way substituents may be placed in the a-position of the glycine moiety of the PNA backbone. Backbones based on natural amino acids other than glycine result in fair to good DNA mimicking properties. Even cyclic substituents, such as cyclohexyl substitution at the aminoethyl linker, are acceptable, provided the right stereoisomer is chosen. By using PNA monomers that have incorporated natural amino acids, chemical functionality can be introduced into the backbone and the physical properties of the PNAs, such as hydrophilicity, hydrophobicity, ionic character, etc. might be finely tuned and controlled. It is believed that this greatly facilitates the optimization of pharmacokinetic behavior, for example (see later).

PNA-DNA chimeras are potentially interesting because they may allow DNA-recognizing enzymes (such as ribonuclease H and **DNA polymerase**) to interact with the DNA part, while the PNA part would provide high binding affinity and specificity. For this purpose, a linker is necessary that connects the two oligomers to allow stacking between the neighboring bases in the PNA and DNA parts of the chimera. Successful reports describe the synthesis of PNA-DNA chimeras of both DNA-3′-N-PNA and DNA-5′-C-PNA type junctions (17). Such chimeras hybridize to complementary oligonucleotides less efficiently than pure PNAs, but they are able to activate ribonuclease H.

5. A Possible Genetic Drug?

The potential use of PNA as an **antisense** or antigene drug for sequence-specific modulation of gene expression has bright prospects. Oligonucleotide analogs can be designed to recognize and hybridize to complementary sequences in a particular messenger RNA and thereby inhibit its translation (see also Antisense Oligonucleotides). Alternatively, oligonucleotides can be targeted to dsDNA and interfere there with transcription of a particular gene (the antigene strategy). These two approaches are depicted in Figure 5. *In vitro* assays examining the effect of PNA on DNA replication, transcription, and translation all look quite promising. The sequence specificity is high, and the biological stability of PNA is sufficient (18). Drawbacks include the poor cellular uptake of PNA and the sensitivity of strand invasion complexes to salt concentrations, which must be addressed before general applications can be developed. Moreover, the pharmacological properties of PNAs have not yet been thoroughly investigated.

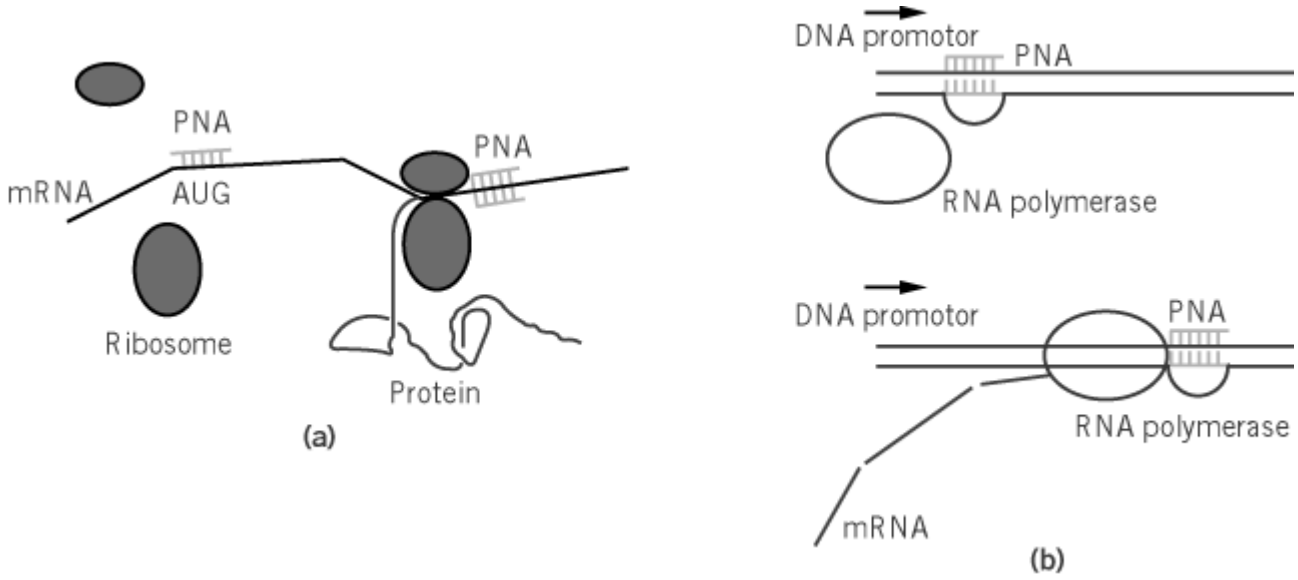
Figure 5. Principles of the antisense and antigene gene-targeting strategies. In normal cells (**a**), DNA is transcribed into
which then is translated into protein. When the cells are treated with an antisense oligomer (**b**), hybridization to a sequen
specific mRNA inhibits expression of the protein at the level of translation. Treatment of the cells with an antigene oligo
complementary to a sequence in the DNA leads to inhibition of transcription of the gene into mRNA.



5.1. Transcription Arrest by PNA

When targeting genomic DNA by the antigene strategy, inhibition should in theory be obtained by the formation of just one PNA-DNA complex in each haploid genome. Because pyrimidine PNAs form extremely stable, strand-invasion complexes upon binding to dsDNA, they should be excellent antigene agents (18). It has been shown that such complexes indeed arrest transcription by both prokaryotic and eukaryotic **RNA polymerases** *in vitro*. PNA bound to the **promoter** clearly blocks the access of the polymerase protein to the DNA, whereas PNA bound within the coding region of a gene sterically blocks polymerase progression (Fig. 6**a**). In therapeutic applications, several issues are, however, still unclear. First, to bind dsDNA, a poly-purine target must be present in the gene of interest. This, of course, limits the number of possible targets. Second, and this could be more serious, the formation of strand-displacement complexes occurs very slowly at physiological salt concentration. Modifications of PNA by intercalators or positively charged lysine residues may, however, improve the binding rates. Furthermore, chemically linking the end of the Watson–Crick and Hoogsteen PNA strands to each other or incorporating pH-independent pseudoisocytosines into the Hoogsteen strand can increase the association rates with dsDNA. It was found that binding of PNA to **supercoiled** plasmid DNA is much faster than to linear DNA, indicating that the DNA topology is an important parameter for the rate of binding. Because transcriptionally active chromosomal DNA is usually negatively supercoiled, this could be of relevance for PNA binding *in vivo*. It has also been shown that binding of PNA to dsDNA is enhanced when the DNA is being transcribed, probably because of partly ssDNA in the transcription bubble.

Figure 6. Translational arrest and transcriptional inhibition. (**a**) Translation initiation is blocked by either a duplex- or a triplex-forming PNA, whereas a triplex-forming PNA is required for translation elongation arrest of the ribosome. (**b**) Transcriptional inhibition is accomplished by homopyrimidine PNAs that form invasion triplexes either at the promoter or the coding region of the gene.



5.2. PNA as an Artificial Promoter

Even though not considered an antigene effect, the ability of PNA to activate transcription is worth mentioning in this context. The resemblance between PNA strand-invasion hybrids and transcriptional initiation complexes allows transcription to start on the looped-out strand of the PNA-DNA complex. Experiments with *Escherichia coli* RNA polymerase show that the looped-out DNA strand acts as a template, and the length of the resulting transcripts corresponds exactly to run-off transcripts initiated at the bound PNA. Such a "PNA promoter" is very strong and might have the potential to activate genes *in vivo*, provided that strand invasion is accessible inside cells. As mentioned, PNA also arrests transcription, but the two processes differ as to the size of the displacement loop. Although arrest works for decamer targets, transcriptional initiation requires a larger loop.

5.3. Translational Arrest by PNA

Because PNA-RNA complexes are not recognized by ribonuclease H, PNA-mediated antisense effects depend on mechanisms involving steric blocking of RNA processing, transport into the cytoplasm, or translation. Studies performed *in vitro* show that translational initiation is blocked by a PNA that forms either a duplex (mixed sequence) or a triplex (pyrimidine-rich), whereas arrest of translational elongation by the ribosome requires a triplex-forming homopyrimidine PNA (Fig. 6**b**). Antisense properties in a cellular context have been possible to assess by microinjection of PNA directly into cultured cells (circumventing the cellular uptake problem), and sequence-specific effects have been confirmed (18).

Bacteria have attracted relatively little attention as targets for antisense agents. However, the demonstration of gene- and sequence-specific antisense inhibition by PNA in *E. coli* opens possibilities for antisense antibacterial drugs and gene-function analysis in bacteria (19). In view of the resistance to current antibiotics displayed by an increasing number of strains of pathogenic bacteria, the possibility of novel antibiotics seems especially important.

5.4. Delivery and Biological Stability of PNA

The prospect of using PNA as a genetic drug makes sense only if PNA is delivered efficiently to cells and distributed so that it interacts with the target mRNA or DNA. Studies conducted with cells in culture indicate that PNA uptake is slow and that PNA ends up in **endosomal** compartments (18). Using a liposome system as an *in vitro* cell model, the PNA penetration properties based on passive diffusion have been investigated in detail and are slow (requiring days) (20). Therefore, PNA molecules need to be modified somehow, either by conjugation to ligands so that active receptor-

mediated cellular uptake **channels** might be exploited or by attachment to moieties that make them attracted to the membrane, so that the local concentration of PNA near or within the cell membranes increases. It has been found that a PNA conjugated to an antibody for transferrin transports across the blood-brain barrier, possibly via the transferrin receptor (21). Most other DNA analogs also show poor uptake properties, similar to those observed with PNA. It is always important, however, to extend uptake studies to *in vivo* situations. Surprisingly, phosphorothioate oligonucleotides, which are taken up only inefficiently in cell culture, have favorable pharmacokinetic behavior in animal models (18).

Agreeing with its chemical remoteness to natural nucleic acids or peptides, PNA exhibits resistance to degradation by cellular **nucleases** and proteinases and remains intact when incubated in serum or cellular extracts. Thus, PNA has ample biological stability for drug development. Furthermore, no signs of general toxicity by PNA have been observed thus far.

6. PNA as a Diagnostic Tool

An increasing number of applications have been described that confirm the potential for PNAs to facilitate the development of novel methodologies in molecular biology, diagnostics, and related fields. A few of these applications are described here.

6.1. PNA-Directed PCR Clamping

The high stability and sequence selectivity of PNA-DNA complexes have been exploited in analyzing single base-pair mutations in DNA by employing **PCR** amplification (22). PNA directed toward the primer binding site, the region adjacent to the primer site, or toward the middle of the PCR region, decreases amplification because PNA cannot function as a primer for **DNA polymerase** . The most efficient and discriminative clamping was observed, as might have been expected, with homopyrimidine PNA decamers. Formation of such PNA_2-DNA triplexes inhibit the polymerase at any PNA binding site. With this technique, a single mismatch in the primer site is detectable.

6.2. PNA and S1 Nuclease as Artificial Restriction Enzymes

PNAS in combination with S1 nuclease have been used as “artificial restriction enzymes” (23). Hybridization of a homopyrimidine PNA oligomer to the complementary target on dsDNA leads to strand displacement of the noncomplementary DNA strand. Upon treatment with nuclease S1, the single-stranded DNA is cut into well-defined fragments. The binding of two PNA molecules to two adjacent targets on the same or opposite DNA strands led to an opening of the entire region, including the intervening base pairs, and thereby provided an accessible substrate for the nuclease and considerably increased the sensitivity to cleavage.

6.3. PNA-Mediated Nucleic Acid Purification

PNA oligomers that carry six histidine residues can be used to purify target nucleic acids by nickel affinity chromatography (24). Moreover, PNAs linked to biotin in combination and **streptavidin**-coated magnetic beads can be used to purify genomic DNA of *Chlamydia trachomatis* directly from urine samples. This “purification by hybridization” approach offers a number of advantages over traditional purification methods. One drawback, however, is that it requires knowledge of a target sequence and a dedicated capture oligomer must be synthesized for each different target nucleic acid. Short pyrimidine PNAs form unprecedently stable triplexes with complementary nucleic acids. Because being short means that their target sequence is prevalent in large nucleic acids, such short PNAs can be used as generic capture probes to purify large nucleic acids. It has been shown that a biotin-tagged PNA-thymine heptamer purifies human genomic DNA efficiently from whole blood by a simple and rapid procedure.

7. Mimic of DNA

Studies of PNA and its complexes with nucleic acids add new perspectives to our understanding of

DNA and also RNA. The base-pair stacking in the PNA-DNA and PNA-RNA duplexes is similar to that of the pure nucleic acid duplexes, showing that neither the absence of backbone charge nor absence of chirality in one of the strands markedly affects the helical stacking. Thus, the helicity can be considered a result of the stacking interactions (mainly dipolar interactions between the nucleobases) in combination with strains from the backbone, rather than arising from phosphate–phosphate repulsion that strives to increase the separation of negative charges along the backbone. An important manifestation of the preferred helical structure is also the helical stacking in PNA-PNA duplexes (10, 11). It is speculated that the helical shape of nucleic acids was selected in evolution because it allows better exposure of signature features of the bases on the helical surface without loss in secondary structure stability and thereby facilitates protein recognition.

The structural similarity between PNA-DNA and DNA-DNA duplexes offers the opportunity to investigate the forces responsible for binding different ligands to dsDNA (25). Assuming that the main binding forces can be divided into electrostatic interactions and hydrophobic contributions, the effect of replacing the negatively charged DNA backbone with a neutral peptide backbone could help assess the role of the phosphate groups in binding a given ligand. Typical molecules that intercalate or bind to grooves exhibit strongly reduced affinities for PNA-DNA complexes. None of the intercalators studied exhibited any significant binding, whereas classical minor groove binders bind weakly to PNA-DNA complexes. No simple ligand has been found that binds to PNA-PNA duplexes. These findings illustrate the importance of electrostatic attractions for ligand binding to DNA.

8. PNA and Prebiotic Chemistry

Identifying the first genetic molecule could provide the key to understanding the origin of life. The difficulties in spontaneously forming nucleotides under prebiotic conditions might be used to argue that nucleic acids (DNA or RNA) were not the first genetic materials on the primitive earth. Therefore, it has been proposed that one or more genetic systems composed of simpler monomers may have preceded the RNA world, an era in which RNA molecules would have acted as both the genetic material and the catalysts. Then, genetic takeover would have allowed the development of RNA-controlled life. PNA is an example of an oligomer that could have preceded RNA because it is simpler than RNA but exhibits all of the important properties of nucleic acids with respect to information storage. PNA oligomers can act as templates for polymerizing of the complementary activated RNA mononucleotides, and an RNA oligonucleotide template facilitates the synthesis of complementary PNA strands. These experiments suggest that transitions between different genetic systems may occur without loss of information. A continuous transition from one genetic system to another is possible only if it is possible to form chimeras, that is, mixed molecules that contain building blocks of both systems. In fact, template-directed formation of PNA-DNA chimeras has been demonstrated (26).

PNA is attractive as a primordial macromolecule because it is simple and stable, but, not least, also because PNA is achiral. Introducing and maintaining homochirality on the primitive earth is often considered a crucial issue. How would the first RNA and DNA molecules (which are chiral) have formed from a random racemic mixture of chemically related subunits, including all the possible optical isomers? One possibility is that some physical selection mechanism resulted in forming a chiral environment before the origin of life, or, which may be more likely, that a general chiral bias was active during evolution and led to a final complete selection of handedness (27). Because homochirality is required for the function of enzymes and nucleic acids, an adaptive process might have selected for homochirality at some stage in prebiotic chemical evolution. The discovery of PNA-PNA helices with the handedness determined by a terminal chiral seed suggests that a molecular precursor of RNA could have provided a mechanism for chiral amplification (28).

9. Concluding Remarks

The development of PNA has had implications for many areas of DNA chemistry, biology, and

technology, ranging from basic molecular recognition, self-assembly, chiral induction, and genetic therapeutic drugs, to our understanding of the structure and function of Nature's genetic material, DNA, and speculation on its prebiotic predecessors and origin. Even some novel materials have their origin in PNA (29). Therefore, PNA should be viewed as a DNA mimic and also as a structural and self-recognizing system in its own right.

Peptide Synthesis

The chemical synthesis of small proteins has only recently become feasible with reliability. Progress in this field has depended on the development of the solid phase procedure and the automated synthesizer by Merrifield to reduce the labor and errors associated with repetitive manual procedures. Difficulties in generating pure peptides arose from accumulated byproducts resulting from synthetic difficulties in chain assembly and deprotection of side-chain functionality. Advances in analytical and purification technologies have provided tools for addressing these problems. A variety of strategies have been developed to overcome the synthetic difficulties, and several laboratories have invested sufficiently in the optimization of the technology to produce synthetic small proteins of sufficient purity as to remove any doubts regarding their biological effects (1).

One of the first examples where a small synthetic protein had a major impact on a biological problem of clinical significance was the development of human immunodeficiency virus (HIV) proteinase inhibitors. Although the gene sequence for the 99-residue protein which dimerized to give the active proteinase, was identified when the DNA sequence of the gene for HIV was determined, cloning and expressing of HIV proteinase proved to be exceptionally difficult for pharmaceutical groups, even for those with records of considerable previous success in biotechnology. Synthetic HIV proteinase, a 99-residue homodimer prepared in the laboratory of Stephen Kent (2), was used in the initial determination of HIV proteinase specificity and inhibitor screening. The availability of this synthetic protein certainly expedited the development of HIV proteinase inhibitors used for the treatment of acquired immune deficiency syndrome (AIDS). This example and others would argue that chemical synthesis of small proteins may be more rapid than cloning and expression for some proteins, and it can provide ready access to sufficient quantities (hundreds of milligrams) of protein for screening or biophysical studies. In fact, the first X-ray crystallography structure (3) of HIV proteinase complexed with an inhibitor, MVT-101, used synthetic HIV proteinase and set the record for the largest synthetic molecule whose structure was confirmed by crystallography.

1. Solution Versus Solid Phase

Traditional approaches to peptide synthesis were based on solution methods using convergent synthetic schemes, with isolation and characterization of each intermediate. This provided well-defined products with confidence in their final structures, but at the price of increased labor and losses at each synthetic step in separating product from reagents and byproducts. Until recently, the synthesis of small proteins (60 to 100 residues) has been dominated by fragment condensation in solution with maximal protection of side chains. The desired protein sequence is divided into peptide segments of about 10 residues, which is about the maximum length of peptide readily prepared by stepwise addition in solution. After each reaction, the product is isolated and fully characterized before proceeding with the next reaction. Once the set of fragments has been prepared, they are combined pairwise to generate segments of approximately 20 residues. These are then combined pairwise to generate fragments of approximately 40 residues, and this fragment condensation continues until the desired sequence is obtained. The protecting groups on side chains are then removed to give the fully unprotected peptide chain, which is allowed to fold, resulting in the desired protein. First, the 80-residue protein is divided into eight 10-residue segments that are prepared by stepwise elongation requiring nine coupling and nine deprotection steps, with isolation of each intermediate to give a completely protected fragment with both amino and carboxyl termini protected. Depending on the role of the segment, either its *N*- or *C*-terminus is deprotected and reacted with its adjacent fragment. This process is continued until the entire protein is assembled, deprotected, purified, and allowed to fold.

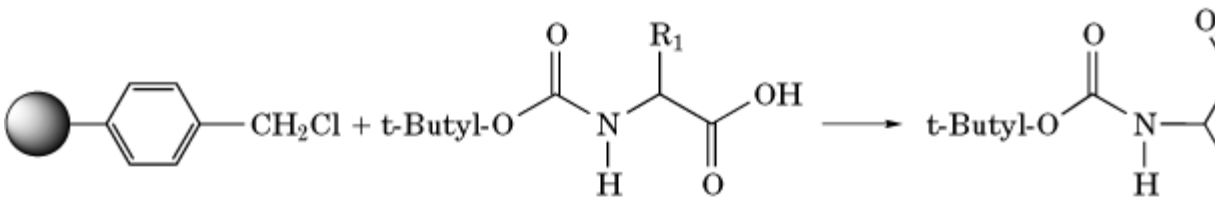
The solid-phase approach utilizes a polymeric protecting group that allows the use of excess reagents to force reactions to near completion by the mass action law and trivial isolation of polymeric product by filtration and washing. Intermediates are not isolated, and purity of the final product depends on complete reaction at each synthetic step and minimization of side reactions during the buildup of the oligomeric peptide and subsequent removal from the polymer with deprotection, to

give the desired product. The advent of high-performance liquid chromatography (HPLC) with more sophisticated techniques such as nuclear magnetic resonance (NMR), **capillary electrophoresis**, and mass spectrometry for purification and characterization of the intermediates and final products allows routine synthesis of peptides in the 50- to 100-residue range. Because of the difficulties in purification of larger peptides and small proteins with only minor differences in structure from byproducts, the unambiguous synthesis of larger peptides and small proteins is best accomplished by assembly of fragments that have been purified and fully characterized. This prevents accumulation of side products with only minor structural differences that can be difficult to remove in the final mixture. Initially, chain assembly was relatively easy to optimize, and the majority of undesirable side products in the final cleavage were due to incomplete deprotection of side chains. Considerable effort over two decades was devoted to understanding the sequence-dependent problems leading to truncated sequences or those missing a residue, but these efforts were hampered by the polymeric support itself, which limited application of the normal methods for characterizing intermediates. This effort has led to the current state of the technology, in which average reaction yields are estimated to be greater than 99.5%. Such yields are essential if multiple sequential chemical reactions are performed without isolation and purification of intermediate products.

