## Preface

The need for spare parts for the human body has never been greater than at present. More people than ever are living longer, but the human body, shaped by millions of years of evolution, isn't keeping up. Spare parts must be available to replace organs and tissues that are worn out from operating beyond their expiration dates, as well as those damaged by injury, disease, or developmental mishaps.

The biomaterials field has come a long way from its empirical beginnings, with researchers taking whatever materials were available and attempting to integrate them into the human body, sometimes with disastrous results. Now, the body's response to foreign materials is better understood than ever before. Furthermore, the past 15 years have seen great strides in tissue engineering. Spare parts consisting of living tissues are poised for significant clinical application. Tissue engineering, especially of tissues derived from the patient's own cells, offers total acceptance by and integration with the patient's body, unlike nonliving materials or living tissues from other humans or species.

The active ingredient in a medicine is only part of the arsenal against disease. The drug must somehow get to the right place at the right time. That's where drug delivery comes in. Drug delivery companies work to devise new dosage forms for medications. The main challenge is to create the technologies for the easier and most convenient systematic delivery systems. For proteins and other macromolecules, however, the oral route is by far the hardest to accomplish.

From a practical perspective, medical applications of polymers fall into three broad categories: (1) extracorporeal uses (catheters, tubing, and fluid lines; dialysis membranes/artificial kidney; ocular devices; wound dressings and artificial skin), (2) permanently implanted devices (sensory devices; cardiovascular devices; orthopedic devices; dental devices), and (3) temporary implants (degradable sutures; implantable drug delivery systems; polymeric scaffolds for cell or tissue transplants; temporary vascular grafts and arterial stents; temporary small bone fixation devices).

Today, biomaterial research has developed into a major interdisciplinary effort involving chemists, biologists, engineers, and physicians. Biomaterials research has provided the clinician with a large number of new materials and new medical devices. As the biomaterials device industry continues to grow, degradable polymers will increase at the expense of traditional biomaterials such as metals and conventional, biostable polymers.

This volume consists of two parts: Part I: Polymers as Biomaterials and Part II: Medical and Pharmaceutical Applications of Polymers. The fundamental questions of polymer synthesis, the types of polymers used for medical purposes, and modification of polymers to increase their biocompatibility, are presented in the first part. The applications of the two major groups of biomaterials—natural biomaterials (polysaccharides, cellulose, chitosan, proteins, etc.) and synthetic biomaterials (polyesters, silicones, elastomers, etc.)—are also reviewed. Part II deals with concrete utilization of polymeric biomaterials in the domains of tissue engineering, ophthalmic delivery, vascular prostheses (grafts), dental and maxillofacial surgery, blood contacting, skin graft polymers, sensors in biomedical applications, medical adhesives, medical textiles, and topical hemostat biomaterials.

The uses of polymers in the pharmaceutical domain fall into two areas: drug polymers and drug carrier polymers for controlled release. Part II provides the groundwork for understanding the fundamentals of drug delivery including conventional, nonconventional, and modulated systems; structure–property relations of selected supports and their role in drug delivery; delivery of drugs to sites such as the gastrointestinal tract, lung, skin, tumors, and blood vessels; and marketing considerations in new drug delivery systems.

This book is truly international, with authors from Austria, Canada, Finland, France, Germany, India, Israel, Italy, Japan, the Netherlands, Portugal, Slovenia, Spain, Switzerland, Thailand, the United Kingdom, and the United States. I am grateful to all the contributors.

# Contents

<i>Preface</i>	v
<i>Contributors</i>	xi

## Part I. Polymers as Biomaterials

1. Polysaccharides as Biomaterials <i>Severian Dumitriu</i>	1
2. Biomimetics <i>Weiyuan John Kao</i>	63
3. Silicones for Pharmaceutical and Biomedical Applications <i>Haissam S. El-Zaim and John P. Heggors</i>	79
4. Biodegradable Polymers as Drug Carrier Systems <i>Abraham J. Domb, Neeraj Kumar, Tzviel Sheskin, Alfonso Bentolila, Joram Slager, and Doron Teomim</i>	91
5. Biodegradable Biomaterials Having Nitric Oxide Biological Activity <i>C. C. Chu</i>	123
6. Hydrogels for Biomedical and Pharmaceutical Applications <i>Akio Kishida and Yoshito Ikada</i>	133
7. Mucoadhesive Polymers <i>Andreas Bernkop-Schnürch</i>	147
8. Polymers for Tissue Engineering Scaffolds <i>Howard W. T. Matthew</i>	167
9. Chitosan: Structure–Properties Relationship and Biomedical Applications <i>Alain Domard and Monique Domard</i>	187
10. Chitosan-Based Delivery Systems: Physicochemical Properties and Pharmaceutical Applications <i>Radi Hejazi and Monsoor Amiji</i>	213