Automation of the solid-phase reaction was initiated almost immediately once a viable synthetic scheme for peptides was evolved, and the first automated synthesizer was announced by Merrifield and Stewart in 1965 (4). Continuous development of synthesizers and the associated chemistry allows the automated addition of 75 residues per day to a growing peptide chain (5). In many cases, the repetitive yields are sufficiently high that useful products can be isolated from the synthetic mixture by HPLC when small proteins are prepared. If one desires to be more confident that the observed properties are uniquely determined by the targeted sequence, then a more conservative approach utilizing fragment condensation is still required.

Illustrative are the solid-phase protocols for the two strategies (Boc and Fmoc) commonly used for the synthesis of peptides. The Boc strategy (Fig. 1) is often combined with a 1% to 2% cross-linked polystyrene support and a benzyl ester linkage to the polymer, requiring strong acid such as hydrogen fluoride for deprotection. The procedure favored by most synthetic laboratories uses an acid-labile linkage similar to the *p*-methoxybenzyl ester linkage of the Wang resin and a base-labile amino protecting group, the fluorenylmethyloxycarbonyl (Fmoc), on the added amino acids (Fig. 2). One can use side-chain protection with similar acid lability to the Wang linkage to give free peptide upon cleavage, or use more stable side-chain protection to give the protected peptide for fragment condensation after purification and characterization. In the latter case, a final deprotection with strong acid such as HF is required.

Figure 1. A common implementation of the BOC strategy for peptide synthesis.



Loading of Merrifield polymer with Boc-protected C-terminal residue

The cycle of chain elongation consists of Boc removal with trifluoroacetic acid (TFA), neutralization with a base such as triethylamine (TEA), and coupling of the next Boc-amino acid (R2) in the presence of a suitable coupling reagent such as disoproplycarbodimide (DIC).

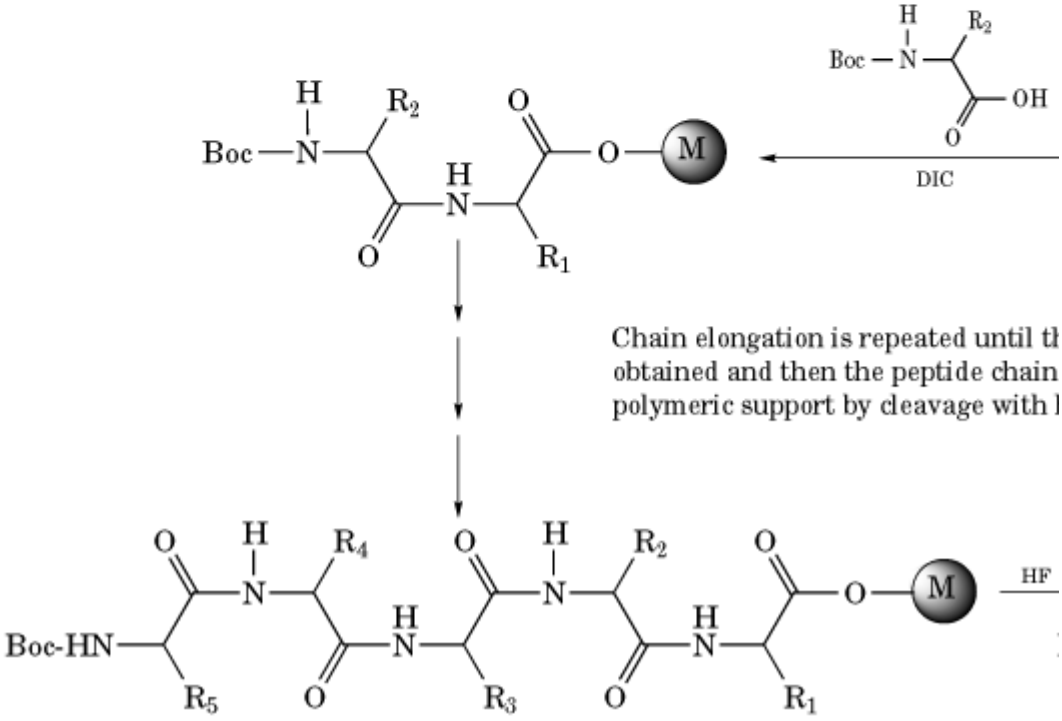


Figure 2. The alternative FMOC/Wang support strategy which allows ready synthesis of protected peptide fragments as

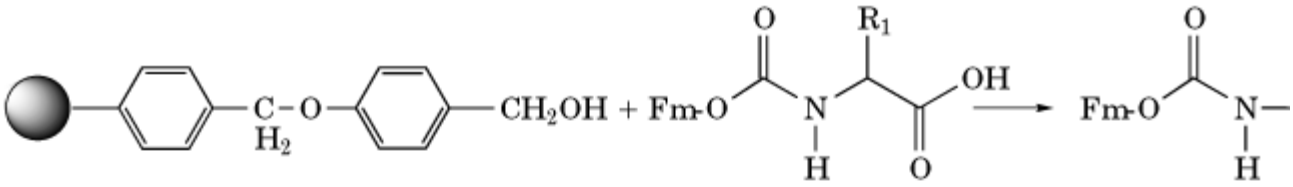
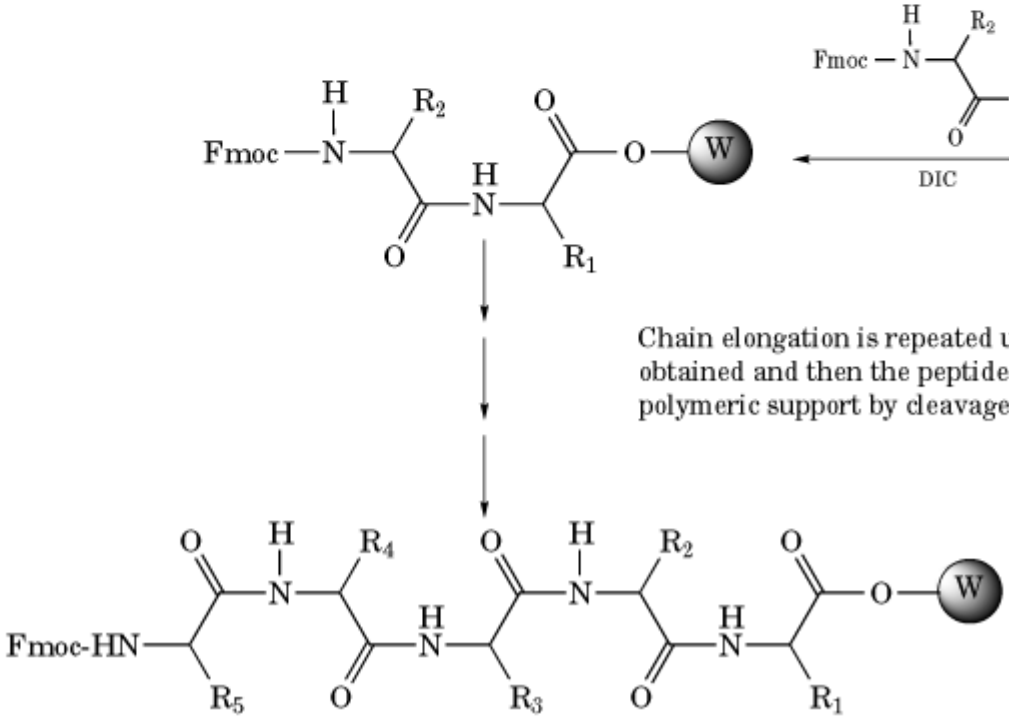


Loading of Wang polymer with Fmoc-protected C-terminal residue

The cycle of chain elongation consists of Fmoc removal with piperidine (Pip), neutralization with a base such as triethylamine (TEA), and coupling of the next Fmoc-amino acid (R2) in the presence of a suitable coupling reagent such as diisoproplycarbodiimide (DIC).

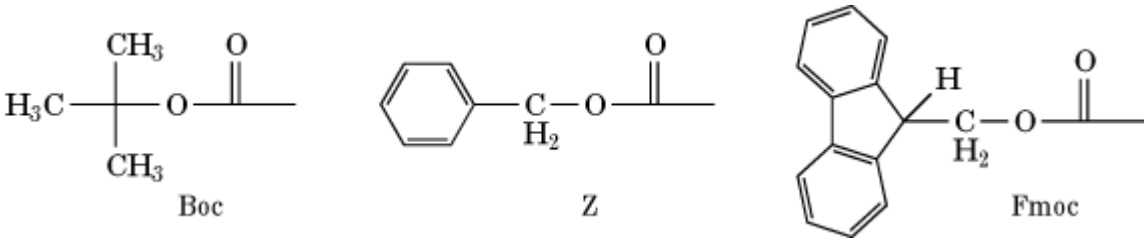


2. Orthogonal and Selective Protection

Because many of the 20 common amino acids have side chains containing chemically reactive groups (**carboxyl**, hydroxyl, imidazole, indole, phenol, **amine**, guanidinium) which could compete for selective peptide bond formation, they must be protected temporarily during assembly to make sure that only the desired a-amino and a-carboxyl groups react to join the protected amino acid to the growing peptide chain with the desired linkage. It is essential that these side-chain protecting groups are stable (orthogonal) to the conditions used for removal of the amino protecting group (Fig. 3) in chain elongation and yet be readily removable at the end of the synthesis. Much effort has been expended developing compatible sets of protecting groups for the 20 naturally occurring amino acids. The peptide chain is routinely assembled stepwise from the *C*- to *N*-terminus because one can

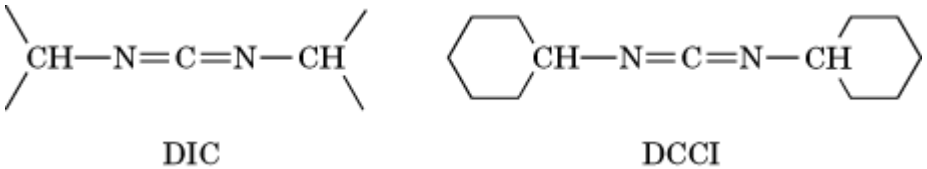
best preserve the chiral integrity of the component amino acids by activating the carboxyl group of a urethane-protected amino acid [ROCO-, where R = *t*–butyl (Boc), R = benzyl (Z), and R = fluorenylmethyl (Fmoc)] for coupling with the *N*-terminal amine of the growing peptide chain. After the addition of a protected amino acid, the amino-protecting group must be removed in order to provide the amine nucleophile for the next reaction. This must be accomplished while retaining the side-chain protecting groups of the growing peptide chain. This leads to the concept of orthogonal protection, in which the a-amino group is protected with a group that can be removed selectively by a mechanism that does not affect the side-chain protecting groups. A common example in solid-phase synthesis would be the use of the Fmoc group, which can be removed repetitively from the a-amino groups under basic conditions, and the use of acid-labile protecting groups, such as Boc or OtBu, on the side chains that must remain throughout chain elongation. If one attempts to couple a peptide to another peptide by activation of the carboxyl group of one of the two, the chiral integrity of the amino acid whose carboxyl group is activated (which is analogous to coupling an acetyl amino acid, which can form a cyclic intermediate, leading to rapid exchange and inversion of the alpha carbon) is often compromised by **racemization**, consequently, a mixture of peptides with *R* and *S* configurations at the activated amino acid results. This leads to the use of special procedures for coupling peptides, as well as a strong proclivity to favor glycine or proline as the *C*-terminal residues in fragment coupling, due to their resistance to racemization. Chemical or enzymatic ligation of peptide fragments offers an alternative approach to simple chemical activation of the *C*-terminal carboxyl group of one fragment and nucleophilic attack by the *N*-terminal amino group of the other fragment.

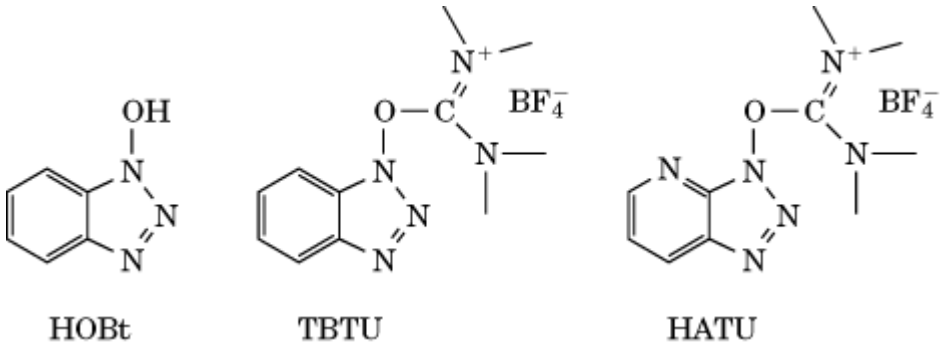
Figure 3. Urethane protecting groups for amino groups in common usage; Boc, *t*-butyloxycarbony; Z, carbobenzoxy (or benzyloxycarbonyl); Fmoc, fluorenylmethyloxycarbonyl.



3. Coupling Reagents

The choice of one of the numerous reagents to activate the carboxyl group for nucleophilic attack by the amine function, to produce the peptide bond, depends on numerous factors. When coupling peptide fragments, reagents that minimize racemization are preferred; a traditional favorite in solution chemistry for coupling fragments has been the azide group. A common procedure is activation by a combination of a diimide, such as 1,3-diisopropylcarbodiimide (DIC) or 1,3-dicyclohexylcarbodiimide (DCCI), with hydroxybenzotriazole (HOBt), or through the use of an activated derivative of HOBt, such as TBTU, to generate the activated HOBt ester *in situ*. Incorporation of multiple sequential sterically hindered amino acids (**valine, isoleucine**, aminoisobutyric acid, etc.) often require the use of special coupling reagents, such as acid fluorides, HATU, etc.) to provide reasonable reaction rates and efficient coupling yields.





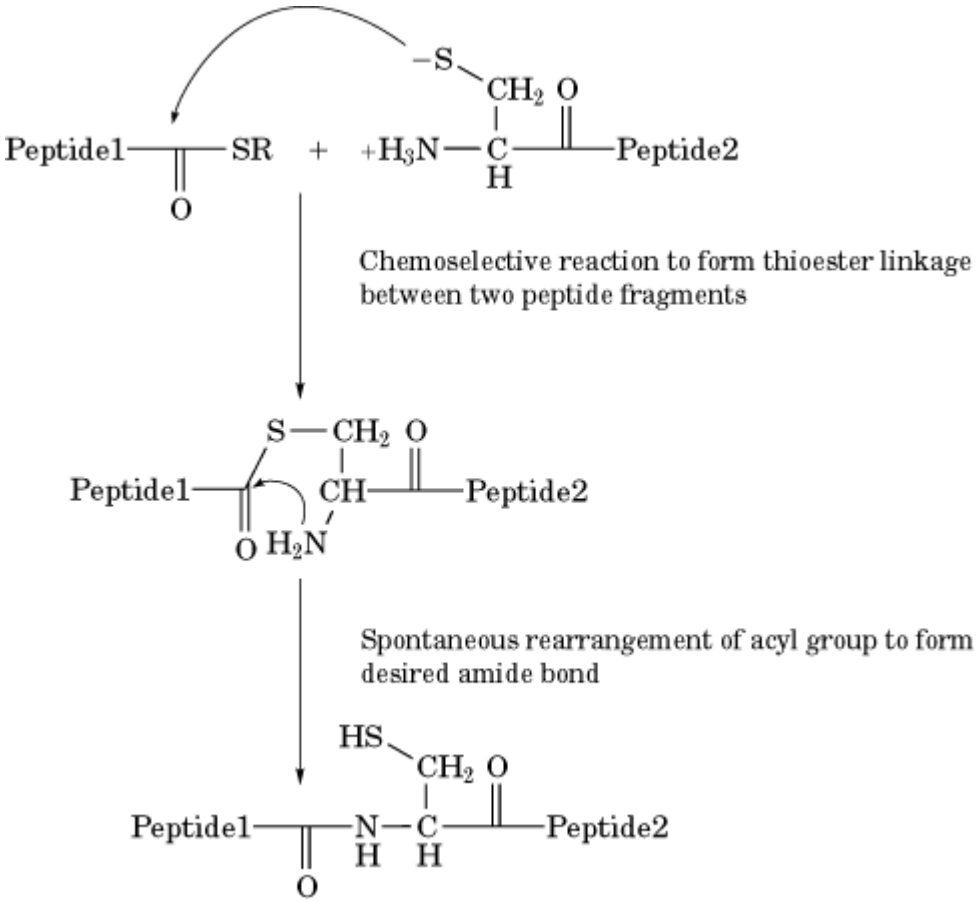
4. Minimal Versus Maximal Protection

In order to get selectivity in the reaction, all reactive groups except the two that are desired to react can be protected transiently with chemically stable protecting groups. This is referred to as *maximal protection* and would be preferred, except for incomplete removal and side reactions associated with deprotection of the fully protected peptide product containing a heterogeneous set of protecting groups. In solid-phase synthesis, assembly of the correct sequence is often quite facile, but incomplete removal of the protecting groups can lead to an intractable mixture. By careful control of reaction conditions (aqueous, pH, etc.), one can eliminate some of the side-chain protection to minimize problems associated with protecting group removal. This is referred to as *minimal protection* and is preferred if selective acylation of the amino terminus by the carboxyl of the *N*-terminal peptide can be achieved.

5. Chemical Ligation

Certain groups of chemical functionality have exceptional affinities for selective reaction, particularly in the formation of small rings. Recent developments have led to the synthesis of large peptide fragments by solid-phase synthesis, removal from the polymeric support and of most, if not all, side-chain protecting groups, and then selective coupling of the unprotected fragments based on chemical ligation. The most developed strategy for this approach is the use of an *N*-terminal cysteine residue with a special reactive *C*-terminal group on the other peptide. This approach was initially conceived by Kemp in his thiol capture strategy (7) and was reduced to a practically successful general approach by the groups of Kent (8-10) and Tam (11-13). For illustrative purposes, the native chemical ligation procedure of Dawson et al. (9) is described (Fig. 4), because it seems to have had the most practical impact. In this case, solid-phase synthesis is used to prepare two unprotected peptide segments that are combined in aqueous solution. The *C*-terminal fragment contains an *N*-terminal cysteine residue, and the *C*-terminal peptide fragment is prepared as the thioester. The thioester is displaced by the thiolate anion of a Cys residue. If the Cys is *N*-terminal, an acyl migration through formation of a five-membered ring occurs to generate the desired stable amide bond. If the sulfur atom of a Cys residue within the peptide chain is involved, then the thioether formed is capable of being displaced by other thiols, until the fragment migrates to the *N*-terminal Cys, when the stable rearrangement can occur. An alternative strategy, using an *N*-terminal b-bromoalanine of fragment two and the *C*-terminal thioester of fragment one to give the same covalent thioester intermediate by thioesterification, has been explored by Tam et al. (12)

Figure 4. Native chemical ligation of two unprotected peptide fragment using thiol–thioester exchange with ligation at the *N*-terminal cysteine residue (9).



While many proteins contain cysteine residues, and some have them optimally spaced for fragment assembly, many do not, and one of the research goals in this area is the extension of these concepts to allow coupling at residues other than the *N*-terminus of cysteine residues. Some success has been achieved with ligation at X–Gly and Gly–X sites (14), as well as at X–His sites (15). Another development that bodes well for the chemical synthesis of larger proteins is the adaptation of chemical ligation to solid-phase using agarose as the polymeric support. This should allow repetitive ligation of smaller fragments to generate the larger protein stepwise on the polymer.

6. Applications

One might question why one would want to prepare small proteins when one can easily express the genetic message in a variety of biological systems, including eukaryotic systems that include post-translational modification. Limitations of normal expression systems to the 20 common amino acids restricts chemical modification of the parent protein for a variety of biophysical and pharmaceutical applications. Incorporation via molecular biology of novel amino acids as spectroscopic probes, or to introduce conformational constraints, is feasible using the suppressor mutation approach pioneered by the Schultz group (16-18). In this case, however, steric limitations of the **protein biosynthetic** machinery preclude the use of certain unusual amino acids or constrained dipeptides (19), which are readily accessible via organic synthesis. The quantities of protein obtained by this approach are generally small, requiring assay methods (enzymatic or spectroscopic) that are sensitive as well as specific.

6.1. Peptide Libraries

The explosion of combinatorial chemistry in the pharmaceutical industry as a paradigm for drug discovery was foreshadowed in the use of peptide libraries by Geysen (20) to map peptide **epitopes** or **antigenic** sites on proteins. Numerous strategies (21-23) to synthesize mixtures of thousands to

millions of peptides and allow selection of those with the desired activities (24) have developed over the past 20 years. Combinatorial synthesis of individual compounds for assay has developed rapidly, because it eliminates the problem of deconvolution of the mixture to identify the individual compound responsible for the observed activity. It also simplifies the pharmacological evaluation of compounds, due to concerns over synergy or the inhibition of activity that is potentially possible in the bioassay of mixtures. Nevertheless, the most effective strategy for lead generation and optimization will be determined by the cost and efficiency of the biological screen versus that of synthesis.

Peptidyl Prolyl *Cis*/*Trans* Isomerases

Only a few cis/trans isomerizations are catalyzed by enzymes. Most of these enzymes catalyze isomerization of C═C double bonds. However, the highly abundant and ubiquitously distributed peptidyl prolyl *cis/trans* isomerases (PPIases) have evolved to accelerate the rotation about a formal single bond. They catalyze the *cis/trans* isomerization of **imide** peptidyl-proline bonds and are inactive toward the -CONH- peptide moiety. In enzyme nomenclature, PPIases are classified under EC number 5.2.1.8.