11. Immobilization of Active Biopolymers from Cold Plasma–Functionalized Surfaces for the Creation of Molecular Recognition and Molecular Manufacturing Systems <i>Ferencz Denes and Sorin Manolache</i>	239
12. Advances in Designed Multivalent Bioconjugates with Dendritic Structure <i>Bogdan Comanita</i>	291
13. Biocompatibility of Elastomers <i>D. J. Chauvel-Lebret, P. Auroy, and M. Bonnaure-Mallet</i>	311
14. Control of Cell–Biomaterial Interactions <i>Danielle C. Giliberti, Kyle K. White, and Kay C Dee</i>	361
<b>Part II. Medical and Pharmaceutical Applications of Polymers</b>	
15. Polymeric Systems for Ophthalmic Drug Delivery <i>O. Felt, S. Einmahl, P. Furrer, V. Baeyens, and R. Gurny</i>	377
16. Dental and Maxillofacial Surgery Applications of Polymers <i>A. Bascones, J. M. Vega, N. Olmo, J. Turnay, J. G. Gavilanes, and M. A. Lizarbe</i>	423
17. Biomaterials in Burn and Wound Dressings <i>Robert L. Sheridan, Jeffrey R. Morgan, and Rashid Mohammad</i>	451
18. Dermocosmetic Applications of Polymeric Biomaterials <i>P. Corvi Mora and P. G. Baraldi</i>	459
19. Textile-Based Biomaterials for Surgical Applications <i>C. C. Chu</i>	491
20. Bioabsorbable Polymers for Medical Applications with an Emphasis on Orthopedic Surgery <i>Pentti U. Rokkanen</i>	545
21. Polymers for Artificial Joints <i>Naohide Tomita, Kazuya Nagata, and Hiroshi Fujita</i>	563
22. Polymeric Occluders in Tilting Disc Heart Valve Prostheses <i>G. S. Bhuvaneshwar, A. V. Ramani, and K. B. Chandran</i>	589
23. Blood-Contacting Polymers <i>T. Avramoglou, J. Jozefonvicz, and M. Jozefowicz</i>	611
24. Surface Modification of Dacron Vascular Grafts: Incorporation of Antithrombin and Mitogenic Properties <i>Matthew D. Phaneuf, Martin J. Bide, William C. Quist, and Frank W. LoGerfo</i>	647
25. Antithrombin–Heparin Complexes <i>Leslie R. Berry, Maureen Andrew, and Anthony K. C. Chan</i>	669
26. Adhesives for Medical Applications <i>Iain Webster and Peter J. West</i>	703
27. Glucose-Sensitive Hydrogel Membranes <i>Jin Ho Lee, Jung Ju Kim, and Kinam Park</i>	739

28. Polymeric Micro- and Nanoparticles as Drug Carriers <i>G. Barratt, G. Couarraze, P. Couvreur, C. Dubernet, E. Fattal, R. Gref, D. Labarre, P. Legrand, G. Ponchel, and C. Vauthier</i>	753
29. Liposomes in Drug Delivery <i>Yuan-Peng Zhang, Boris Čeh, and Danilo D. Lasic</i>	783
30. Liposomes for Cancer Therapy Applications <i>Lawrence D. Mayer, Rajesh Krishna, and Marcel B. Bally</i>	823
31. Systemic Cancer Therapy Using Polymer-Based Prodrugs and Progenes <i>Leonard W. Seymour</i>	843
32. Anticancer Drug Conjugates with Macromolecular Carriers <i>F. Kratz, A. Warnecke, K. Riebeseel, and P. C. A. Rodrigues</i>	851
33. Enzyme–Prodrug Therapies of Cancer <i>Richard J. Knox, Roger G. Melton, and Ronit Satchi</i>	895
34. New Lipid/DNA Complexes for Gene Delivery <i>Kenneth W. Liang and Leaf Huang</i>	929
35. Gene Delivery by Cationic Liposome–DNA Complexes <i>Nejat Düzgüneş, Sérgio Simões, Pedro Pires, and Maria C. Pedroso de Lima</i>	943
36. Biological Stimulus-Responsive Hydrogels <i>Takashi Miyata and Tadashi Uragami</i>	959
37. Biocompatible Polymers in Liver-Targeted Gene Delivery Systems <i>Edwin C. Ouyang, George Y. Wu, and Catherine H. Wu</i>	975
38. Bioartificial Pancreas <i>Riccardo Calafiore</i>	983
39. Transdermal Delivery of Drugs <i>B. B. Michniak and A. El-Kattan</i>	1007
40. Drug Delivery via Mucosal Routes <i>Nimit Worakul and Joseph R. Robinson</i>	1031
41. Bioadhesive Drug Delivery Systems <i>A. David Woolfson, R. Karl Malcolm, Paul A. McCarron, and David S. Jones</i>	1063
42. Recent Developments in Drug Delivery to the Nervous System <i>Dusica Maysinger, Radoslav Savic, Joseph Tam, Christine Allen, and Adi Eisenberg</i>	1083
43. Glucose-Mediated Insulin Delivery from Implantable Polymers <i>Larry R. Brown</i>	1101
44. Drug Targeting to the Kidney: The Low-Molecular-Weight Protein Approach <i>R. F. G. Haverdings, R. J. Kok, M. Haas, F. Moolenaar, D. de Zeeuw, and D. K. F. Meijer</i>	1117
<i>Index</i>	<i>1141</i>