Initially, PPIases were identified in the cytosol of kidney cells from their ability to accelerate the *cis* to *trans* isomerization of chromogenic tetrapeptides of the type succinyl-Ala-Xaa-Pro-Phe-4-nitroanilides (where Xaa is any natural amino acid) by an assay that utilizes the conformational specificity of **chymotrypsin** (1). Briefly, in this *cis/trans* assay, the *trans* prolyl bond isomer of the substrate succinyl-Ala-Ala-Pro-Phe-4-nitroanilide (about 92% of the total) is cleaved completely at the anilide bond in a few seconds when high concentrations (≫mM) of the proteinase are used. The remaining *cis* isomer of the peptide (8%) is resistant to chymotrypsin until it undergoes *cis* to *trans* isomerization. When monitored by the absorbance of the released product (4-nitroaniline), the isomerization is the **rate-limiting** step for proteolyzing the *cis* isomers indirectly. It can be quantified as a first-order reaction with a half-time of about 90 s at 10°C. This kinetic phase, which is equivalent to a quasi-irreversible *cis* to *trans* isomerization, has an accelerated rate in the presence of catalytic amounts of a PPIase. The calculated rate constants depend linearly on the PPIase concentration. This assay could not demonstrate catalysis in both directions, but this was possible with NMR (2, 3). The standard assay was greatly improved by dissolving the assay peptides in LiCl/trifluoroethanol to increase the fraction of *cis* isomer (4).

PPIases were initially anticipated to be folding/rearrangement catalysts for proteins bearing *cis* prolyl bonds in the native state because the slow *trans* to *cis* interconversion following **protein synthesis** on the ribosome will seriously limit the rate of *in vivo* **protein folding** . Indeed, PPIases increase the rate of the slow kinetic phases in *in vitro* refolding of many denatured proteins known to be limited in rate by prolyl isomerization. In support of a physiological role in protein folding, the involvement of a PPIase in triple-helix formation in type I pro-collagen was shown in chick embryo fibroblasts *in cellulo* (5). However, the biological functions of PPIases are not yet well understood, and they may have more general roles than affecting only *de novo* protein folding.

According to our current knowledge, the enzyme class of PPIases comprises three families with unrelated amino acid sequences: **cyclophilins** (abbreviated Cyp), **FK506**-binding proteins (abbreviated FKBP), and parvulins. An additional subfamily, the prokaryotic trigger factors, exhibits weak sequence similarity to FKBP proteins but lacks FK506-binding ability (6). The amino acid sequences of several dozen different PPIases are known, encompassing molecular masses from 10.1 kDa (92 amino acids in length) for *E. coli* parvulin (7) to 158 kDa for the NK-TR1 cyclophilin of human, large granular lymphocytes (8). Typically, *Escherichia coli* cells harbor two cyclophilins, four FKBP-like PPIases, the archetype of parvulins, along with the SurA protein containing two parvulin domains, and the ribosome-bound trigger factor. Among the 470 predicted coding regions in the free-living bacterium Mycoplasma *genitalium*, which has the smallest known genome of any

free living organism, a trigger factor homologue is the sole PPIase present (9).

Members of the PPIase families resemble perfectly evolved enzymes for catalytic efficiency (10). For oligopeptide substrates, both the Michaelis constant, $\boldsymbol{K_m}$, and the turnover number, k_{cat}, are large and yield values of k_{cat}/K_m of up to $>10^7 M^{-1}s^{-1}$ These bimolecular rate constants approach the **diffusion-controlled** limits for enzyme reactions (see Enzymes). With $k_{cat}/K_m = 1.1 \times 10^6 M^{-1}s^{-1}$, the *E. coli* trigger factor catalyzing refolding of a denatured **ribonuclease T1** variant exemplifies a particularly efficient catalysis in protein folding (11). This efficacy results from having extended secondary binding sites to bind the unfolded protein substrate favorably. These subsites encompass the two protein domains flanking the central PPIase domain of the enzyme. Many of the PPIase enzymes are specific only for certain amino acid residues flanking the proline in the primary structure, but this is less important with the cyclophilins. Conversely, a **hydrophobic** side chain of the amino acid preceding the proline enhances catalysis by FKBPs.

PPIases applied in catalytic amounts cannot alter the *cis/trans* equilibrium of the substrates, as expected. When protein refolding is hindered by misfolding and protein aggregation, an increase of the yield of native protein is not obtained by supplementing the refolding buffer with a PPIase. Thus, an important aspect of **chaperones** is missing in PPIases (12).

Immunosuppressive compounds, like cyclosporin A, FK506 and rapamycin, bind tightly to the respective active site of cyclophilins and FKBPs and inhibit their enzymatic activities reversibly and competitively and have inhibition constants in the picomolar to micromolar range. Cross-inhibition of the different classes does not occur. At the present time, no specific reversible inhibitors for parvulins and trigger factors have been reported.

Definitive identification of the natural substrates of PPI-ases has not been reported yet. Nevertheless, a number of binding proteins, which may include the putative cellular substrates, were identified by chemical **cross-linking**, affinity chromatography, the yeast two-hybrid screen, and by co-purification. For example, the nuclear parvulin-like PPIase Pin1 has affinity for NIMA protein kinase in the two-hybrid system. The catalytic activity of this isomerase is involved in **cell-cycle** control in **eukaryotes** (13). For the trigger factor family, association with nascent chains derived from secreted and cytosolic proteins and specific affinity for the 50S subunit of the *E. coli* ribosome are indicated by cross-linking and fractionation of enzyme activity (6, 14, 15). On the other hand, the same PPIase has been detected as an indispensable component of the heterooligomeric complex of the chaperone GroEL with the degradable fusion protein CRAG. This system has been used to determine the requirements for rapid degradation of abnormal, misfolded proteins by the proteinase ClpP in *E. coli* cells (16). When a trace of copurifying protein of the ryanodine receptor was analyzed, it became obvious that intracellular calcium release channels on the **endoplasmic** or sarcoplasmic reticulum (ryanodine receptor, RyR) and the **inositol** 1,4,5-triphosphate receptor constitute heterooligomeric complexes of the type $((RyR)_4/(FKBP12)_4)$ with either cytosolic FKBP12 or FKBP12.6 (17, 18). A dysfunctional state, associated with the impairment of the receptor-mediated Ca^{2+} retardation of the channel, arises from inhibiting PPIase activity with both FK506 and rapamycin (19). Furthermore, FKBPs and cyclophilins in the range of 40 to 60 kDa were found as components of the unactivated **steroid receptor** complex, associated with the **hsp90** component of the receptor (20). Interestingly, two members of different families of proteins that assist protein folding, an enzyme and a chaperone, coexist as binding partners in this receptor complex.

Peptidyl Transferase

Peptidyl transferase is an integral part of the large subunit of ribosomes and catalyzes **peptide-bond** formation in the elongation step of translation during protein biosynthesis. Peptide-bond formation involves an acyl group *O*-to-*N* migration and converts an ester to an amide. Peptidyl-transfer RNA in the P site is the ester bond of high energy content that donates its peptidyl group to the amino group of aminoacyl-tRNA bound in the A site of the ribosome. The peptidyl transferase reaction is often measured by the puromycin reaction, in which puromycin acts as the acceptor substrate to form peptidyl-puromycin. In bacteria, peptidyl transferase activity can be detected in the 50 S ribosomal subunit, and several ribosomal proteins are thought to play a role in the activity. The primary activity of peptidyl transfer, however, is a **ribozyme** activity encoded in the 23 S rRNA. The peptidyl transferase activity of *Escherichia coli* and *Thermus aquaticus* ribosomes are resistant to

conventional protein extraction procedures (1), and the formation of a G-C pair between G2252 in the conserved hairpin loop of *E. coli* 23 S rRNA and C74 in the 3′-terminal region of tRNA is a prerequisite for the peptidyl transfer reaction. These findings suggest that not all the large subunit proteins are necessarily required for peptidyl transferase activity. It has been shown recently that *E. coli* 23 S rRNA synthesized by *in vitro* transcription with T7 **RNA polymerase** exhibits the primary peptidyl transfer activity in the absence of any ribosomal proteins *in vitro*, and that the truncated domain V transcript alone has this activity (2).

Peptidyl transferase is also involved in the termination reaction of protein synthesis and hydrolyzes the ester bond between the peptide chain and tRNA at the P site of the ribosome (see Release Factor). Peptidyl transferase is inhibited by various antibiotics, such as chloramphenicol, lincomycin, carbomycin (prokaryotes), and cycloheximide (eukaryotes).

Perinuclear Space

The perinuclear space is the lumenal space between the inner and outer nuclear envelope bilayers that separate the nucleus from the **cytoplasm**. The width of the space is between 100 Å and 500 Å. Because the outer nuclear membrane is continuous with the endoplasmic reticulum, the perinuclear space is continuous with the **lumen** of the endoplasmic reticulum.

Permissive Condition

The condition under which a **conditional lethal mutant** grows is called the permisisive condition, in contrast to the nonpermissive condition or restrictive condition, which restricts growth (see Conditional Lethal Mutations).

Peroxidase

Peroxidases occur throughout the biosphere and **catalyze** the oxidation of various substrates at the expense of peroxide. Peroxidases are involved in **plant** growth hormone metabolism, the production

of thyroxine, neutrophil-mediated detoxification reactions, prostaglandin biosynthesis, and lignin degradation, to name a few. Although peroxidases are found in plants, animals, and **microorganisms**, the most thoroughly understood are the nonmammalian heme-containing peroxidases. They all are single polypeptide chains in the range of 30 to 40 kDa and contain a single ferric protoporphyrin IX as the **prosthetic group**. Based on sequence analysis and now **X-ray crystallographic** structures, the nonmammalian peroxidases have been divided into three classes (1): intercellular (Class I), extracellular fungal (Class II), and extracellular plant peroxidases (Class III). The extracellular enzymes are glycosylated, and in the case of Class III enzymes there often are many **isozymes** with varying degrees of glycosylation. The extracellular peroxidases contain two **calcium-binding** sites and at least four disulfide bonds presumably for the additional stability required of secreted enzymes.

Now a wealth of structural information is available about peroxidases because of recent crystal structure determinations. Coupled with the cloning and expression of several peroxidases in recombinant systems, this has opened the way for using protein engineering methods to study structure–function relationships.

1. Catalytic Cycle

The overall peroxidase cycle occurs in three distinct steps:

$$\underset{}{Fe^{3+}P + H_2O_2 \rightarrow \underset{\text{Compound I}}{Fe^{4+}=O\ P\cdot} + H_2O} \qquad (1)$$

$$\underset{}{Fe^{4+}=O\ P\cdot + S \rightarrow \underset{\text{Compound II}}{Fe^{4+}=O\ P} + S\cdot} \qquad (2)$$

$$Fe^{4+}=O\ P + S \rightarrow Fe^{3+}P + H_2O + S\cdot \qquad (3)$$

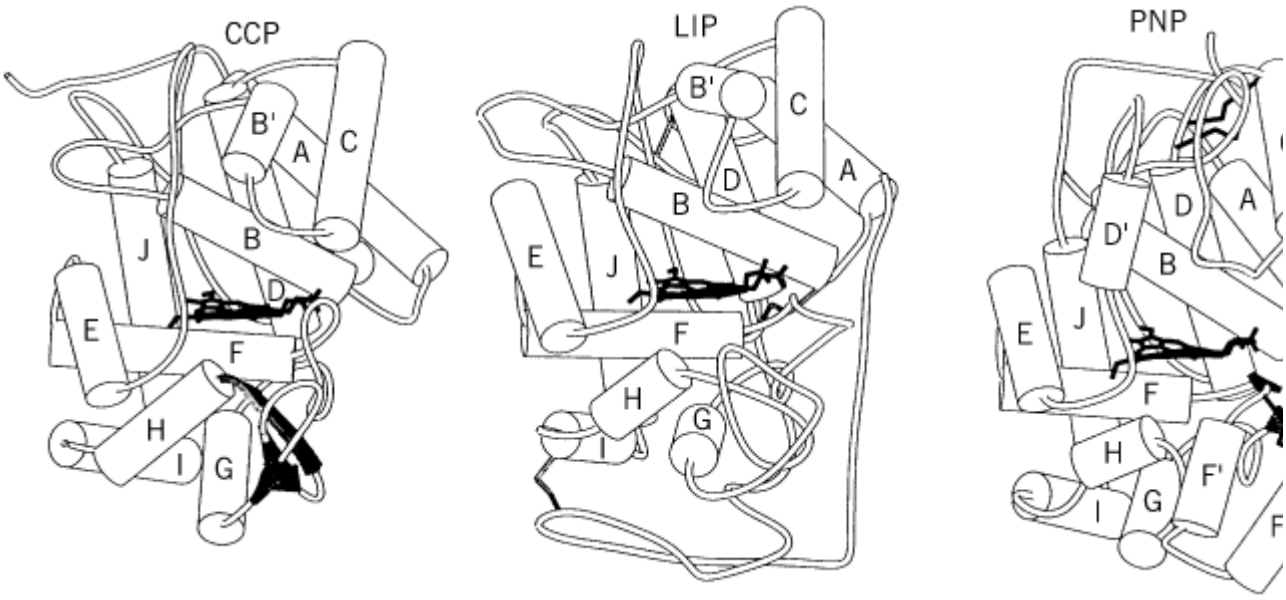
where P is the enzyme porphyrin whose heme iron is indicated, and S is the substrate. In Step 1, the peroxide removes two electrons from the enzyme to give what is called Compound I. In doing so, the peroxide O–O bond is broken, produces water, and the second peroxide-derived oxygen atom remains coordinated to the iron. One electron is removed from the iron to give the oxy-ferryl intermediate ($Fe^{4+}=O$), and a second electron is removed from the porphyrin to give a porphyrin p cation radical. In some peroxidases, an amino acid side chain is oxidized to a radical rather than the porphyrin. Normally, the formation of Compound I is quite easy to follow because the resting enzyme is red/brown in color, whereas Compound I is green. In Step 2, the porphyrin radical is reduced, producing a substrate radical, S·. Because of porphyrin reduction, Compound II is no longer green, but red. Finally in Step 3, Compound II is reduced by a second substrate molecule. In plant peroxidases, the substrates are normally small aromatic molecules. Once substrate radicals form, they dimerize or disproportionate in nonezymatic reactions.

2. Three-Dimensional Structures

From 1980 to 1993, only one nonmammalian heme peroxidase crystal structure was known, cytochrome ***c*** peroxidase. Since then an additional six structures have been determined (2), and there may well be more on the way. Representative examples of Class I, II, and III peroxidases are shown in Fig. 1. The sequence identity can be as low as 15% between peroxidases, yet the crystal structures have a similar fold independent of sequence homology or **phylogenetic** origin. This underscores the important "rule" in structural biology that tertiary structure is far more conserved than primary structure. All of the various peroxidases consist of a core of 10 alpha helices, two of which, the B

and F helices, sandwich the heme in place. The various peroxidases differ in structure primarily on the surface. For example, Class III peroxidases have two additional a-helices on the surface (F′ and F″), where cytochrome *c* peroxidase has a **beta**-sheet structure. It is thought that these additional helices in the Class III enzymes may play a role in substrate binding.

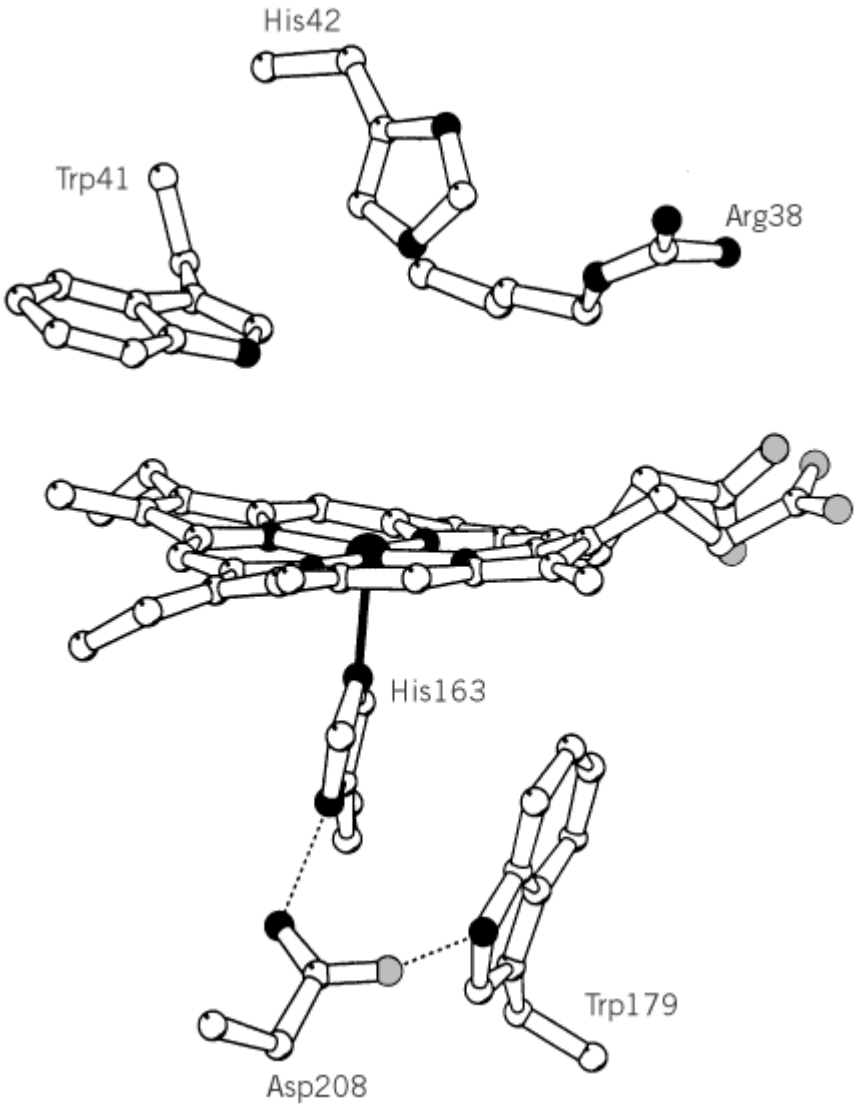
Figure 1. Representative crystal structures from each of the three primary classes of nonmammalian heme peroxidases: C (CCP, cytochrome *c* peroxidase); Class II (LIP, lignin peroxidase); Class III (PNP, peanut peroxidase). The a-helices are as labeled cylinders, and the b-sheet structure as shaded ribbons.



3. Active-Site Structures

Not surprisingly, the active sites of heme peroxidases are highly conserved (Fig. 2). The proximal pocket contains the His residue coordinated to the heme iron. This His ligand donates a hydrogen bond to the conserved Asp residue. It is thought that this interaction imparts a greater imidazolate character to the His ligand, resulting in extra negative charge on the His residue that stabilizes the Fe^{3+} state of the heme. This is one reason that peroxidases exhibit a lower redox potential in the Fe^{3+}/Fe^{2+} couple than the globins, even though the globins and peroxidases both use a His ligand. Directly adjacent to the His ligand, Most peroxidases have an aromatic residue stacked parallel to and in contact with the His ligand. This residue is Phe in most peroxidases, but Trp in the two known Class I peroxidase structures. For the class I peroxidases, the Trp indole ring N atom donates a hydrogen bond to the conserved proximal Asp residue (Fig. 2).

Figure 2. The active site structure of ascorbate peroxidase, a representative example of a nonmammalian heme peroxidase.



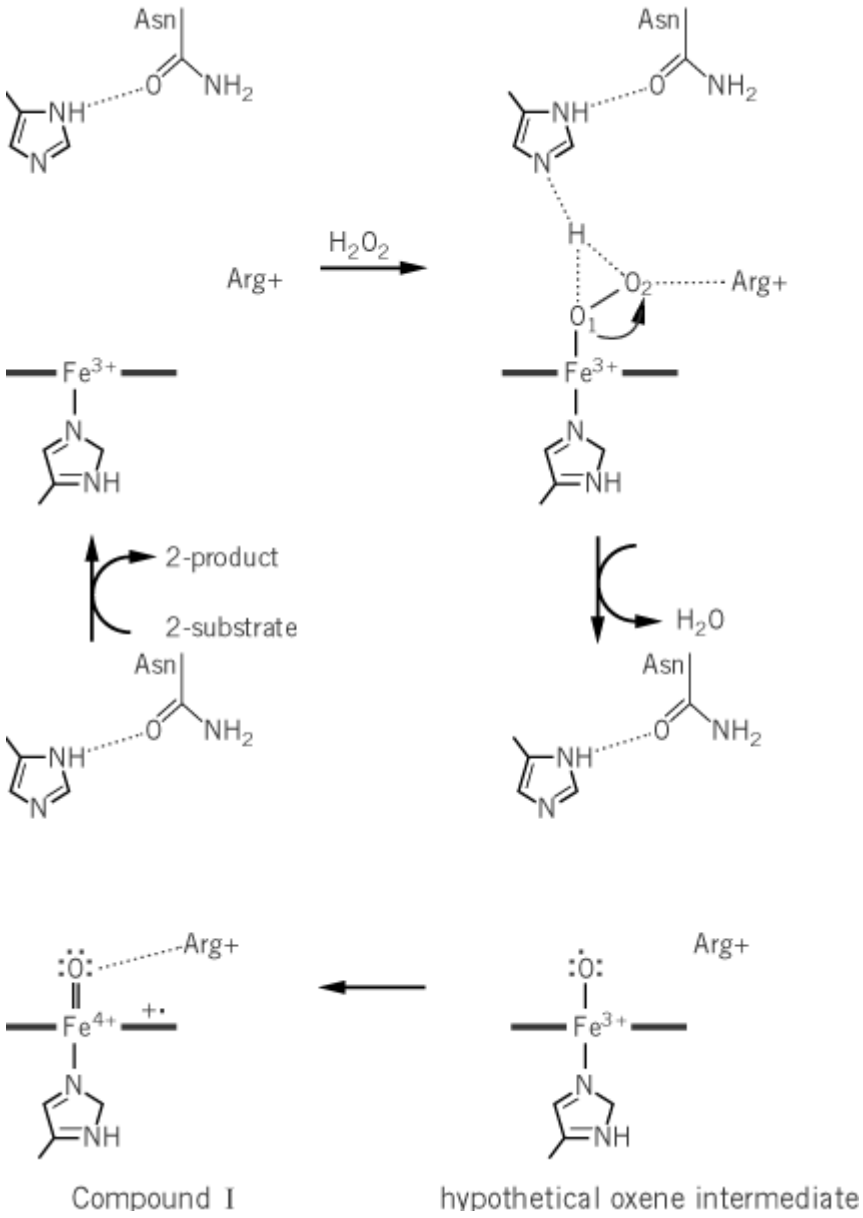
The B helix provides key catalytic residues on the opposite, distal side of the heme. It is thought that the distal His and Arg residue operate in concert to help cleave the peroxide O–O bond. Stacked parallel to the distal heme surface is a conserved aromatic residue, which is Phe in the known crystal structures, except for the Class I peroxidases, which use Trp.