# Polysaccharides as Biomaterials

Severian Dumitriu

*University of Sherbrooke, Sherbrooke, Quebec, Canada*

## I. INTRODUCTION

Polymers have found applications in virtually every discipline of medicine, ranging from simple extracorporeal devices to intricately designed implants. Since each medical application has its own highly specialized requirements, a range of diverse materials with good biocompatibility but different chemical and physicochemical properties must be available.

Polysaccharides constitute an important component of life matter. Polysaccharides display a perfect biocompatibility and biodegradability, which are the basic characteristics for polymers used as biomaterials. They have several characteristics not found in other natural polymers. Recently, specific properties of antivirals, antitumorals, gene modulators, etc., have been discovered for various classes of polysaccharides.

This chapter presents all polysaccharide classes with applications as biomaterials and as pharmaceutical systems. For the first group—polysaccharides used as biomaterials—a special emphasis is given to the presentation of membranes, implants, skin replacements, matrices for cellular engineering (scaffolds), and hemostatic agents. The second group—polysaccharides used as pharmaceutical systems—describes mainly the use of polysaccharides as components for drug conditioning and drug delivery systems fabrication. This chapter presents a review of the literature based on the three books previously published: *Polymeric Biomaterials*, *Polysaccharides in Medicinal*

*Applications*, and *Polysaccharides: Structural Diversity and Functional Versatility*, all edited by S. Dumitriu and published by Marcel Dekker, Inc.

## II. BACTERIAL POLYSACCHARIDES

Encapsulated bacterial diseases are still the most prevalent and serious infections in humans. There is increasing research of the chemical basis of immunogenicity to capsular polysaccharides and prevention of bacterial infections through immunization.

The capsular polysaccharides of bacteria are attractive vaccine candidates because they constitute the most highly conserved and most exposed bacterial surface antigens. They can be readily isolated and purified; they are non-toxic; and they are immunogenic in humans (with few exceptions) (1). Another important feature is that capsular polysaccharides can be chemically and physically defined, which is necessary for control over their efficacy as human biologicals. In fact, the use of capsular polysaccharides as immunoprophylactic agents against human disease caused by encapsulated bacteria is now firmly established (2,3). Efficacious vaccines composed of the capsular polysaccharides of *Nisseria meningitidis*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Salmonella typhi* have been developed as commercial products (Table 1).

A new generation of highly successful semisynthetic glycoconjugate vaccines in which the polysaccharides were

conjugated (covalently linked) to protein carriers were developed (1). During the last 15 years, comprehensive studies specially directed to the development of glycoconjugate vaccines as potential human vaccines have been reported (Table 2) (9–11).

Complex carbohydrates are essential cell surface components. Generally, the surface carbohydrates of bacteria are polysaccharides, either capsular polysaccharides or a part of cell wall lipopolysaccharides (LPS) (22–24). Bacterial cells are protected by capsules in inadvertent surroundings (25–29).

Capsular polysaccharides (CPS) are generally negatively charged (30). All structures of bacterial polysaccharides published until early 1982 have been recorded in a review (31).

Generally, bacterial polysaccharides have repetitive units that may consist of monosaccharides and octasaccharides and they may be linear or branched.