4. Catalytic Mechanism

Most of the effort in understanding the peroxidase mechanism has centered on the formation of Compound I. It is thought that the distal His and Arg residues operate in concert to ensure that the peroxide O–O bond is cleaved heterolytically (3; Fig. 3). The distal His operates as an acid/base catalyst by removing a proton from the incoming peroxide and delivering it to the peroxide O2 atom. As shown in Fig. 3, the distal His donates a hydrogen bond to an invariant Asn residue, which ensures that the Nd2 of the distal His is free to accept a proton from the incoming peroxide. The Arg residue may help to stabilize a developing negative charge on the leaving O2 atom. The net result is heterolytic fission of the peroxide O–O bond. This leaves behind an “oxene” O atom that contains only six valent electrons, a potent oxidant. The oxene center removes one electron from the iron atom, to give Fe^{4+} and one from a neighboring organic group, normally the porphyrin. The crystal structure of Compound I (4) shows that the distal Arg residue swings in to hydrogen-bond with the

iron-linked oxygen atom. This may account in part for the stability of the Fe^{4+} = O center in Compound I.

Figure 3. The catalytic mechanism of Compound I formation.



The formation of Compound I is stoichiometric and has a second-order rate constant of between 10^7 and $10^8 M^{-1}s^{-1}$ for most heme peroxidases. Site-directed mutagenesis has been used to probe this mechanism by amino acid substitution of key catalytic groups in the active site. Changing the distal His to Leu (5) lowers the rate of Compound I formation by 10^5, demonstrating that the distal His is indeed a critical residue. Somewhat surprisingly, the nature of the proximal ligand is not important for Compound I formation because a Gln that replaces the proximal His residue affects only the stability of Compound I and not the rate of formation (6).

5. Enzyme Substrate Complexes

All of the known heme peroxidase structures show that one heme edge is accessible to small aromatic molecules that are typical peroxidase substrates. It is generally thought that small substrates interact at this site and deliver electrons directly to the heme, resulting in reduction of the Compound I porphyrin radical or Compound II $Fe^{4+} = O$ center. Nevertheless, there is no direct structural evidence for this view. To date, only the structures of two heme peroxidase-substrate complexes are known. Manganese peroxidase oxidizes Mn^{2+} to Mn^{3+}, and the Mn^{3+} operates in a complex with dicarboxylic acids as a diffusible oxidant of lignin. The crystal structure of manganese peroxidase (7) shows that Mn^{2+} coordinates with protein carboxylates and one heme propionate. Cytochrome *c* peroxidase is unusual among the known heme peroxidase structures because its substrate is another protein, cytochrome *c*. The crystal structure of the cytochrome *c* peroxidase–cytochrome *c* complex (8) has provided important insights into the nature of interprotein **electron transfer** reactions.

6. Heme Halo Peroxidases

The crystal structure of one heme halide peroxidase is known (9). Chloroperoxidase (CPO) is secreted by the mold *Caldariomyces fumago*, where it functions to chlorinate 1,3-cyclopentanedione to the natural product 2,2-dichloro-1,3-cyclopentanediol (caldariomycin). The catalytic cycle of CPO is similar to other heme peroxidases. However, in CPO the oxidizing power of Compound I is used to oxidize Cl^- ions to HOCl, and then the HOCl operates as an organic chlorinating agent. Traditional heme peroxidases cannot catalyze this reaction probably because the redox potential of Cl^- is too high. However, CPO operates at very low pH (≈3) where the redox potential and hence the reactivity of Compound I may be significantly increased over other peroxidases that operate closer to physiological pH.

CPO consists of a single 30-kDa polypeptide chain, one heme group, and one disulfide bond. The crystal structure shows at least 14 different sites of **glycosylation**. The fold is unlike that of other heme peroxidases, and the proximal ligand is a Cys residue not His. This is very similar to cytochromes P450, which also use a Cys ligand. As a result, CPO shares spectral features characteristic of P450s. The most significant is the 450-nm band in the visible absorption spectrum when the enzyme is reduced in the presence of carbon monoxide to give the Fe^{2+}–CO complex.

6.1. Reactions Catalyzed by Chloroperoxidase

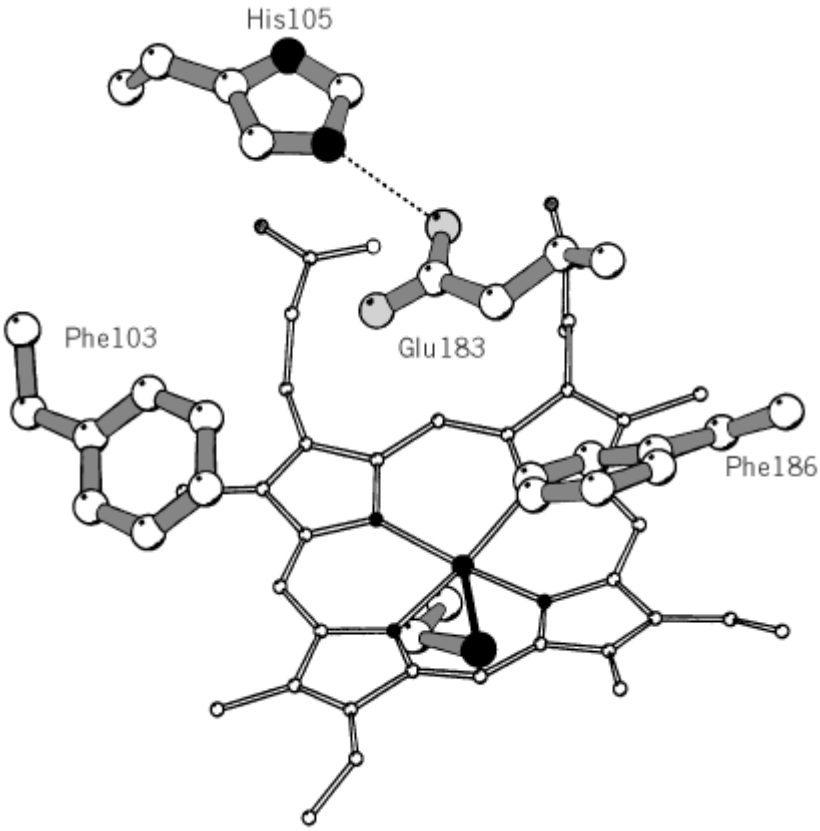
CPO is one of the most diverse of the known heme enzymes. In addition to operating as a chloroperoxidase, CPO exhibits activities characteristic of traditional heme peroxidase, catalase, and cytochrome P450s:

Halogenation (normal function)	$RH+H_2O_2+Cl^-+H^+ \rightarrow R\text{-}Cl+2H_2O$
Dehydrogenation (heme peroxidases)	$2RH+H_2O_2 \rightarrow R\text{-}R+2H_2O$
H_2O_2 decomposition (catalase)	$2H_2O_2 \rightarrow O_2+2H_2O$
Oxygen insertion (P450)	$R+H_2O_2 \rightarrow R\text{-}O+H_2O$

Sulfoxidation and epoxidation reactions catalyzed by CPO proceed with a high degree of enantioselectivity (10, 11). Even the typical peroxidase dehydrogenation reactions proceed with enantioselectivity, something other peroxidases cannot do. The CPO crystal structure provides some insights into these unusual functional properties. Although CPO is a helical protein, the overall fold is unique not the typical peroxidase fold. In addition, the heme is accessible from the top distal surface, not the heme edge. Bracketing the distal heme pocket near the $Fe^{4+} = O$ center are two key

Phe residues and other **hydrophobic** groups that form a shallow pocket that is the most probable site for substrate binding (Fig. 4). The asymmetrical nature of this pocket can account for the observed enantioselectivity.

Figure 4. The active site structure of chloroperoxidase. Glu183 most likely serves the same acid/base catalytic role as the distal His in traditional heme peroxidases. The two Phe residues shown help form the substrate binding site that enables this enzyme to catalyze enantioselective sulfoxidation, epoxidation, and electron transfer reactions.



Like other peroxidases, CPO forms Compound I with an Fe^{4+} = O center and porphyrin radical. The catalytic groups, however, are quite different in CPO. Directly adjacent to the peroxide binding site, CPO has a Glu residue rather than His, and there is no active-site Arg in CPO.

7. Other Heme Peroxidases

Although the nonmammalian heme peroxidases have received most of the attention, the heme-containing peroxidases are very diverse. Mammals produce well-known peroxidases like myeloperoxidase, **lactoperoxidase**, and thyroid peroxidase. Although these peroxidases contain heme and have active sites similar to the nonmammalian heme peroxidases, these enzymes are larger and have different three-dimensional structures (12). The best understood is myeloperoxidase. The function of myeloperoxidase in white blood cells and the related eosinophil peroxidase is to oxidize halides and thiocyanate ions to produce HOCl, HOBr, and HOSCN, which are potent antipathogen oxidizing agents. The marine worm *Amphitrite ornata* produces a dehalogenating heme-containing peroxidase (13). *Mycobacterium tuberculosis*, the causative agent in tuberculosis, produces a heme catalase/peroxidase that metabolizes the most widely used antituberculosis drug, isoniazid. Strains resistant to isoniazid have a point mutation in the catalase/peroxidase, which implicates the peroxidase as a drug activator (14). Other bacteria, such as *Pseudomonas aeruginosa*, produce a

cytochrome *c* peroxidase that contains two heme groups (15).

8. NonHeme Peroxidases

A number of peroxidases do not have heme as the prosthetic group. The fungus *Curvularia inaequalis* produces a chloroperoxidase that utilizes vanadium (VO_3) as a cofactor (16). Vanadium bromoperoxidases are also well known in **algae** (17). NADH peroxidase uses a flavin (18), and glutathione peroxidase is unique in utilizing an essential selenocysteine residue at the active site to oxidize glutathione and reduce hydroperoxides (19). There also are peroxidases that contain no metal center or other cofactors, such as the haloperoxidase of *Pseudomonas pyrrocinia* (20). In many of these, a detailed understanding is just developing based on recent advances in cloning and expression of these unusual and interesting peroxidases.

Pertussis Toxin

Among the several virulence factors implicated in the pathogenesis of whooping cough, a major role is played by pertussis toxin (PT), which is also a major determinant in the development of antipertussis protective antibodies (1). PT is active on a variety of cells and causes a wide range of effects, due to the **ADP-ribosylation** of different trimeric cytosolic **G proteins** involved in cell signal transduction (2).

PT is composed of five different subunits: S1 (21 kDa) is the catalytic part, and S2, S3, two copies of S4, and S5 form the cell-binding pentamer B. Despite the heterogeneity of the components of B and lack of an appreciable primary structure similarity, the overall structural organization of PT is closely similar to those of other oligomeric toxins having B units (3-7). The B pentamer is disk-shaped, and its subunits fold in six antiparallel b-strands with a-helices lining the central pore (6). S2 and S3 possess additional domains with a lectin-like fold, which were suggested to determine the different sugar-binding properties of PT being different from those of cholera toxin and enterotoxins (6). In fact, PT binds to **glycoproteins**, such as fetuin , having an Asn-linked branched mannose core with terminal N-acetylglucosamine (8).

At variance from cholera toxin, the carboxyl terminus of S1 enters the B oligomer central pore only halfway, and there are fewer protein–protein contacts (4, 6). The similarity with cholera toxin is very high in the active site, with overlapping glutamate and tyrosine residues essential for activity. His35 occupies a central position in the **NAD**-binding cavity of PT, as is also the case with the active sites of diphtheria toxin and exotoxin A from *Pseudomonas*. Little information is available on the internalization of PT or the mechanism of membrane translocation of S1 (8). That the structural and functional organization of PT is similar to that of cholera toxin, entertotoxins, and shiga toxins suggests there are further similarities in their mode of cell penetration.

Reduction of the S1 subunit in the presence of detergents frees an ADP-ribosyltransferase activity specifically directed toward the a subunit of several trimeric G proteins. At variance from cholera toxin and entertotoxin, PT catalyzes the ADP-ribosylation of a *cysteine* residue present in a Xaa-Cys-Gly-Leu-Xaa motif contained in the carboxyl-terminal part of the a subunit of several trimeric G proteins, including G_i, G_o, and G_{gust}. G_s has a tyrosine residue in the position of the cysteine and is not modified by PT. Another difference from cholera toxin is that the S1 enzymic activity is greatly enhanced by ATP and other adenine nucleotides (9). The result of the S1-catalyzed ADP-ribosylation of G_i and G_t is different from the cholera toxin or entertotoxin modification of G_s because the carboxyl-terminal cysteine residue of G_i and G_t is centered in the area of interaction between the G protein and plasma membrane receptor. As a consequence, the inhibitory physiological effects normally mediated by these G proteins are not transmitted. The PT oligomer B has biological functions independent of the ADP-ribosyltransferase activity, such as that of inducing the proliferation of T lymphocytes (10).

Pest Regions

One of several features of proteins that have been proposed lead to their rapid **protein degradation** is the presence of so-called PEST regions: protein domains that are enriched in **proline, glutamic acid, serine**, and threonine residues. These regions were first described by Rechsteiner and co-workers in the mid-1980s after searching for structural features of proteins that correlate with short half-lives. They developed a computer-based algorithm locating the presence of at least one P, E, S, or T residue in a hydrophilic stretch of at least 12 amino-acid residues and flanked by a positively charged residue. Consequently, PEST regions do not represent a specific sequence per se, but they are instead a general feature of the relevant protein domains. Less than 10% of mammalian proteins of known amino acid sequence have such PEST regions, but a high percentage of short-lived proteins do. In some cases, proteins become more stable after removal of their PEST regions, and a few examples have been shown where transplantation of PEST regions into long-lived proteins causes their rate of degradation to be increased.

The mechanism by which PEST sequences may influence degradative rates has remained elusive. Some PEST-containing proteins are degraded by **proteasomes** in a **ubiquitin**-dependent manner, and they require different E2 and E3 enzymes (see Ubiquitin). On the other hand, PEST regions may simply correlate with rapid hydrolysis because they often contain **consensus sequences** for known protein **kinases**, and **phosphorylation** often signals ubiquitin conjugation and degradation. Also, proline-rich hydrophilic domains are likely to exist as unfolded loops on the surface of protein structures and to be more susceptible to interactions with **molecular chaperones**, kinases, and other proteinases. Theories involving degradation by calpains and proline endopeptidase have, however, proved false.

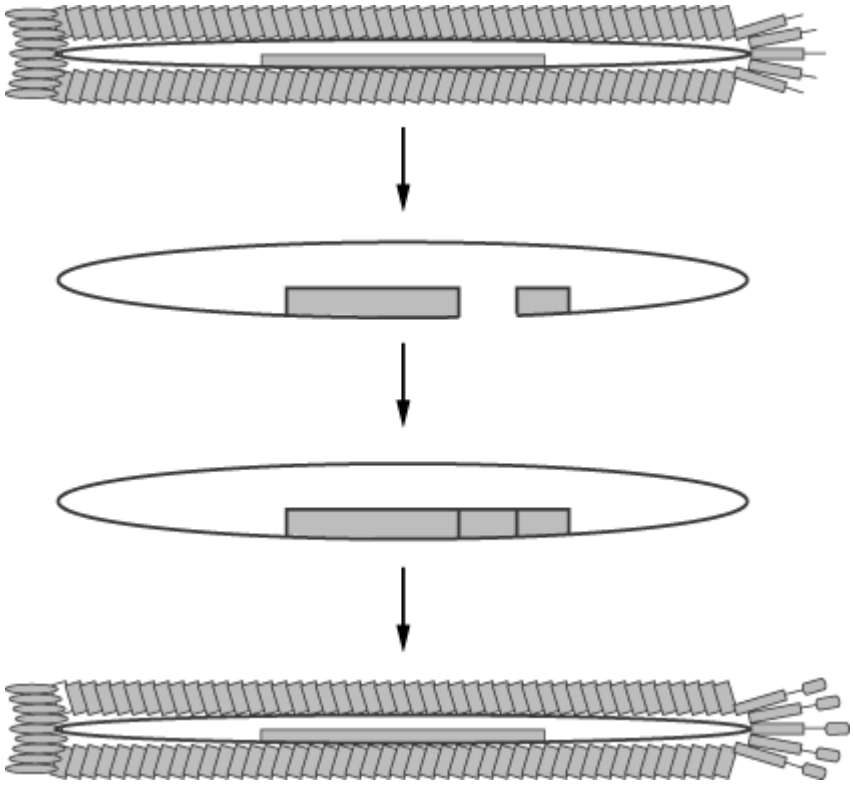
Phage Display Libraries

Phage display libraries are a variant of expression libraries in which **cloned** DNA inserts are expressed as polypeptide **fusion proteins** with bacteriophage capsid proteins, so that the foreign proteins are “displayed” on the exterior of the modified **virus** particle (Fig. 1) (1-3). Because the virus also contains a DNA genome, a physical linkage is maintained between the displayed peptide

and its encoding DNA sequence. This linkage is the core of the power of phage display. Although the displayed proteins behave in many respects as soluble factors, they remain associated with their DNA code as part of an infectious particle. Thus, even trace amounts of display phages with desired activity can be amplified by infection, and the active peptide sequences can be decoded by DNA sequencing.

Figure 1. Schematic illustration of phage display. A double-stranded copy of the phage genome is cleaved enzymatically, and foreign DNA is inserted in-frame into a capsid gene. After introduction of recombinant phage DNA into bacterial cells, novel fusion phage are generated with foreign peptides displayed as capsid fusion proteins on the phage surface.



Several different bacterial viruses have been modified to serve as phage display vectors. By far the most common type of vector is derived from the filamentous Ff bacteriophage (4). The popularity of this virus is due first to the fact that it packages a relatively small single-stranded DNA genome, providing some advantages in mutagenesis and DNA sequencing, and second to the robust technologies that have been developed for displaying both short peptides and larger proteins. Other viruses that have been adapted for phage display include lambda phage and **T4 phage**. Future directions in this field will likely include vector construction using human enteric bacteriophages for the purpose of mucosal vaccine development. In addition, certain human viruses could conceivably be modified as viral display vectors for human gene therapy applications.

Filamentous phage display vectors fall into two categories. First are the phage vectors, which accommodate foreign DNA fused to one of several capsid genes within the phage genome. Phage vectors are adequate for peptide display, but larger polypeptide–capsid fusion proteins tend to interfere with phage assembly or infectivity. This interference can be tolerated if the phage can incorporate a preponderance of normal capsid proteins, with only a small proportion of fusion capsid proteins present. Such a situation occurs in the second category of vectors, called “phagemids,” in which the foreign DNA and the capsid gene are both cloned into a special type of plasmid containing

the phage DNA-packaging signal. Foreign DNA is thus cloned as a gene fusion with the phagemid capsid protein. A phagemid is not infectious by itself, but in the presence of a "helper" phage the phagemid DNA can be packaged into an infectious virus particle that displays a mixture of normal and fusion capsid proteins. Using phage and phagemid vectors, a great number of foreign sequences have been expressed as viral capsid fusion proteins, including peptides, **antibodies**, **enzymes, DNA-binding proteins**, RNA-binding proteins, and regulatory proteins (reviewed in Ref. 4). Furthermore, any of these proteins can be diversified to form combinatorial phage display libraries, which can then be screened to identify novel proteins with desirable properties.

Phage display screening is a robust technology that typically operates through affinity selection of phage-encoded molecules that interact with target proteins (1). A phage display library typically expresses billions of different peptides or polypeptides. The active minority of the library can be fractionated from the noninteracting majority by affinity partitioning over a solid-phase target. Phages that bind are then readily eluted and amplified by infection of a suitable bacterial host, and further rounds of selection can be performed. This iterative selection process provides a powerful means to obtain specific peptide aptamers, as well as sequence–activity relationship (SAR) data for any target of interest.

Phage display has proven to be a powerful means of obtaining functional probes to study any target of interest. Thus, peptide aptamers can be used to characterize target function in much the same way that antibodies have been used historically to detect, trap, and inhibit their targets. However, unlike animal-based antibody technologies, phage display can yield peptide or antibody functional probes without requiring immunogenicity or immunization by the target. Furthermore, the complexity of modern phage display libraries exceeds the genetically encoded complexity of the immune system. Thus, phage display technologies are likely to continue to find increasing applications throughout the biological and medical sciences.