Cell wall lipopolysaccharides of gram-negative bacteria consist of a lipid moiety, a core oligosaccharide, and a polysaccharide moiety which is made up from repeating units (32). Mammalian glycoproteins contain oligosaccharides with different complexities, which are bound to hy-

droxyamino acid units or asparagine units of proteins. In proteoglycans, polysaccharides are bound to polypeptides.

The crystal structure of the complex of an anti-Id Fab with a Fab specific for a *Brucella* polysaccharide antigen has previously been reported (33). To complement this study, the binding characteristics and immunological properties of this Ab2 and two others raised with a second anti-*Brucella* antibody were investigated, including quantitative kinetic measurements by surface plasmon resonance (34). Protective immunity to encapsulated bacteria is related to antibody response to polysaccharide (PS) antigen, interactions with T and B cells, and host defense mechanisms (35).

*Klebsiella pneumoniae* is one of the most frequently isolated gram-negative pathogens in severe nosocomial infections. Alvarez et al. (36) have demonstrated the existence of *K. pneumoniae* clinical isolates deficient in the lipopolysaccharide O side chain, the major factor for resistance to complement-mediated killing in this bacterial species. These isolates are complement resistant, and their mechanisms to resist complement were investigated by selecting transposon-generated complement-sensitive mutants. One mutant with a drastically reduced capacity to grow in nonimmune human serum carried the transposon inserted in an open reading frame of a gene cluster involved in capsule synthesis. Four additional clinical isolates representing four different K serotypes were studied, and results showed that capsular polysaccharide is a major complement resistance factor in these O side chain-deficient isolates.

Barnett et al. (37) compared responses to pneumococcal conjugate and polysaccharide vaccines in 48 otitis-free and 64 otitis-prone children. Pre- and postimmunization concentrations of antibodies to pneumococcal serotypes 6B, 14, 19F, and 23F were measured by enzyme-linked immunosorbent assay. Postimmunization mean concentrations of antibodies to all four serotypes were significantly higher for children receiving conjugate vaccine than for those receiving polysaccharide vaccine; the difference in responses was primarily due to a better response to conjugate vaccine in the otitis-prone group. Significantly higher postimmunization concentrations of antibodies to all four serotypes and to one of the four serotypes were found in otitis-prone children and otitis-free children who received conjugate vaccine, respectively. Pneumococcal conjugate vaccine has the potential to reduce the incidence of disease due to vaccine serotypes, even among children with recurrent otitis media.

Protein antigens induce significant mucosal immunoglobulin A (IgA) and systemic IgG responses when administered intranasally (i.n.) with the glyceride-polysorbate-based adjuvant RhinoVax (RV) both in experimental

animals and humans (38). The pneumococcal polysaccharide conjugates (PNCs) induced significant systemic IgG and IgA antibodies after i.n. immunization only when given with RV and, for serotype 1, serum IgG titers were comparable to titers induced by subcutaneous immunization. In addition, i.n. immunization with PNC-1 in RV elicited detectable mucosal IgA. These results demonstrate that RV is a potent mucosal adjuvant.

Zhong et al. (39) describe the generation, molecular structure, and protective efficacy of a human monoclonal antibody (MAb) reactive with the capsular polysaccharide of serotype 8 *Streptococcus pneumoniae*. In vitro studies revealed MAb D11-dependent complement deposition on the capsule of serotype 8 organisms via either the classical or the alternative complement pathway. In vivo, MAb D11 prolonged the survival of both normal and C4-deficient mice with lethal serotype 8 *S. pneumoniae* infection.

### III. CELLULOSE AND ITS DERIVATIVES

Polysaccharides currently used in medicine on a large scale include cellulose, cellulose derivatives, heparin, dextrin, pullulan, hyaluronic acid, and alginate.

Cellulosics, regenerated cellulose and its methyl, ethyl, amino ethyl, and acetate-phthalate derivatives (40) have been widely investigated as membranes in artificial kidneys, encapsulating materials for controlled drug delivery (41), sutures and bandages (42), and blood-compatible materials (43), and are used mostly for blood purification, as anticoagulant, and as plasma expander in aqueous solution.

#### A. Blood Purification

##### 1. Hemodialysis

Hemodialysis is a therapeutic treatment of chronic renal disease to remove an excess of water and uremic toxins from the patient blood by dialysis under the extracorporeal blood circulation. The most important part of the hemodialysis system is the semipermeable membrane installed in the dialyzer. The first semipermeable membrane was reported in 1944 using cellophane. Cellulosic membranes are still used for the hemodialyzer, largely synthetic semipermeable membranes made of polysulfone (PS), polyacrylonitrile (PAN), poly(methyl methacrylate) (PMMA), and ethylene-vinyl alcohol copolymer (EVAL) (44).

The cellulosic hemodialysis membrane can be divided into regenerated cellulose and cellulose acetate (di- and triacetate). In the early years of hemodialysis therapy, flat-, tube-, hollow fiber-type membranes were employed. At present almost 100% of hemodialyzers appear to be made from hollow fibers. The cellulose membrane for hemodial-

ysis is regenerated from cuproammonium solution of refined cotton linters. Cellulose hollow fibers are regenerated from cellulose acetate by deacetylation (45). Current extensive efforts to improve hemodialysis membranes are focusing on removal of  $\beta$ -microglobulin and improving blood compatibility. The improvement of hemocompatibility of cellulose membranes is achievement by surface modification through uretanation, acylation/sulfation, chloroacetylation/sulfonation, and polyacylation (46–48).

Ishihara et al. (49) have synthesized a water-soluble graft polymer composed of a cellulose and polymer having a phospholipid polar group, poly(2-methacryloyloxyethyl) phosphocholine (MGC) as a coating material on the cellulose hemodialysis membrane. The MGC could be coated on the hollow fiber probe and the performance of the probe did not decrease even after the coating. By recording rapid changes in the glucose concentration from 100 to 200 mg/dL, the time to reach 90% of the maximum value was within 7 min. To determine the glucose concentration in subcutaneous tissue, the hollow fiber probe modified with MGC was applied to human volunteers.

Both cellulose diacetate and triacetate are used for hemodialysis. The blood compatibility of the cellulose acetate membrane seems to be excellent if monolayer coverage of the surface with serum albumin is employed (50).

Collodion, a cellulose trinitrate derivative, was the first polymer to be used as an artificial membrane, and it played a central role in further investigations and applications (51,52). Cellophane and Cuprophane (53–57) membranes replaced collodion later because of their better performance and mechanical stability. However, due to their alleged lack of hemocompatibility, membranes made from unmodified cellulose lost their market share. They have been replaced by modified cellulosic and synthetic dialysis membranes which show a better hemocompatibility than unmodified cellulose membranes. Most of the new membrane materials are also available in high-flux modifications and for this reason are suitable as well for more effective therapy modes, such as hemodiafiltration and hemofiltration. The success of hemodialysis as a routine therapy is also the success of membrane development, because both a reproducible membrane production and an unlimited availability of dialysis membranes have increased the number of dialyzed patients to about 1 million worldwide in 1999 (58).

Dialysis membranes made from regenerated cellulose are under dispute because of their alleged lack of hemocompatibility. The introduction of membranes from synthetically modified cellulose, like cellulose acetate or Hemophan, has proven, however, that hemocompatible membranes can be fabricated from cellulose by means of chemical surface modifications (59,60). Diamantoglou et

al. (59) have synthesized a series of cellulose carbamate derivatives to profit from the excellent hemocompatibility pattern of the urethane family. In vitro investigations on membranes made from these cellulose modifications proved a direct relationship between the degree of modification and hemocompatibility. This was proven for the following three representative hemocompatibility parameters: complement C5a generation, thrombin-antithrombin (TAT) III formation, and platelet count (PC). As already shown for modifications made from cellulose esters, a direct dependency between improved hemocompatibility and the degree of substitution (DS) in the cellulose molecule could be found.

## 2. Plasmapheresis

Plasmapheresis is a therapeutic treatment of blood to separate only plasma from the whole blood of a patient through extracorporeal circulation when the plasma contains pathogenic substances which are mostly high molecular weight proteins. The separated plasma is discarded and substituted with fresh plasma. The plasma separation is based on ultrafiltration by hollow fiber membrane with pore size from 0.1 to 0.5  $\mu\text{m}$ , prepared from cellulose acetate, polyvinyl alcohol, polyethylene, and polypropylene.

## 3. Virus Removal

Cellulose is a very good candidate as the filter material since the cellulose surface exhibits the least protein adsorption of the conventional polymer surfaces. The membrane is prepared by coagulation of the cuproammonium solution. It was proved that this filter with an average pore size of 35 nm could completely remove hepatitis C virus (61,62).