Phagocytosis

Phagocytosis is the ability of a cell to internalize large particles, as exemplified by the feeding of phagocytic amoebae, which is one type of endocytosis. Phagocytosis is initiated by the binding of large extracellular particles (eg, bacteria) to specific cell-surface receptors, either directly or indirectly. Indirect recognition involves host-derived opsins, such as antibody or **complement** fragments, that coat the particles and serve as ligands for some phagocytic receptors. The best-characterized opsins are antibodies that bind to surface **antigens** on infectious microorganisms and form an antibody coat in which the tail region of each antibody molecule (the **Fc region**) is exposed. Binding of the antibody-coated particles to specific Fc receptors on phagocytic cells initiates phagocytosis. Ligands for other receptors, including complement receptors (see Complement System), integrins, cell-surface lectins, and certain glycosylphosphatidylinositol **(GPI)-anchored** proteins [eg, CD14 (1)], also activate phagocytosis.

A common feature of the phagocytic events mediated by these various receptors is that particle internalization depends on the polymerization of actin. Activated cell-surface receptors transmit signals to the cytoplasm that induce actin polymerization (2, 3). During Fc receptor-mediated phagocytosis at least, these activation signals involve the small GTP-binding proteins Rac/Rho/CDC42 and **tyrosine kinases**. The localized polymerization of actin at the site of particle attachment to the cell pushes plasma membrane around the particle, allowing further opsin-receptor interactions (zippering) and the progressive envelopment of the particle within a membrane invagination tightly apposed to the particle surface. When engulfment is completed, the forming phagocytic vesicle, or phagosome, is sealed and detaches from the cell surface.

In most cases the phagosome fuses with resident compartments of the endocytic pathway (endosomes and **lysosomes**) to acquire the spectrum of hydrolases that digest the phagosome content. The resulting digestion products are transferred to the cytosol and used to synthesize cellular constituents or are secreted from the cell. In multicellular organisms, phagocytosis is primarily associated with defense against infection by ingesting invading microorganisms and the scavenging of **senescent**, damaged, or **apoptotic** cells (1) and cellular debris. These functions are generally performed by specialized white blood cells, such as macrophages and neutrophils, that act as "professional" phagocytes. These cells are extremely active. In humans, for example, macrophages remove around 10^{11} senescent red blood cells every day. However, most cells are capable of phagocytosis when challenged with appropriate ligands.

Many invasive bacterial, fungal and protozoan pathogens use phagocytosis to enter cells. Some, such as *Listeria* and *Yersinia*, use cadherins or integrins, respectively, as receptors to initiate endocytic events similar to those described previously. Others, such as *Shigella*, secrete proteins that activate phagocytosis directly. Then the fate of the phagocytic vesicle varies according to the nature of the pathogen internalized. *Listeria*, *Shigella*, and *Trypanosoma cruzi* induce lysis of the phagosome membrane to gain access to the cytoplasm. Other agents (*Legionella*, *Salmonella*, *Mycobacterium avium*) reside and replicate within phagocytic vesicles and produce components that prevent fusion with lysosomes, thus avoiding the hydrolytic consequences of endocytosis, or modify the environment within the phagosome to minimize the effects of the hydrolytic environment (4, 5).

Phalloidin

Phalloidin is a cyclic heptapeptide found in the highly poisonous mushroom *Amanita phalloides*. Phalloidin binds with very high affinity to F-actin and stabilizes these filaments by preventing depolymerization. It contains several uncommon amino acids and is resistant to all proteolytic enzymes tried thus far. While phalloidin has the ability to be highly toxic to a cell due to the changes that it will induce in actin polymerization, it is now known that the toxicity of *Amanita phalloides* is due mainly to the a-and b-amanitins (potent inhibitors of **RNA polymerase** II), since phalloidin is not absorbed from the gastrointestinal tract (1). Nevertheless, phalloidin has been an extremely important drug in answering structural, biochemical, and cell biological questions about actin.

Phalloidin does not bind to monomeric actin (G-actin), but binds with a 1:1 stoichiometry to protomers within the F-actin filament. This is the opposite mode of binding of DNase I (see DNase 1 Sensitivity), which binds with high affinity to G-actin but not to F-actin. As a result of this selective binding, both may be used to assay the concentrations of G- vs F-actin within a fixed cell. The phalloidin-stabilized filament resists depolymerization that would otherwise be induced by a reduction of the actin concentration, by chaotropic agents, **cytochalasins**, heat denaturation, and proteolysis (2). The critical concentration is the concentration of the monomeric species of actin at which it is in equilibrium with **polymers**, and this is about 10^{-6} M for muscle actin. Phalloidin reduces this critical concentration by a factor of about 25. These properties of phalloidin have made it a very useful tool for labeling actin filaments within a cell (using fluorescent derivatives of phalloidin) and for stabilizing actin filaments used in structural and biophysical studies.

Phase Problem

To determine the structure of a molecule by X-ray crystallography, after collecting and processing the data, the electron density r(x y z) in the crystal unit cell can be calculated at every position x y z:

$$\rho(xyz) = \frac{1}{V}\sum_{h}\sum_{k}\sum_{\ell}|F(hk\ell)| \times \exp[-2\pi i(hx + ky + \ell z) + i\alpha(hk\ell)] \quad (1)$$

To use this equation requires that the values of both $F(hk\ell)$ and $a(h\ k\ \ell)$ for each reflection $h\ k\ \ell$ are known. The $F\ (hk\ell)$'s are easily found because (apart from corrections) they are proportional to the square root of the measured scattered intensities $I\ (h\ k\ \ell)$. The phase problem is that the phase angles $a(h\ k\ \ell)$ are not provided directly by the experimental data. This fundamental problem greatly delayed the use of X-ray crystallography initially, but it is hardly a problem anymore. For small molecules, it has long been solved by direct methods. In the crystallography of macromolecules, several methods exist to determine the phase angles of the reflections:

1. isomorphous replacement
2. molecular replacement
3. **MAD** (multiple-wavelength anomalous dispersion)

Classical direct methods are applicable to macromolecular crystals, only if the protein is small and the X-ray data can be collected to high resolution (1).

Phase Variation, Pili

Certain enterotoxigenic strains of *Escherichia coli* produce pilus-like appendages called *colonization factor antigens* (CFAs) that are longer than common type I pili. Production of type I pili or CFA is mutually exclusive in these bacteria and thus represents a specialized example of bacterial phase variation. That displayed by type IV pili of *Neisseria gonorrhoeae*, is the best-characterized system. The *N*-terminal domain of *N. gonorrhoeae* pilin is **hydrophobic** and highly conserved among different variants. Other regions of the pilin molecule, however, known as *minicassettes*, vary widely in amino acid sequence. There is also wide variation at the DNA level between the various copies of the **genes** that encode a particular pilin protein. In *N. gonorrhoeae* the expression of the *pilE* gene is controlled at transcription by a two-component regulatory system; this comprises the transcriptional activator PilA and the sensor component PilB, which **phosphorylates** PilA. If Pil^+ and Pil^- respectively represent the phenotypes when functional pili are assembled or not on the bacterial cell surface, then phase variation represents the fluctuation that occurs between Pil^+ and Pil^-. There are several types of phase variation (1).

1. The first arises because the expressed protein has two possible sites (P^+ and P^s) at which subsequent processing can take place. When cleaved **proteolytically** at P^+, the pilin protein assembles into normal pili (Pil^+). In contrast, when it is cut at P^s it no longer contains the hydrophobic region required for assembly. The protein is secreted and lost from the cell, so there is no pili formation (Pil^-).

2. The second type of phase variation is similar to the first in that it again gives rise to a pilin protein that is aberrant and not capable of forming pili *in vivo*. Although the pilin gene is present in multiple copies in the chromosome, generally only one of these has a **promoter** and is expressed. This gene is designated *pilE*, where *E* represents expression. Those gene copies that are not expressed are termed *pilS*, where *S* represents silent. Both the *pilE* and *pilS* genes contain a number of internal repeated DNA sequences. Homologous recombination, which involves exchanges of the interior regions of the genes, can lead to unequal exchange of DNA because of the repetitive nature of the sequences. As a result, the PilE protein produced may be larger in size than normal. As before, this cannot be processed in such a way that pili formation is possible, hence the **phenotype** is Pil^{-}.

3. The third mechanism of phase variation concerns the *pilC* gene. The expressed protein PilC, which has been detected by immunoelectron microscopy at the tip of the pili, is an important protein in the assembly and functioning of intact mature pili. Towards the 5′ end of the *pilC* coding sequence there is a long run of G bases. Slipped-strand mispairing during synthesis alters the number of G bases and generates a frameshift mutation . This again gives rise to Pil^{-} phenotype. Note, however, that pili of normal appearance are produced in this case and that another phase-variable pilus-associated protein replaces PilC in its assembly function, but it lacks the ability to bind to epithelial cells (2). Phase variation probably evolved to allow the bacterium to escape the immune response of its host and to allow it to adapt to new cell types (1).

Phenotypic Lag

After a cell sustains a mutation, there may be a delay of one or more generations before the mutant **phenotype** is expressed. This delay has two causes. First, a recessive mutation may be **complemented** by the wild-type **allele** on another chromosome. In mitotically dividing **diploid** cells, at least a one-generation delay occurs before the phenotype is expressed. Under most laboratory conditions, haploid organisms also have more than one chromosome per cell and show a lag of one or two generations. Secondly, when a mutation that gives rise to a mutant protein first appears, the cell may have many copies of the **wild-type** protein. Expression of the mutant phenotype may be delayed until these preexisting proteins are diluted or degraded. A classical example from *Escherichia coli* genetics is resistance to **bacteriophage** T1. Resistance is conferred by mutations that alter the phage **receptor** on the cell surface, but several generations are needed before the preexisting sensitive receptors are diluted. Even dominant phenotypes may fail to be expressed until the cellular concentration of the wild-type protein falls. Phenotypic lag complicates the determination of mutation rates from fluctuation tests (1-4).

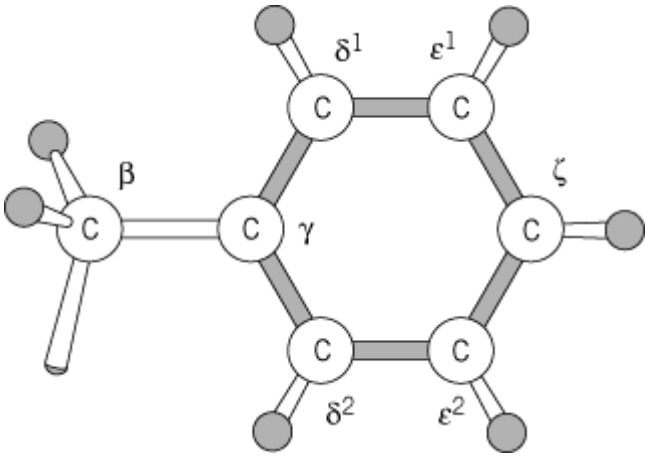
Phenylalanine (Phe, F)

The amino acid phenylalanine is incorporated into the nascent polypeptide chain during **protein biosynthesis** in response to two **codons**—UUU and UUC—and represents approximately 3.9% of the residues of the proteins that have been characterized. The phenylalanyl residue incorporated has a mass of 147.18 Da, a **van der Waals volume** of 135 $Å^3$, and an accessible surface area of 218 $Å^2$. Phe residues are changed infrequently during divergent evolution; they are interchanged in **homologous** proteins most frequently with tyrosine and leucine residues.

Phe is one of the three amino acids with an aromatic ring in its side chain:



which has **absorbance** and **fluorescence** spectral properties that are very useful in quantifying proteins and analyzing their structural properties. The other two—tyrosine and tryptophan—predominate, however, so Phe residues are useful only in their absence. The aromatic ring of Phe residues is comparable chemically to that of benzene or toluene; consequently, it is largely nonpolar (except for the tendency of the electrons of the peripheral H atoms to be drawn into the aromatic ring) and is chemically reactive only under extreme conditions that are not applicable to proteins.

Tyr residues occur primarily within the interiors of folded protein structures, and approximately 50% are totally buried; normally, they are still rotating rapidly by 180° rotations about the C_b–C_g single bond. They tend to occur primarily in **alpha-helices**, although also in **beta-sheets**, and they favor the a-helical conformation in model peptides.

Phenylketonuria

The metabolic disorder phenylketonuria (PKU) was first described in 1934 by A. Følling, who was investigating the excretion of ketone bodies in the urine of two mentally retarded children. The reagent in use, acidified $FeCl_3$, typically turns a purple-red color with ketones. The urine of these children turned bright blue-green instead. Examination of additional mentally retarded children uncovered eight more who were similar, both clinically and in their urine reactions. Følling subsequently demonstrated that the responsible urinary constituent was phenylpyruvic acid, thus the name phenylketonuria. In addition to mental retardation, affected children share a number of clinical features, including irritability, seizures, eczema, and a "mousy odor." They tend to be more lightly pigmented than others in the same family.

The rarity of this disorder in the general population and the occurrence of more than one affected person in a sibship suggested recessive inheritance. The equal occurrence of males and females and the fact that the parents and other relatives were not affected was consistent with autosomal recessive inheritance.

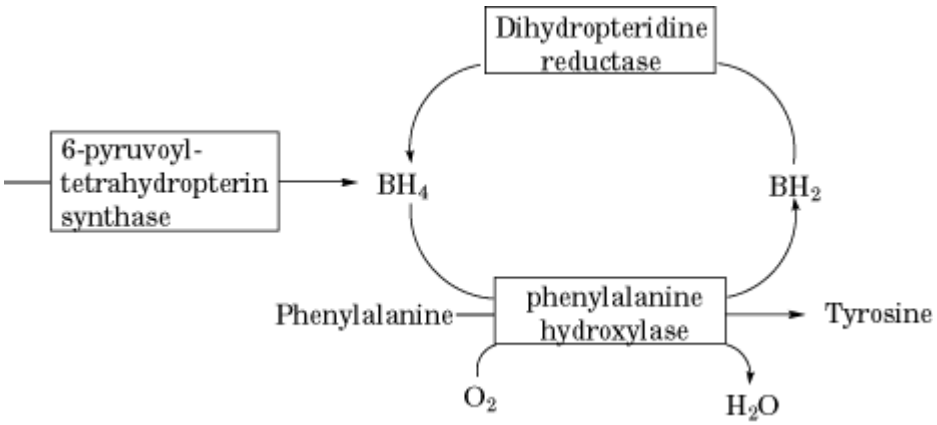
1. The Biochemistry of PKU

F{ø}lling suggested that patients who have PKU have a block in metabolism of phenylalanine, and in 1947 G.A. Jervis proposed that the metabolic error is in the conversion of phenylalanine to tyrosine. He subsequently proved this hypothesis by showing that liver from a PKU patient cannot make the conversion. Thus, PKU was among the earliest examples of a *metabolic error*, a term proposed by A.E. Garrod in 1909, and it has served as a model for other metabolic defects.

Phenylalanine is efficiently reabsorbed in the kidneys, leading to maintenance of very high blood levels. In normal persons, the blood phenylalanine is ca. 60 μM. The level in PKU patients can be 40 times higher. This leads to formation and excretion of otherwise rare metabolites of phenylalanine, such as phenylpyruvic acid, phenylacetic acid, and *o*-hydroxyphenylacetic acid. These metabolites very likely contribute to the clinical features of PKU by interfering with various metabolic and developmental processes.

Phenylalanine hydroxylase (PAH; L-phenylalanine-4-monooxygenase; EC 1.14.16.1) is the enzyme that is ordinarily nonfunctional in PKU. The predicted polypeptide molecular weight is 51,862 daltons, but the enzyme is usually a homotetramer. It catalyzes the oxidation of L-phenylalanine, using tetrahydrobiopterin as a cofactor (Fig. 1). Production of PAH occurs almost entirely in the liver. A large number of PAH alleles are known. Some produce completely inactive PAH; others produce PAH that has reduced or normal activity. Persons whose allelic combinations produce PAH activity <1% of normal have classical PKU. If there is some activity, a mild form of the disorder may result. Heterozygotes, with one normal and one inactive allele, are phenotypically normal even though the total enzymic activity is reduced.

Figure 1. Three enzymes that are important in the conversion of phenylalanine to tyrosine. Additional enzymes and cofactors are required to form BH_4. Reduced activity of phenylalanine hydroxylase (PAH) can result from structural modifications of PAH or from deficiency of BH_4.



2. Treatment of PKU

Humans cannot make phenylalanine or tyrosine and must depend on diet for these two essential amino acids. The phenylalanine content of foods is in excess of body requirements for protein synthesis, and the surplus is metabolized via tyrosine. This suggested the possibility of reducing the accumulation of phenylalanine by reducing the dietary intake. Such efforts, initiated in 1953 by H. Bickel, ultimately proved successful. The low-phenylalanine diet must be introduced soon after birth of an affected infant in order to avoid permanent damage to the developing central nervous system.

With the development of an effective method of treatment, the urgency of neonatal diagnosis became apparent. In the early 1960s, R. Guthrie developed a microbial test using whole blood from a heel stick. This rapid and inexpensive test made large scale screening possible, and required screening of newborns for elevated blood phenylalanine has become widespread in western countries. Once the central nervous system has matured fully, persons with PKU are somewhat less sensitive to increased blood levels of phenylalanine. This includes not only regulation of protein intake but also avoidance of the artificial sweetener aspartame, which is a dipeptide derivative of aspartic acid and phenylalanine. However, long-term studies have shown benefits of continued treatment of adults.

Although dietary regulation has been highly successful, it is not a perfect treatment. Treated patients show mildly depressed IQ compared to non-PKU controls. One suggested cause is increased dysmyelination with age in the presence of elevated blood phenylalanine. Also, tyrosine is lower in PKU patients, treated or untreated, and this may lead to deficiency of neurotransmitters.

In view of the single gene and its single protein product that are defective in PKU, this disorder would seem a good candidate for gene therapy. It has not been considered a high priority, however, because of the effectiveness of dietary restriction of phenylalanine. When procedures for gene therapy have been sufficiently developed and tested, it is likely that they will be applied to PKU. Introduction of functional PAH genes during the neonatal period should cure the metabolic defect. This, in effect, was the case with one young boy who received a liver transplant for reasons unrelated to his PKU status.

The successful treatment of PKU by diet has led to the problem of maternal PKU, which occurs in successfully treated women who are homozygous for PKU and whose offspring therefore are heterozygous. The developing fetus, although genotypically normal (but heterozygous), depends on the mother to regulate blood phenylalanine. The fetus is also highly susceptible to moderate increases in blood phenylalanine. Prior to conception and during pregnancy, a PKU mother must regulate her blood phenylalanine levels rigorously to avoid damage to the fetus. The recommended maximal level is 360 μM.

One consequence of introducing screening was the recognition that some children have levels of phenylalanine that are above normal but that do not reach the levels that lead to pathology and that do not require dietary management. These cases of "hyperphenylalaninemia," defined as plasma levels >120 μM, are often due to homozygosity for PAH alleles that have low but nonzero enzyme activity. In other instances, the hyperphenylalaninemia is transient in neonates and disappears with time.

3. Other Defects That Interfere with Metabolism of Phenylalanine

In rare instances, high levels of blood phenylalanine are due to deficiencies of PAH activity caused by other loci. The cofactor 5,6,7,8-tetrahydrobiopterin (BH_4) is produced from 7,8-dihydrobiopterin (BH_2) by the enzyme dihydropteridine reductase (DHPR). The gene that codes for DHPR is on chromosome 4 at 4p15.31. In one form of PKU, loss of activity of this gene leads to absence of BH_4 and therefore to inactivity of PAH (Fig. 1). Because BH_4 is a cofactor in several other reactions that are important to brain function, dietary management of blood phenylalanine levels does not restore a normal phenotype. Such cases occur in 1 to 2 births per million.

A second rare variant of PKU is due to deficiency of 6-pyruvoyl tetrahydropterin synthase (Fig. 1), one of several enzymes necessary for BH_2 synthesis. This enzyme is coded by a gene on chromosome 11 at 11q22.3-q23.3. As in the case of DHPR deficiency, the neurological effects are not prevented by management of diet.

4. Molecular Genetics of PAH

The gene that codes for PAH is on chromosome 12 at 12q24.1. It is some 90 kb long with 13 exons. The messenger RNA is 2,677 nt long, consisting of 472 nt in the 5′ untranslated region, 1,356 nt (452 codons) in the coding sequence, and 849 nt in the 3′ untranslated region. Exons 1 to 12 are relatively small, varying in size from 57 nt to 197 nt. Exon 13 has 890 nt, of which 41 are coding. Introns vary in size from 1.0 kb to 23.5 kb.

Some 200 distinct mutations associated with PKU have been identified in the PAH gene. There are presumed to be many more that are associated with unrecognized hyperphenylalaninemia or that are normal variants. Some normal variants are known, and in a few instances they are polymorphic. Of the mutations that cause PKU, approximately three-fourths are nucleotide substitutions that lead to amino acid substitutions or premature chain termination. Another 25 or more are nucleotide substitutions that interfere with normal splicing of the RNA transcript. A number of small gene deletions have also been identified. A high frequency of mutations is found in exon 7, thought to be due to ascertainment bias rather than mutational hotspots. Almost any change in amino sequence in this region of the PAH molecule is likely to interfere with function.

A relatively small number of these mutations account for the majority of the cases of PKU, and particular mutations may be prevalent only in a limited population. Because several different mutations may occur with relatively high frequencies in a population, most so-called homozygotes are in fact compound heterozygotes, that is, the two alleles involve different mutations. Both, however, are nonfunctional. Comparison of mutations in European and Asian populations shows quite different spectra, indicating that most of the extant mutations arose after separation of the major races.

5. Population Genetics of PKU

The frequency of patients with PKU varies considerably among populations. In Norway, where PKU was first discovered, the frequency is ca. 1 in 14,000 births. Among Northern Europeans in general, the frequency is ca. 1 in 10,000 births, with a higher incidence of 1/4,500 in Ireland. Among U.S.

whites, the frequency is 1/8,000. The frequency among African-Americans is ca. 1/50,000. The frequency is very low in Ashkenazi Jews and Asians. A frequency of homozygotes of 1/10,000 corresponds to a gene frequency of 0.01 and a frequency of heterozygotes of 2%.

Investigation of PKU has been aided by the discovery of eight polymorphic DNA variants within the PKU gene. These were originally recognized as restriction fragment length polymorphisms, although now PCR is used for some sites. One of the sites involves different numbers of short tandem repeats, providing several alleles. Altogether, there are about 800 possible combinations (*haplotypes*) of "alleles" at these sites, of which only about 75 have been observed. Within a population, many fewer are observed, and usually only a few reach substantial frequencies.

The study of mutant-allele—haplotype associations in a variety of populations has provided insight into the origin and spread of the genes in historic and prehistoric periods. For example, the mutation R261Q is widespread in Europe but is always associated with haplotype 1. In general, haplotype 1 has a normal PAH allele. The interpretation is that this particular mutation arose on a haplotype 1 chromosome, and all R261Q mutations are descended from that single mutational event. In contrast, the R408W mutation occurs in northwest Europe on a haplotype 1 background and in eastern Europe on a haplotype 2 background. This suggests that two independent mutations occurred, one in a Celtic population and the other in a Slavic population.

Phosphate Buffers

Phosphate buffers are commonly used in biological work. Phosphoric acid, $O{=}P(-OH)_3$, has pK_a values of about 2, 7, and 12. All three hydroxy groups are identical and, indeed, all four oxygen atoms are identical on the NMR time scale as a result of rapid hydronations and dehydronations. Thus, 2 is the pK_a for the first H^+ to dissociate, even though it is coming equally from each of three groups. The next pK_a is raised to 7 because it is much harder for H^+ to dissociate from the charged $H_2PO_4^-$ ion than from the neutral H_3PO_4 molecule and, similarly, for the third pK_a. Hence, the Henderson–Hasselbalch equation for orthophosphate is

$$\begin{aligned} \mathrm{pH} &= 2 + \log\frac{[H_2PO_4^-]}{[H_3PO_4]} = 7 + \log\frac{[HPO_4^{2-}]}{[H_2PO_4^-]} \\ &= 12 + \log\frac{[PO_4^{3-}]}{[HPO_4^{2-}]} \end{aligned} \qquad (1)$$

The large separation of the pK_a values means that, for a buffer of $H_2PO_4^-$ and HPO_4^{2-}, the

concentrations of H_3PO_4 and PO_4^{3-} are negligible, and the p_a values of 2 and 12 become irrelevant.

An advantage of phosphate as a buffer is that salts such as NaH_2PO_4 and Na_2HPO_4 are solid and both can be weighed out in the appropriate quantities; hence, the reproducible preparation of phosphate buffers need not involve adjustments of pH. Care must be taken, however, that the salt used, hydrate or anhydrous, does not lose or gain water on storage. Another advantage is that phosphate is transparent in the UV, down to wavelengths at which proteins may be estimated by their peptide bond absorbance, where carboxylate ions also absorb.

The main disadvantage is that with a doubly charged buffering species, the pK_a of 7.2 is three times more sensitive to changes in ionic strength than a buffer with only singly and zero charged components. Another disadvantage is that phosphate can support algal or fungal growth as a nutrient. Phosphate will also sequester and precipitate many cations, especially Ca^{2+} (see Calcium Signaling).

1. Diphosphate (pyrophosphate)

A variant of phosphate buffer is diphosphate (pyrophosphate). The acid, $HO–P(=O)(OH)–O–P(=O)(–OH)–OH$, has two strongly acidic groups, with pK_a values near 2, as with orthophosphate. The $–P(=O)(–OH)–O^-$ groups generated are electron-withdrawing, and so the next $–OH$ group has its pK_a lowered from the 7.2 of orthophosphate to 6.2 (at an ionic strength of 0.1 M; with its more strongly charged ions, the dissociation constants of diphosphate are even more sensitive than orthophosphate to changes in ionic strength). The $–P(=O)(–O^-)_2$ group, however, is slightly electron-donating, so that the final pK_a is raised to 8.4. Hence, the Henderson–Hasselbalch equation for pyrophosphate in the neutral pH region is

$$\mathrm{pH} = 6.2 + \log \frac{[HP_2O_7^{3-}]}{[H_2P_2O_7^{2-}]} = 8.4 + \log \frac{[P_2O_7^{4-}]}{[HP_2O_7^{3-}]} \qquad (2)$$

Diphosphate can be hydrolyzed to orthophosphate, and the equilibrium strongly favors orthophosphate, but diphosphate is stable for long periods of time in neutral and alkaline conditions, even on heating.

Phosphatidylinositol

Phosphatidylinositol, generally abbreviated as PI or PtdIns, is a glycerophospholipid that has *myo*-inositol (one of nine stereoisomers of hexahydroxycyclohexane) as the polar head group. It is found in the membranes of eukaryotes and some eubacteria. Because of the anionic phosphodiester group, it contributes to the negative charge of the phospholipid bilayer. The free hydroxyl groups of PI can be phosphorylated or glycosylated to produce a wide variety of inositol phospholipids with specific functions. Two distinct types of inositol phospholipid have particularly important functions in eukaryotes that are described in separate entries:

1. Phosphatidylinositol phosphates are key components of several intracellular signaling pathways, either as the intact molecules or after they are cleaved by phospholipase C to **1,2-diacylglycerol** and an **inositol phosphate**.

2. Glycosylphosphatidylinositols (or GPIs) can be covalently attached to the C-terminus of many proteins and are responsible for anchoring them to the membrane (see Membrane Anchors and GPI Anchor). GPIs may also occur in a "free form" without attached protein. Although the role of these free GPIs in mammalian cells is uncertain, they are an essential part of te protective coat used by many protozoal parasites.

Phosphatidylinositol Kinases

Phosphoinositides serve important functions in controlling the regulation of growth and differentiation in cells, as well as serving as substrates for the generation of inositol trisphosphate, IP_3 (see Inositol Lipids and Phosphates). In response to a variety of growth factors and **cytokines**, phosphatidylinositol (PI) is phosphorylated sequentially, to form the polyphosphoinositide PI-3′,4′,5′-P_3 (PIP_3). These phosphorylations are catalyzed by the enzyme PI 3′-kinase. The lipid products of this enzyme are not substrates for phospholipases, but instead have direct regulatory properties themselves.

PI 3′-kinase has a number of **domains** for protein–protein interactions that contribute to its regulation and localization. The enzyme consists of a catalytic (p110) and regulatory (p85) subunit. p85 has two **SH2 domains** and one SH3 domain, which play a crucial role in regulation of the activity and targeting of the enzyme. Upon growth-factor-receptor activation, p85 is recruited to receptors phosphorylated on tyrosine residues, or their substrates. The occupancy of these SH2 domains in p85 causes activation of the enzyme, while also serving to target it to the plasma membrane, or in some cases to intracellular membranes, where its lipid products can bind to proteins (1).

The generation of 3′ phosphoinositides appears to play an important role in signal transduction. Activation of PI 3′-kinase is necessary for the full expression of a number of tyrosine kinase receptors, including those for insulin, **nerve growth factor**, and others (1). Activation of the enzyme has been shown to prevent apoptosis in a number of cell types. Moreover, a retrovirus encoding PI 3′-kinase was found to induce hemangiosarcomas in chickens, and mutations in the enzyme were associated with increased life span in Caenorhabditis *elegans*. Many advances in identifying the role of PI 3′-kinase have come from the use of pharmacological inhibitors, such as wortmannin (1).

The targets of the lipid products of PI 3′-kinase have received a great deal of attention. PI 3′-kinase appears to play a universal role in membrane trafficking, perhaps explaining its wide importance in signal transduction. Cell adhesion molecules can also cause its activation, linking these events to changes in the actin cytoskeleton. Although there have been numerous reports on the essential role that PI 3′-kinase plays in most aspects of signal transduction, most attention has focused on downstream changes in **phosphorylation** . There have now been a number of protein kinases that are activated after PI 3′-kinase activation. One group belongs to the calcium-independent protein kinase C family members, especially z and q. Additionally, PIP_3 can induce a phosphorylation cascade. This involves the activation of the **serine/threonine kinases** PDK and Akt, which is also known as protein kinase B (PKB). It is now thought that PIP_3 can bind to the **pleckstrin homology** (PH) domain of these kinases, effectively recruiting them to the plasma membrane or intracellular membranes for activation. While PDK appears to be controlled mainly by targeting, it can phosphorylate and activate Akt, which in turn can phosphorylate a variety of intracellular substrates,

including transcription factors, other kinases, proteins controlling apoptosis, and others (1).

Phosphofructokinase

Phosphofructokinase, or PFK (EC 2.7.1.11), is one of the best characterized allosteric enzymes. It catalyzes the step of glycolysis in which fructose-6-phosphate (FRU-6P) is phosphorylated to fructose-1,6-bisphosphate (FRU-1,6P_2) using either ATP or pyrophosphate (PP_i) as a phosphate donor. This enzyme is present in most types of eukaryotes and eubacteria but occurs rarely in archaebacteria. PFKs from animals, yeast, and most bacteria use ATP as a phosphate donor. Those that use PP_i are found in plants, protozoa, and some bacteria, often in addition to ATP-dependent enzymes. The amino acid sequences of most of the ATP-dependent PFKs are homologous, indicating that they form an evolutionary gene family. This family includes both "small" bacterial enzymes and "large" enzymes from mammals and yeast. It is a good model of enzyme evolution and of the appearance of "new" regulatory functions. PFK in most organisms is a highly regulated enzyme that has several allosteric effectors, and it controls (at least in part) the rate of glycolysis. The PFK from *Escherichia coli* has become a paradigm for the concerted allosteric model (1). X-ray crystallography, site-directed mutagenesis, and enzyme kinetic studies on bacterial ATP-dependent PFKs have also explained their catalytic and regulatory properties in some detail.

1. Isoenzymes

In humans (and probably in other mammals), there are three homologous types of PFK polypeptide chains, the muscle M, liver L, and platelet P isoenzymes. They are encoded by different genes, located on chromosomes 21, 1, and 10, respectively. All have several introns. The few cases of alternative splicing reported always lead to deletion of one exon and formation of a nonfunctional enzyme. Even though the M, L, and P type proteins are different, they share enough similarities assemble into active, multiple, heterologous oligomers, usually tetramers. The many different PFK isoforms generated in this way have somewhat different catalytic and regulatory properties, such as saturation by ATP and Fru-6P or sensitivity to allosteric effectors (2). Some species, such as *E. coli*, also have other minor proteins with PFK activity, but have unrelated amino acid sequences indicating that they do not belong to the main family of PFKs.

2. Metabolic Role

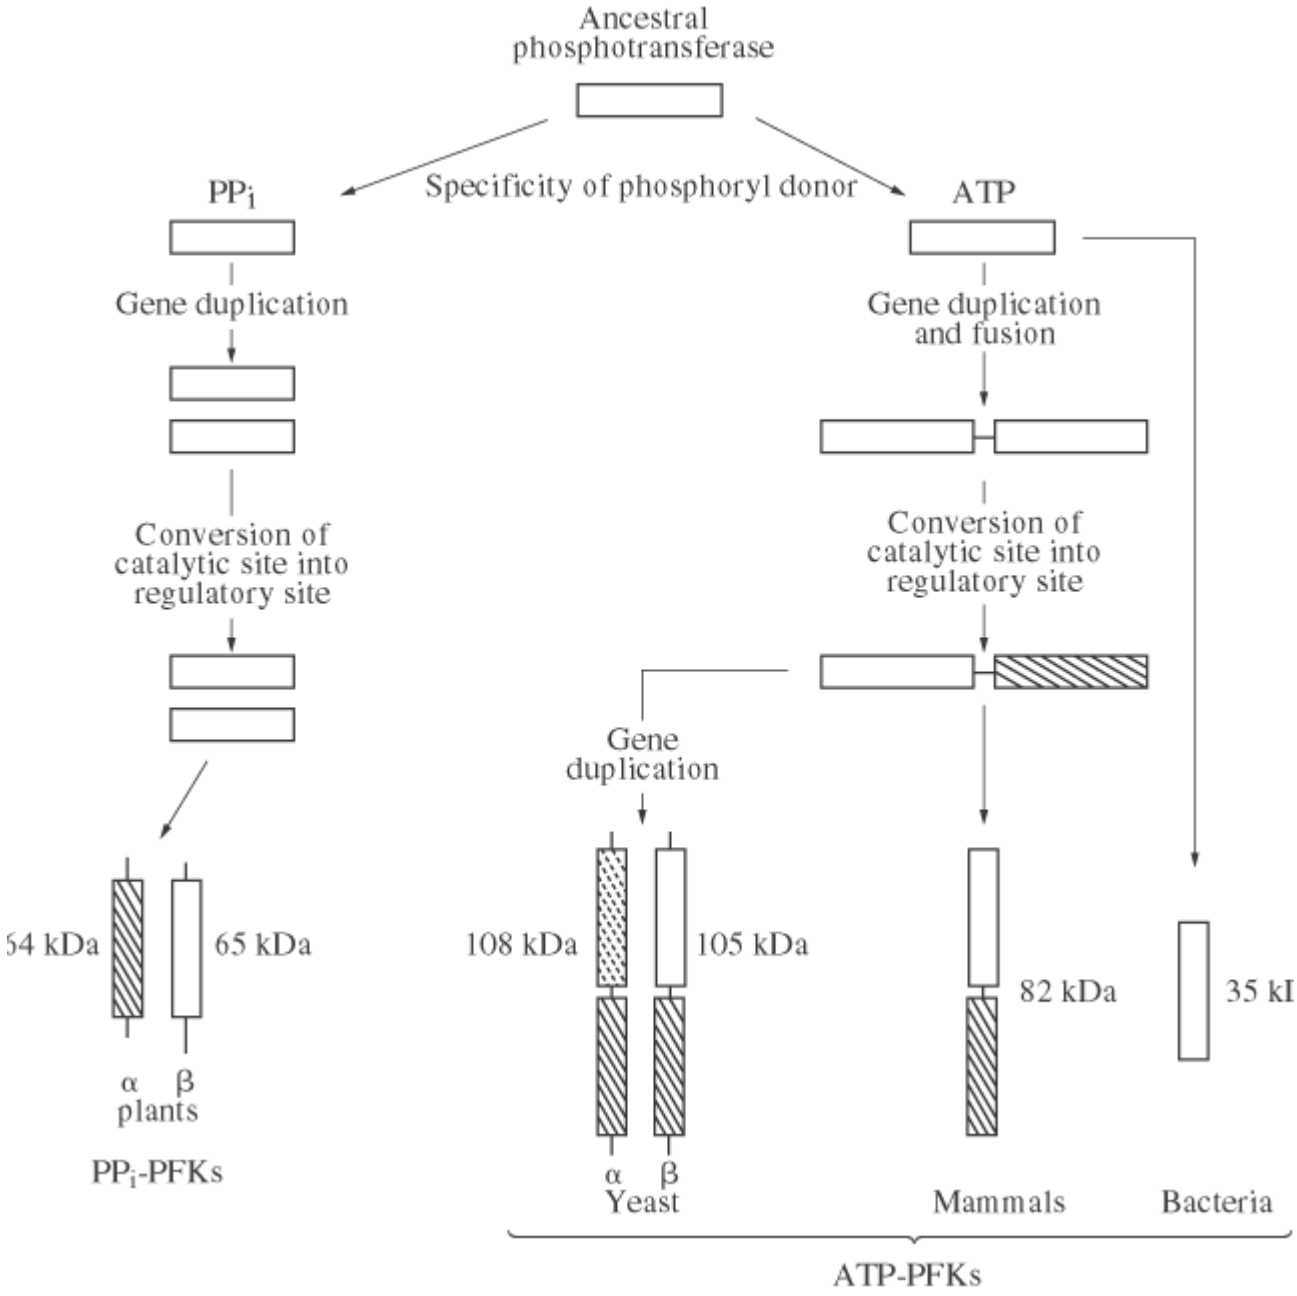
The reaction catalyzed by PFK, using either ATP or PP_i, is irreversible under physiological conditions. Its complex regulation by adenine nucleotides and by various metabolites indicates that PFK controls the production of cellular energy and the carbon flux between glucose and pyruvate. In several instances, the activity of PFK is coupled to that of pyruvate kinase because Fru-6P, the substrate of PFK, is an allosteric activator of one form of pyruvate kinase. This coupling is stronger in bacteria, where phospho *enol*pyruvate (PEP), the substrate of pyruvate kinase, is the allosteric inhibitor of PFK. In some microorganisms (Gram-positive bacteria and mycoplasms, but not *E. coli*), the genetic expression of these two enzymes is coordinated. They catalyze reactions seven steps apart in glycolysis. In these cases, the genes that code for PFK and pyruvate kinase are adjacent on the chromosome and constitute an operon under transcriptional control by the same promoter (3).

The enzymatic (and sometimes genetic) coupling between two enzymes that each catalyze irreversible phosphoryl transfer steps is probably crucial for controlling the glycolytic flux, especially in anaerobes that use glycolytic fermentation as their main energy-producing pathway.

3. Primary Structures and Evolution

Most of the ATP-dependent PFKs, whether from animals, yeasts, or bacteria, have homologous sequences and belong to an evolutionary gene family. The simplest members of this family are bacterial PFKs whose polypeptide chains are about 35 kDa. Mammalian PFKs are approximately twice as large, about 80 kDa, and have an internal sequence repeat. Their N- and C-terminal halves are homologous and both resemble bacterial PFKs. This suggests that they have been produced by tandem gene duplication and fusion (4). All of the important active site residues are conserved in the N-terminal half, indicating a catalytic function, whereas replacement of several crucial residues, notably that of Asp127 by Ser, suggests that the C-terminal half is inactive. Yeast PFK is composed of two types of related chains, a of 108 kDa and b of 105 kDa. Each has a segment homologous to mammalian PFKs and unrelated N- and C-terminal extensions. These chains have formed by duplication of a mammalian-like gene followed by independent acquisition of terminal extensions (Fig. 1). The distribution of residues crucial for catalysis, plus various kinetic studies, suggest that the active site is carried by the N-terminal half of the b-chain and that the a-chain has only a regulatory role. Homologous residues are referred to here by their numbers in the *E. coli* enzyme.

Figure 1. Evolution of PFKs suggested by the comparison of their primary sequences. The unrelated segments are represented by thin lines. Among the homologous segments, those that have retained a catalytic function are open, and those that have lost their catalytic abilities and evolved to acquire a regulatory function are crossed. The special weak crossing on the N-terminal segment of the yeast a chain reflects that the evidence in favor of a pure regulatory role is weaker than for the other eukaryotic PFKs.



PP_i-dependent PFKs are made of two homologous chains, each of which has a segment distantly related to bacterial PFKs. This suggests that all PFKs might derive from the same ancestral protein (Fig. 1). The conservation of critical residues indicates that the catalytic site is on the b-chain and that the a-chain is regulatory.

4. Quaternary Structure

Bacterial and mammalian PFKs are active as tetramers and are inactivated upon dissociation into dimers (see Quaternary Structure). The allosteric inhibition of the PFK from *Thermus thermoaquaticus* by PEP involves such a dissociation. The crystal structures of bacterial PFKs explain why an oligomeric state is required for activity. The Fru-6P binding site is at the interface between two subunits. The fructose moiety interacts with one subunit and the 6-phosphate group with the other (5). Under some conditions, tetrameric mammalian PFKs associate further into octamers and even more complex structures. They are active, but the role of this aggregation is not

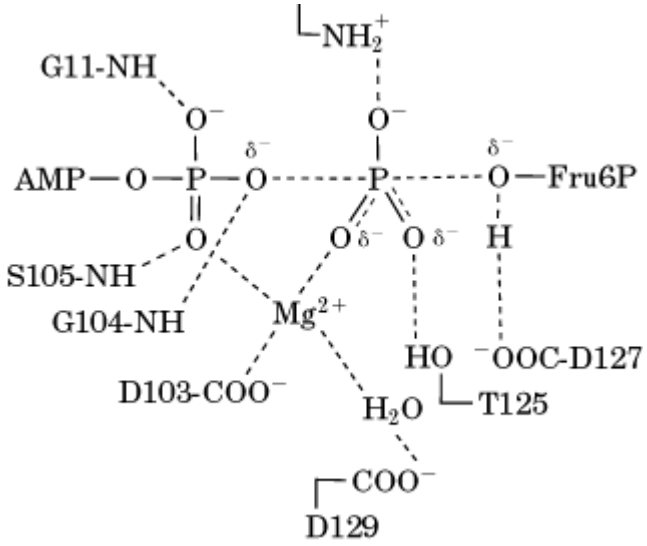
clear. PP_i-dependent PFKs also have a tetrameric structure that contains two a- and two b-chains. Yeast PFK is active only as an octamer that has four a- and four b-chains.

5. Catalytic Mechanism of Phosphoryl Transfer

Experiments with chiral (^{16}O, ^{17}O, and ^{18}O)-ATP have shown that transfer of the g-phosphate from ATP to Fru-6P occurs directly within a ternary complex (6) without a phosphoryl–enzyme intermediate. Steady-state kinetics are compatible with a random order of substrate binding, and the pH-dependence of the maximum velocity suggests that $Mg^{2+}\cdot ATP^{4-}$ is the most active ionic form (7).

X-ray crystallography of bacterial PFKs and site-directed mutagenesis suggest that several PFK active site groups are involved in catalyzing phosphoryl transfer (Fig. 2). The deprotonated side chain of Asp127 acts as a base and abstracts a proton from the 1-OH group of Fru-6P so as to increase its nucleophilicity. Mutation of Asp127 to Ser decreases the catalytic rate constant 10^4-fold (8). The transferred phosphoryl group is stabilized by interactions with the magnesium ion, by the positive charge of Arg72, and by a hydrogen bond with Thr125. The deprotonated side chains of Asp103 and Asp129 hold the magnesium ion that contributes electrostatic catalysis. The amide NH of Gly104 makes a hydrogen bond with the bg-oxygen bridge to facilitate cleavage of the O–P bond (5). X-ray crystallography also shows that the active site of *E. coli* PFK takes two conformations, one "open" that binds substrates and releases products and one "closed" in which catalysis occurs (5). Rapid kinetics have shown that conformational changes indeed occur in *E. coli* PFK upon substrate binding (and/or product release) and that these changes are slow enough to be rate-limiting in some conditions for the catalytic cycle (9).

Figure 2. The transition state of the reaction catalyzed by PFK with the main interactions within the active site as suggested by X-ray crystallography (5) and site-directed mutagenesis. The residues shown are conserved in all of the active PFKs except for Thr125, replaced by a serine in eukaryotic PFKs, which conserves an OH group. The partial covalent bonds are indicated by broken lines, and the hydrogen and electrostatic bonds by dotted lines.



6. Purification and assay of activity

Most PFKs are purified by affinity chromatography using a nucleotide analog covalently coupled to a resin. The usual assay measures the formation of Fru-1,$6P_2$ by coupling it to the disappearance of

NADH using aldolase, triosephosphate isomerase, and glycerol-phosphate dehydrogenase (10, 11).

7. Regulation of activity

The catalytic activities of all PFKs are sensitive to pH, ionic strength, divalent metal ions and/or their chelators (the real substrate is the ATP – Mg^{2+} complex), and phosphate, NH_4^+, and K^+ ions (10, 11). In addition, PFKs often have complex regulatory properties, such as sensitivity to allosteric effectors and/or a cooperative saturation by the substrate Fru-6P. Only a few (eg, that from *Dictyostelium discoideum*) follow Michaelis–Menten kinetics under all conditions studied.

7.1. Allosteric Effectors

The activities of PFKs are modulated by several allosteric effectors that differ among various organisms (Table 1). Most of these effectors do not modify the maximum velocity, but affect only the saturation by Fru-6P, influencing the cooperativity and/or half-saturating concentration. All PFKs are activated by an increase in levels of ADP and/or AMP, which would express a shortage of cell energy (see Adenylate Charge). In addition, most eukaryotic PFKs are strongly inhibited allosterically by ATP, and show nonhyperbolic ATP saturation. Because of this inhibition by ATP, PFK in the liver is almost inactive with the *in vivo* concentrations of Fru-6P and ATP, and the total PFK activity is much too low to account for the glycolytic flux measured *in vivo*. This discrepancy between the expected and measured glycolytic flux led to the discovery of the most potent allosteric activator of eukaryotic PFKs, Fru-2,6P_2, which relieves allosteric inhibition by ATP (12). The concentration of Fru-2,6P_2 in mammalian cells is controlled by hormones that act on cell metabolism through cAMP and protein kinase A. Fru-2,6P_2 decreases when cAMP increases. This hormonal control of PFK activity via Fru-2,6P_2 regulates the balance between the degradation of glycogen and the synthesis of glucose and/or lipids. Fru-1,6P_2 also activates PFKs, but with a much lower affinity than Fru-2,6P_2 (12).

Table 1. The Main Effects of PFK in Different Organisms

PFKs from	Activation	Inhibition
Bacteria	ADP or GDP[a]	PEP
Mammals[b]	AMP.ADP	Citrate
	Fru-2.6P_2	ATP
Yeast	AMP.ADP	Citrate
	Fru-2.6P_2	ATP

[a] ADP is probably the physiological effector, but GDP has been used to activate bacterial PFKs in many kinetic studies because ADP is also a competitive inhibitor of the substrate ATP.

[b] The three different isotypes of PFK in mammalian cells are sensitive to the same effectors but to varying extents.

Most eukaryotic PFKs are also allosterically inhibited by citrate, the first metabolite in the Krebs cycle. Citrate inhibition is responsible for the “Pasteur effect” in yeast, a decrease of glucose consumption upon shift from anaerobic to aerobic growth. Indeed, the reoxidation of NADH by

oxygen via the respiratory chain raises the level of the Krebs cycle intermediates, and the citrate inhibition of PFK decreases the rate of glycolysis.

Bacterial PFKs are insensitive to citrate, but are sensitive to feedback inhibition by PEP, the penultimate end product of glycolysis.

7.2. Appearance of "New" Regulatory Functions upon Evolution of Sites

The variety of allosteric effectors of PFKs can be explained by their evolution. Bacterial PFKs originally possessed an active site that binds both ATP and Fru-6P, plus an effector site that binds ADP or PEP. After the gene duplication and fusion that doubled the polypeptide chain, the active site on the N-terminal half retained its function, whereas that on the C-terminal active site evolved into a regulatory site (Fig. 1). The Fru-6P subsite became the activation site for Fru-2,6P_2 and the ATP subsite became an inhibitory site. Similarly, evolution could have modified an inhibitory site for PEP in bacterial PFKs into one for citrate in eukaryotic PFKs. The evolution from bacterial to eukaryotic PFKs has also created the structural elements needed for communication between the active site and the "new" regulatory sites.

7.3. The Cooperativity of *E. coli* PFK toward Fru-6P and the Concerted Model of Monod, Wyman, and Changeux

The steady-state kinetics of *E. coli* PFK were the first to be analyzed according to the concerted allosteric model. Quantitative agreement between experimental data and predictions from the model was remarkable (1). According to the model, the protein is in equilibrium between two conformational states, R and T. The active R state has a much higher affinity for Fru-6P and for the activator ADP (or GDP), whereas the inactive T state has a much higher affinity for the inhibitor PEP. In the absence of ligand, the equilibrium between the R and T states of free PFK largely favors T, and the a ratio $T_0/R_0 = 4\times10^6$ (1). The simplicity of the concerted model is that a unique transition between the two states R and T is involved in both the cooperativity toward Fru-6P and the influence of allosteric effectors. Some bacterial PFKs show sigmoïdal saturations by Fru-6P only in the presence of the inhibitor PEP, confirming that the transition into an inactive state induced by PEP and the cooperativity toward Fru-6P are related.

The crystal structure of the complex between a bacterial PFK and an analog of the inhibitor PEP shows that the latter is bound to a regulatory site remote from the active site and that the protein has changed its quaternary conformation. The change induced by PEP closes the Fru-6P binding site (13). This is consistent with the observation that PEP inhibits by decreasing PFK's apparent affinity for Fru-6P. Some residues that bind PEP are also involved in binding the allosteric activator ADP when PFK is in its active conformation. The opposite effects of binding activators and inhibitors to a single effector site result because it has two mutually exclusive conformations, that agree with the concerted allosteric model. The quaternary structure of the inactive conformation is less stable, which explains the PEP-induced dissociation of the PFK from *T. thermoaquaticus* .

However, the transition between the two states R and T seen by X-ray crystallography cannot explain entirely the cooperativity of *E. coli* PFK toward Fru-6P. In the absence of ligand, free PFK is not in the inactive T_0 state because (1) its crystal structure is that of the R state (14), and (2) it binds Fru-6P with high affinity and without any cooperativity (15). Presteady-state kinetics show that binding substrates and/or effectors to *E. coli* PFK is accompanied by conformational changes within the R state, which are slow enough to be rate-limiting for the catalytic cycle. Thus, the cooperativity of *E. coli* PFK is in part independent of the transition between the crystallographic R and T states and is due to a change in the rate-limiting step from a conformational change at low Fru-6P concentrations to phosphoryl transfer at high Fru-6P (9). Such a kinetic origin of cooperativity explains observations with some mutants that are difficult to fit with the concerted model, such as values of the Hill coefficient larger than the number of Fru-6P binding sites (16) and reversal of the influence of effectors, where PEP becomes an activator (17) and GDP an inhibitor.

7.4. Phosphorylation of Mammalian PFKs by Protein Kinase A

Mammalian PFKs are phosphorylated on specific sites by protein kinase A. This produces changes in kinetic properties and in the tendency to aggregate into octamers, but the physiological role of this phosphorylation is unknown.

Phospholipases

Phospholipases hydrolyze membrane phospholipids (see Lipases). The lipid substrates for these enzymes are usually quite specific. Hormone-regulated phospholipase C (PLC) can hydrolyze a number of membrane phospholipids, including phosphatidylchloline and phosphatidylethanolamine. Phosphatidylinositol (PI) and its phosphorylated derivatives (polyphosphoinositides) are the most common substrates involved in second messenger generation, producing soluble **inositol phosphates**, such as inositol trisphosphate (IP_3), that are involved in calcium signaling.

Phospholipase D enzymes usually prefer phosphatidylcholine as substrate, generating phosphatidic

acid and choline. Phosphatidic acid has been proposed to mediate a variety of biological responses involved in mitogenesis and protein trafficking (1).

The turnover of polyphosphoinositides occurs in a cycle of hydrolysis and resynthesis, called the "PI cycle." PI is phosphorylated sequentially on the 4′ and 5′ hydroxyl groups of the inositol ring, to produce PI-4′,5′-P_2. Upon hormonal activation, PLC subsequently catalyzes the phosphodiesteratic cleavage of this lipid, resulting in the generation of diacylglycerol and IP_3 in the cell. After its degradation, PI can be resynthesized by the phosphorylation of diacylglycerol to PA, via the activity of a diacylglycerol kinase and the subsequent resynthesis of PI via PI synthase. Thus, this cycle results in the generation of two potential second messengers, the membrane-associated diacylglycerol, which can activate protein kinase C, as well as IP_3, which can lead to the mobilization of intracellular calcium levels.

Several forms of PI-PLC have been identified (1). These proteins all exhibit an absolute requirement for calcium and are equally capable of hydrolyzing PI and the polyphosphoinositides PIP and PI-4′,5′-P_2. These proteins exist in three subfamilies, b, g, and d, each with multiple members. They have a number of conserved and divergent domains, reflecting their differential regulation. All three subclasses have a pleckstrin homology (PH) domain, which probably mediates some type of interaction with lipids in the membrane, and an EF-hand motif, presumably involved in **calcium binding**. Moreover, there are two additional conserved domains, designated X and Y, that contain the catalytic core of the enzyme; there is also a conserved C2 domain, also likely to be required for calcium interaction. PLCg, which is regulated by tyrosine kinase receptors, contains two **SH2 domains** and one SH3 domain and has been shown to undergo **phosphorylation** of tyrosine residues. PLCb is responsible for regulation through G-protein-coupled receptors and is generally regulated by a subunits of the Gq family of heterotrimeric G proteins, linked to a subset of such receptors. Additionally, their bg subunits have also been shown to regulate PLCb, although the efficacy of this activation is not comparable to that seen with Gqa. PLCb can also act as an activator of the GTPase activity of Gq, effectively behaving as a GTPase activating protein (GAP).

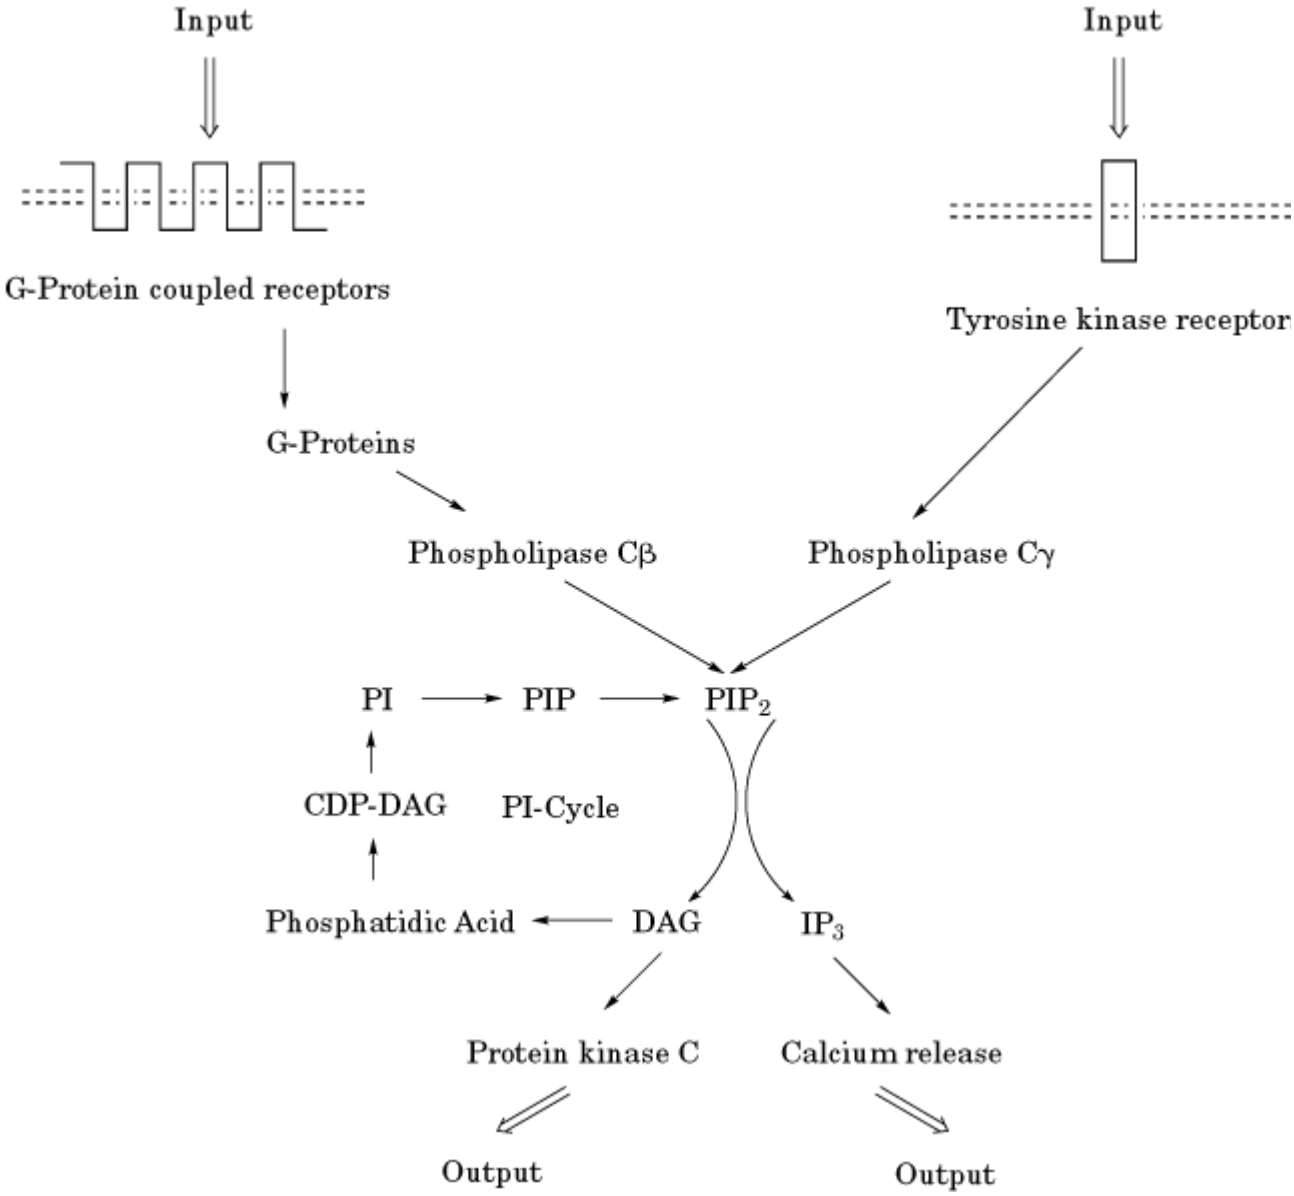
Phospholipases C

1. Historical Perspective

The phosphatidylinositol (PI)-specific phospholipases C have emerged as key and determining components of the PI cycle of signal transduction. In this pathway, the action of any of several extracellular agents (including hormones, **cytokines**, neurotransmitters, and xenobiotics) results in activation of PI-specific phospholipases C that cleave phosphatidylinositol bisphosphate (PIP_2) (1-3). This results in the formation of inositol trisphosphate (IP_3) and **diacylglycerol** (DAG), which act as important second messengers involved in the regulation of calcium signaling and protein kinase C, respectively (Fig. 1).

Figure 1. Regulation and function of the phosphatidylinositol (PI) cycle. The scheme illustrates two mechanisms for

activation of the PI cycle through (*1*) direct phosphorylation of phospholipase C g by tyrosine kinase receptors, and (*2*) C proteins in the case of G-protein-coupled receptors. The two products of PIP $_2$ hydrolysis, IP_3 and diacylglycerol (DAG) function as second messengers in activating calcium release and protein kinase C, respectively. Resynthesis of PIP_2 from DAG completes the PI cycle.



Early insight into the PI cycle came from studies by Hokin and Hokin, who identified turnover of inositol phospholipids in cells stimulated with acetylcholine. Work over the ensuing decades resulted in the delineation of the biochemical components of the PI cycle and the realization of its intimate connection to changes in calcium levels in the cells. Thus, it became appreciated that specific phospholipases of the C type were activated in response to acetylcholine and other hormones. It was also appreciated that PIP_2 was the preferred substrate in this pathway and that this was coupled to changes in calcium homeostasis (3). It was then determined that the IP_3 product of this reaction acted directly on specific **receptors** internal to the cell to cause changes in the levels of free calcium. Contemporaneously, a direct connection was made between DAG and protein kinase C, demonstrating a second messenger function for DAG (4, 5).

2. Regulation of Phospholipase C

PI-specific phospholipases C have been purified and cloned. They exist as a family of related phospholipases with close similarity in catalytic activity and preference for PIP_2 as a substrate, but with distinct mechanisms of regulation (1). Notably, the two best-studied members of the family, phospholipase Cb and phospholipase Cg, are coupled through distinct mechanisms to two different classes of membrane receptors. **G protein**–coupled receptors regulate phospholipase Cb through direct activation by hetero-trimeric G proteins. On the other hand, phospholipase Cg is tyrosine phosphorylated (see Phosphorylation, Protein) by transmembrane tyrosine kinase receptors (and also by nonreceptor tyrosine kinases) through interactions with specific **SH2** modules in phospholipase Cg that are recognized by specific SH2-binding **domains** in the tyrosine kinases (Fig. 1).

2.1. Role of Phospholipases C in Signal Transduction and Cell Biology
Given their intimate coupling to two major classes of transmembrane receptors, phospholipases C serve a critical role in allowing the ligands of these receptors to regulate the intracellular levels of calcium and the activity of protein kinase C. This is accomplished by the activity of the two products of the phospholipase C reaction. IP_3 is a hydrophilic and diffusable small molecule that interacts specifically and with high affinity with the IP_3 receptor in the endoplasmic reticulum. This results in release of calcium from stores in the endoplasmic reticulum into the cytosol. In turn, free calcium appears to coordinate a variety of cellular responses through the activation of various enzymes, including protein kinases and **phosphodiesterases** (see Calcium Signaling). Simultaneously, DAG, which is formed in the membrane, activates several members of the protein kinase C family. Protein kinase C is capable of phosphorylating a variety of substrates that result in the regulation of diverse biological responses. Protein kinase C is also activated potently by **phorbol esters**, which are plant toxins that cause a myriad of cellular responses, including effects on blood cell activation, cell growth regulation, tumor promotion, memory formation, immune responses, inflammatory reactions, hormone release, and neurotransmission, most likely through activation of protein kinase C (4). Therefore, the two products of the phospholipase C reaction serve as critical second messengers, often acting in synergy to regulate a variety of cellular responses.

Phosphorous Isotopes

Phosphorus is element number 15 in the periodic table and has valence states of 3 or 5 (1). Seventeen isotopes have been identified (2), ranging in atomic mass number from ^{26}P to ^{42}P, most of which

have physical half-lives of seconds or milliseconds and do not have important applications. Only one stable isotope of phosphorus is found in nature (^{31}P).

The most important **radioactive** isotope of phosphorus is ^{32}P (half-life = 14.29 days) (see Radioisotopes). It undergoes beta-minus decay to ^{32}S, which is stable. Phosphorus-32 yields one beta particle per decay, with an energy of 1.71 MeV maximum, 0.695 MeV on average. Another useful radioisotope of phosphorus is ^{33}P (half-life = 25.4days). It yields one beta particle per decay, with an energy of 0.1667 MeV maximum, 0.0486 MeV on average.

Phosphorus-32 is usually prepared in an accelerator by bombarding a stable sulfur target with deuterons according to the reaction ^{34}S(d,a)^{32} P. It may also be prepared by accelerator deuteron bombardment of ^{31}P according to the reaction ^{31}P(d,p)^{32}P or by reactor neutron-activation according to ^{31} P(n,g)^{32}P. Carrier-free radioisotope is prepared by reactor production according to the reaction ^{32}S(n,p)^{32}P.

Phosphorus-32 was first made by Fermi in 1934 using neutrons from a radium–beryllium source (3). In 1935, Hevesey made ^{32}P by the same method and studied the metabolism of phosphorus compounds in rats (3). Hevesey also studied blood volume using ^{32}P-labeled red blood cells. When it was found that ^{32}P killed blood cells, Lawrence produced it in a cyclotron and in 1938 was the first to use it as a therapeutic radioisotope for treatment of leukemia in humans (3). Phosphorus-32 is presently used as an effective treatment for polycythemia vera (4, 5), for treatment of painful bone metastases from prostate and other cancers (6), for restenosis stents in treating heart disease, and in colloidal form for direct intratumoral injection, or *infusional brachytherapy* (7). The systemic use of ^{32}P has been limited by concerns over potential leukemogenic effects.

As a diagnostic agent, ^{32}P has been used to study skeletal growth and bone tumor kinetics. In molecular biology, ^{32}P is used primarily to label **nucleic acids**, which have one phosphorous atom per nucleotide, and for **phosphorylation** of proteins. Phosphorus-32 is readily detected by beta-particle liquid scintillation counting, **Cerenkov radiation detectors**, autoradiography, and fluorography.

Phosphorylase Kinase

Phosphorylase kinase (E.C. 2.7.1.38) catalyzes the **phosphorylation** of residue Ser14 in relatively inactive glycogen phosphorylase *b*, converting it to the much more active phosphorylase *a*. Its discovery in 1955 by Fischer and Krebs, and their later demonstration that the enzyme converting phosphorylase *a* to *b* is a protein **phosphatase** that removed the phosphate, provided a firm basis for further investigation of the first metabolically interconvertible enzyme system to be discovered. These investigators and their colleagues characterized phosphorylase kinase and demonstrated that it was itself activated by phosphorylation by cyclic AMP (cAMP)-dependent **protein kinase** (cAPK), thus suggesting the famous cascade system for the regulation of glycogen metabolism by hormones. In addition, it was discovered in this same laboratory that Ca^{2+} is required for activity, and later by Drummond et al. that the activation of glycogenolysis is coordinated to muscular contraction by the release of calcium from the endoplasmic reticulum in response to nervous stimulation (see Calcium Signaling). It was not until 1978 that the small calcium-binding protein calmodulin was found to be an integral part of phosphorylase kinase and responsible for the allosteric activation by Ca^{2+}. Calmodulin was designated subunit d because three other subunits, the regulatory a and b and the catalytic g, were already known. Each is present in four copies, so the **holoenzyme** may be represented as $a_4b_4g_4d_4$ with an overall molecular weight of 1.3 million. This enormous protein presents a formidable challenge to investigators, but the subunits have been isolated and their primary sequences determined, while progress is being made on their functions and on the complex regulation of this enzyme. The gene for the catalytic domain of subunit g has been **cloned**, and the structure of the subunit determined by X-ray crystallography, so the molecular basis of the catalytic activity has been elucidated. The comprehensive review by Picket-Gies and Walsh (1) covers the literature until 1986 and can be used as the essential reference for this article. It is suggested for further reading.

1. Structure and Function

The molecular weights of the subunits have been determined by sequence analyses (2) and are a = 138,422, b = 125,205, g = 44,673, and d = 16,680. Various analyses by electron microscopy of $a_4b_4g_4d_4$ show a bilobed butterfly-like structure that may be cleaved by **trypsin** into two halves, suggesting that the subunits are arranged as a bridged dimer of octamers ($a_2b_2g_2d_2$), while another study found a “chalice” form. These observations have been reconciled by a three-dimensional model that can account for all views (3). Essentially there are three twofold axes of symmetry relating the four abgd_protomers, resulting in a tetrahedral arrangement. Proteolytic digestion suggests that the b subunits play an essential role in holding the holoenzyme together, but there are additional interactions of other subunits. Lithium bromide causes dissociation into two complexes, agd_and gd;_both of these have activity toward phosphorylase *b* equal to that of the holoenzyme.

The determination of the amino acid sequences of all four subunits provided valuable insights into their various functions. The g subunit proved to have substantial homology with the catalytic subunit of cAPK. There is an additional *C*-terminal region (approximately residues 286 to 386) that can be removed by **chymotrypsin**, to yield a catalytic domain (residues 1 to 285) with full activity and no calmodulin/Ca^{2+} sensitivity. The C-terminal or regulatory **domain** contains two calmodulin-binding domains, suggesting a double binding mode that accounts for the unusual phenomenon that calmodulin binds to the isolated g subunit in the absence of calcium, becoming subunit d, and suppresses its activity. **Troponin** C, which is **homologous** to calmodulin, also binds to the g subunit and may provide a more direct link between the calcium activation of skeletal muscle contraction and glycogenolysis. The a and b subunits are highly homologous, suggesting a common ancestral protein. Both have calmodulin-binding domains, but apparently only one extrinsic calmodulin binds per pair of a/b units, known as d′ subunits, in the intact holoenzyme in the presence of excess

calcium, resulting in four d′ subunits in all. The b subunit contains two sites for phosphorylation by cAPK, on Ser26 and Ser700. The two sites appear to be phosphorylated equally rapidly, and either one results in an increase in activity of the holoenzyme, but a total of only one phosphate per subunit is found. The rate of phosphate incorporation into the b subunit is 5- to 10-fold faster than that into the a subunit and is a prerequisite for the latter, suggesting a conformational change. The a subunit is phosphorylated at Ser1018 by cAPK, with resultant increases in activity. Both the a and b subunits have several sites for autophosphorylation, but the evidence that this phenomenon has significance for *in vivo* regulation is ambiguous.

Kinetics of the phosphorylase kinase reaction were studied using a tetradecapeptide from phosphorylase *b* (residues 5 to 18) that contained the phosphorylatable Ser14 in order to avoid substrate-directed effects. The **kinetic mechanism** was found to be rapid equilibrium random Bi–Bi, indicating that either ATP or the protein can bind first and that the phosphoryl transfer step in the ternary complex is rate-limiting. Several studies on the effects of deleting or substituting various amino acid residues of the peptide permit one to conclude that the kinase shows a marked preference for peptides having the natural sequence around Ser14, while the latter is also important because a Thr14 peptide has a very low rate of phosphorylation. Because the first 18 residues of phosphorylase *b* are disordered, it is not surprising that the corresponding peptide, presumably in a random conformation, should be a good substrate for the kinase. The kinase must, however, recognize more than just the *N*-terminal peptide, because the intact protein substrate has a $\boldsymbol{K_m}$ at least fivefold lower and a maximum velocity (V_{max}) fivefold greater. Phosphorylase kinase will also phosphorylate Ser7 of glycogen synthase, but this is also the target for other kinases, including cAPK (which does not act on phosphorylase), so the physiological significance of its action on this and several other proteins is not known.

The high-resolution structure of the crystallized catalytic domain of the g subunit has been determined by Johnson et al. (4) and compared to other protein kinases (5). The structure is very similar to that of cAPK and contains the same catalytic residues in equivalent positions. These include Lys57 to interact with the phosphates of ATP and Asp167 to interact with the Mg^{2+} of ATP/Mg^{2+}. An *N*-terminal lobe, mostly **b-sheet**, is connected to the a-helical *C*-terminal lobe by polypeptide chain, allowing opening and closing of the active site cleft between the two lobes. The suggested catalytic mechanism is that Asp149 abstracts a proton from the substrate serine residue and the resultant alcoholate ion attacks the terminal phosphate of ATP. In cAPK, an activation segment has Thr197 phosphate, which interacts with Arg165, next to the catalytic Asp166, and other basic residues, but in phosphorylase kinase this is replaced by Glu182, which forms an ionic link with Arg148 of the catalytic loop and serves the same function of maintaining Asp149 and other catalytic residues in the correct orientation.

2. Regulation

Because so many results from *in vitro* studies may have no physiological significance, only those most likely to apply *in vivo* will be considered here. Because nearly all the phosphorylase and 20% to 40% of the kinase are associated with the glycogen particle in muscle, the kinase action on phosphorylase must occur with the latter bound to glycogen by its catalytic face, leaving the control face with Ser14 exposed to the cytosol (see Glycogen Phosphorylase). It is relevant, then, that glycogen decreases the K_m for phosphorylase *b* 10-fold; and this is likely to be via conformational changes in the substrate, because glycogen has no effect on phosphorylation of the tetradacapeptide containing residues 5 to 18. The **allosteric** inhibitor of phosphorylase *b*, glucose-6-phosphate, also inhibits kinase activity on the protein, but not on the peptide, suggesting augmentation of the metabolite feedback. There is a good correlation between the increase of Ca^{2+} levels due to nervous or electrical stimulation, muscle contraction, and the activation of both phosphorylase kinase and its substrate, and this occurs without changes in either the level of cAMP or the phosphorylation state of the kinase. The molecular basis is the allosteric activation due to binding of Ca^{2+} to the d subunit

and, at higher Ca^{2+} levels, of the binding of Ca^{2+}-calmodulin to the a/b_subunits (the d′ subunits). In contrast, the administration of adrenaline can cause coordinated changes in cAMP levels, activation of cADK and phosphorylase kinase, and formation of phosphorylase *a* . A point still in contention is whether or not Ca^{2+} is still an obligate requirement for kinase catalysis, as *in vitro* experiments suggest, but the increased affinity for the metal ion after phosphate incorporation into the b and_a_subunits may allow low endogenous levels to suffice. Heilmeyer (2) summarizes current knowledge of regulation, including a possible role for an allosteric ATP/Mg^{2+} site on the a subunit that may stimulate binding of the same substrate to the g subunit by displacing inhibitory ADP. He suggests that an ancestral gd phosphorylase kinase, responsive only to Ca^{2+}, could not handle all the signals needed to regulate the conversion of phosphorylase *b* to *a* . The addition of the two regulatory subunits b and_a permitted regulation by cAMP-dependent phosphorylation, extrinsic calmodulin, and substrate binding (ATP/Mg^{2+}).

Phosphorylation, Protein

Phosphorylation is a common, and usually reversible, post-translational modification of proteins. The amino acid residues that can be phosphorylated are listed in Table 1. Protein phosphorylation is either an intermediate step in the course of an **enzymatic** reaction or a more durable modification that regulates protein properties. This entry focuses on regulatory protein phosphorylation. In this context, the phosphorylation reaction is catalyzed by protein **kinases**, which form a specific class of phosphoryl-transferases, generally transferring the phosphoryl group from the g position of ATP (Fig. 1**a**, see exceptions below) to the side chain of an amino acid residue. The dephosphorylation reaction corresponds to the transfer of the phosphoryl group to a water molecule (ie, the hydrolysis of the phosphoester bond). Both reactions are energetically favorable and occur readily in the presence of the appropriate catalyst, a protein kinase or **phosphatase**. In a living cell, the level of phosphorylation of a protein is the result of a dynamic equilibrium between its rates of phosphorylation and dephosphorylation. As mentioned above, the phosphoryl donor is usually ATP, in complex with Mg^{2+}. *In vitro*, for some protein kinases, ATP or Mg^{2+} can be replaced by GTP or Mn^{2+}, respectively. In somewhat artificial conditions (ie, very low levels of ATP and high levels of ADP), protein kinases can catalyze the transfer of phosphoryl group from the phospho-amino acid of a protein to ADP, generating ATP. Although secreted proteins or peptides are known to be phosphorylated, the regulatory phosphorylation reactions that have been well-characterized to date take place within cells.

Figure 1. Major pathways of regulatory protein phosphorylation/dephosphorylation. (**a**) The most general case, observed in all types of living organisms, corresponds to phosphorylation of serine, threonine, or tyrosine residues by protein kinases using ATP/Mg^{2+} as phosphoryl donor. The dephosphorylation is catalyzed by a protein phosphatase,

usually distinct from the protein kinase. The activity of both the protein kinase and phosphatase can be regulated by intracellular or extracellular stimuli. The phosphorylated or the dephosphorylated forms of the protein substrate, or both, may be responsible for the biological response observed. (**b**) Although not as common as the previous phosphorylation system, the two-component system is widespread in eubacteria and has also been found in archaebacteria and eukaryotes. A "sensor protein kinase" autophosphorylates histidine residues in response to an environmental stimulus, using ATP/Mg^{2+} as phosphoryl donor. The phosphate is then transferred to an aspartate residue of a "response regulator," which may be located on the same polypeptide chain as the sensor kinase, or on a distinct one. The phosphorylated response regulator triggers the biological response. (**c**) The third phosphotransferase system has been described in bacteria only. In this system coupled to sugar transport, the phosphoryl group is transferred successively from phosphoenolpyruvate (PEP) to histidine and cysteine residues of several proteins (indicated with roman numerals) and to an incoming sugar. In addition to its function in sugar metabolism, this system has been shown to be coupled to several biological responses. HPr, histidine-containing phosphocarrier protein (see the text for references); Pi, inorganic phosphate; Ⓟ, phosphate.

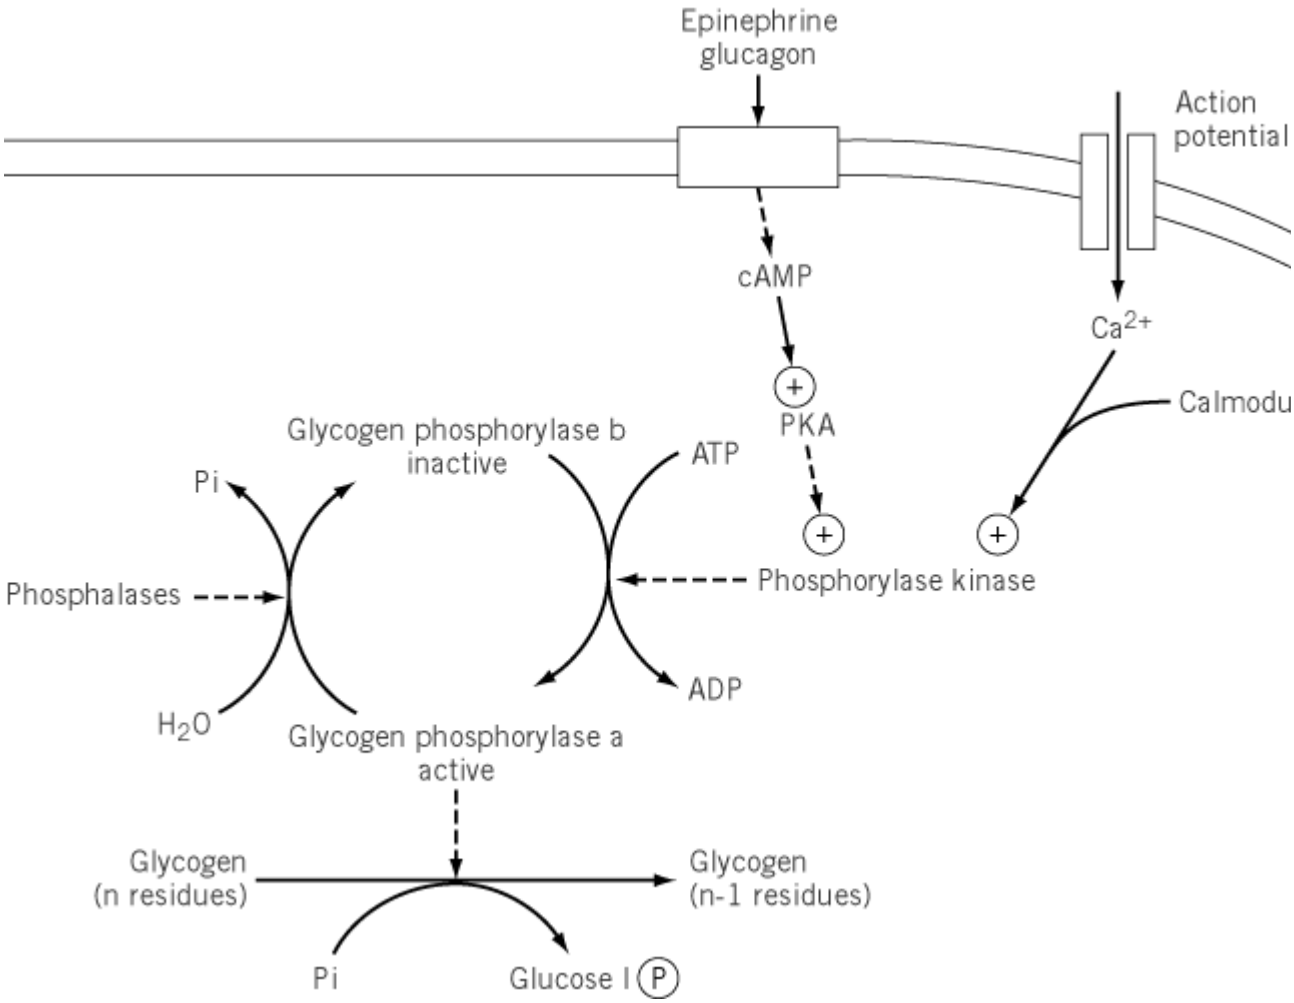
Basic amino acid	Histidine, arginine, lysine	Phosphoramidate
Thiol	Cysteine	Phosphate thioester
Acyl	Aspartate, glutamate	Mixed phosphate-carboxylate acid anhydride

1. Historical Perspective

Regulation by protein phosphorylation was discovered by Edmund Fischer and Edwin Krebs in the course of their studies of glycogen metabolism between 1955 and 1958 (1, 2). It was known from the work of Carl and Gerty Cori that glycogen phosphorylase, the enzyme that degrades glycogen, exists in two forms, an active form (phosphorylase a) and an inactive form (phosphorylase b). Fischer and Krebs showed that the only difference is that phosphorylase a is phosphorylated and they identified phosphorylase kinase, the protein kinase that phosphorylates phosphorylase b on Ser14, transforming it into the active phosphorylase a (Fig. 2). The same authors later showed that cyclic AMP, the intracellular second messenger formed under the action of epinephrine or glucagon, exerts its effects on glycogen catabolism by activating a protein kinase. This protein kinase, cyclic AMP-dependent protein kinase (or protein kinase A, PKA), phosphorylates and activates phosphorylase kinase. In skeletal muscle, they demonstrated that phosphorylase kinase is also activated by Ca^{2+}**-calmodulin**, allowing the coupling of metabolic events with contraction. Although it was originally thought that these reactions might be specific for the regulation of glycogen, the subsequent work of Paul Greengard and others showed that phosphorylation of proteins accounts for the action of many extracellular signals, and several protein kinases activated by cyclic GMP, Ca^{2+}-calmodulin and Ca^{2+}**-lipids** were discovered (3-5). During the same period, the protein phosphatases involved in the regulation of glycogen metabolism started to be studied methodically (6). This opened a new field, because it is now apparent that regulation of protein phosphatases is as important as regulation of protein kinases in the control of cell function. Another major step in the study of protein phosphorylation was the discovery of phosphorylated tyrosine residues by Tony Hunter in 1979 (7). Phosphotyrosine raised considerable interest when it was discovered that it is increased in cells transformed by **viruses**, and that v ***-src***, and v***- abl***, two major viral **oncogenes**, are tyrosine kinases. Shortly thereafter, it was shown that growth factor receptors, which are **transmembrane** proteins, have an intrinsic tyrosine kinase activity associated with their intracellular domain (8) (see Tyrosine Kinase Receptors). This tyrosine kinase activity is stimulated upon binding of the growth factor to the extracellular domain of the receptor. Thus, it became evident that, in spite of its low abundance in normal cells, phosphotyrosine residues are a key step in the control of cell growth and differentiation. More recently, molecular cloning of **genes** has identified a very large number of protein kinases and phosphatases in all living organisms that have been studied. It is now apparent that protein phosphorylation is a fundamental mechanism of signal transduction used by all cells to regulate the properties of their proteins in response to external or internal clues. The list of fundamental biological processes regulated by protein phosphorylation would be nearly endless, but would include gene expression, energy production and storage, cell division and differentiation, as well as synaptic plasticity in the nervous system, which is thought to underlie learning and memory.

Figure 2. Regulation of glycogen degradation. The main pathways regulating glycogen degradation, the study of which l to the discovery of protein phosphorylation, are illustrated. Glycogen is degraded stepwise by glycogen phosphorylase. Schematically, glycogen phosphorylase exists in either a dephosphorylated inactive form (b) or a phosphorylated active form (a). The transformation of b-form to a-form is catalyzed by phosphorylase kinase. Phosphorylase kinase itself is activated by two independent pathways. In skeletal muscle, Ca^{2+} entering the cell during the action potential binds to calmodulin and activates phosphorylase kinase directly. In addition, phosphorylase kinase is activated by phosphorylatio by cAMP-dependent protein kinase (PKA). PKA is directly stimulated by cyclic AMP (cAMP), which is generated in response to the stimulation of adenylyl cyclase by various seven-transmembrane-segment G-protein-coupled receptors (e receptors for epinephrine or glucagon). Dephosphorylation and inactivation of glycogen phosphorylase is catalyzed by several enzymes, the study of which led to the description and classification of protein phosphatases. See the text for references. Pi, inorganic phosphate; , phosphate; ⊕, activation.



2. Phosphorylation in Prokaryotes

Studies of protein phosphorylation in prokaryotes initially lagged behind those in eukaryotic cells. However, the paramount role of regulation by protein phosphorylation is now recognized in both Archea and Bacteria (9, 10). Bacteria possess ATP-dependent phosphorylation systems, using protein kinases that have sequence **homologies** with those of eukaryotes. These protein kinases phosphorylate serine or threonine residues and are, in many cases, regulated by cellular metabolites, rather than by second messengers. An original enzyme of bacteria is isocitrate dehydrogenase kinase/phosphatase of enteric bacteria, which has combined phosphatase and kinase activities located