## 4. Hemostasis

Oxidized cellulose has been used as hemostat. This is an acidic polysaccharide produced by oxidation of cellulose with periodic acid or nitrogen oxide. A more effective method for homeostasis is to use oxidized cellulose gauze together with a liquid-type hemostat. Wiseman et al. (63) evaluated two adhesion barriers composed of oxidized regenerated cellulose (ORC) in a model of bowel surgery, with and without bleeding. They concluded that with hemostasis both absorbable fabrics of ORC reduced adhesion formation between the injured cecum and abdominal side wall. The effectiveness of INTERCEED Barrier, but not nTC7, was reduced but not eliminated in the presence of bleeding. This confirms similar observations in models of gynecologic surgery.

A particularly interesting application of oxidized cellu-

lose is as a barrier for the prevention of surgical adhesions (64). The use of oxidized cellulose (Surgicel®) was largely unsuccessful in animal models in reducing surgical adhesions in a reproducible fashion.

## B. Drug Delivery Systems

Hydrophilic matrices based on polysaccharide carriers remain a highly popular design of sustained release dosage form. Control of drug release from tablets containing polysaccharide excipient system was found to be capable using a variety of different formulations and process methods to provide a variety of different release modalities which were capable of matrix-dimension independence. Controllability of drug release was achieved by manipulation of the synergistic interactions of the heterodisperse polysaccharides (65).

Release data from ethylcellulose (EC) matrix tablets were analyzed to determine which release equation provided the best fit to the data and to observe the effect of drug solubility on the release mechanism(s) (66). Theophylline, caffeine, and dyphylline were selected as nonelectrolyte xanthine derivatives, with solubilities from 8.3 to 330 mg/mL at 25°C. At high drug loading, drug was released by a diffusion mechanism with a rate constant that increased with an increase in aqueous solubility. At low drug loading, polymer relaxation also became a component of the release mechanism. However, its contribution to drug release was less pronounced as solubility decreased, becoming negligible in the case of theophylline.

Microcrystalline cellulose (MCC), sodium carboxymethylcellulose (NaCMC), hydroxypropylmethylcellulose (HPMC), hydroxyethylcellulose (HEC), hydroxypropylcellulose (HPC), and ethylcellulose were used for the production of time-controlled acetaminophen delivery systems using a spray-drying technique. The influence of factors such as polymer concentration, inlet temperature, and drug/polymer ratio were investigated (67). Dissolution studies in pH 1 dilute HCl and pH 6.8 phosphate buffer dissolution media showed that formulations consisting of 1% polymer with a drug/polymer ratio of 1:1 exhibited the slowest drug release, with the spheroids coated with NaCMC and HEC showing the longest T50% values (45 and 53 min at pH 1 and 49 and 55 min at pH 6.8, respectively). Slightly better sustained drug release in pH 6.8 dissolution medium was reached, showing the following trend: HEC > NaCMC > MCC > EC > HPMC. Concerning the additives, the trends in dissolution T50% of drug revealed TA > SA > CA > OA > PVP > PA > DBS in acidic pH 1 dissolution medium and PVP > OA > TA > SA > PA > CA > DBS in phosphate buffer at pH 6.8 (67).

Hydroxypropylmethylcellulose has been the most widely used hydrophilic drug carrier. Matrix tablets were prepared by wet granulation (68), slugging (69), or direct compression (70). The drug release was controlled through variations in the molecular weight of the polymer, drug solubility, the drug/polymer ratio, the particle size of the drug and polymer, and the addition of different additives (71,78).

The available grades of HPMC have varied molecular weight, degree of substitution, and particle size. The drug and HPMC particles sizes also influence the drug release parameters, although to a lesser extent. The major disadvantage of single-unit hydrophilic matrix systems such as tablets or capsules has been the possibility of uncontrolled erosion as a result of mechanical stress during passage through the gastrointestinal tract, causing erratic drug release and absorption.

A multiple-unit indomethacin delivery system based on HPMC as the hydrophilic carrier material was developed by a novel technique using the insolubility of cellulose ether at elevated temperatures and the ionotropic gelation of the polysaccharide, sodium alginate with calcium ions (79).

In order to develop nasal powder preparations with higher bioavailability for peptide delivery, the effect of a combination of hydroxypropylcellulose and microcrystalline cellulose used as base materials and microenvironment for the drugs in the preparations was examined (80). Significant enhanced absorption of leuprolide, calcitonin, and FITC-dextran was attained by the addition of a small amount of HPC to MCC. It is suggested that MCC works as an absorption enhancer by causing a locally high concentration of drugs in the vicinity of the mucus surface. On the other hand, HPC works to increase retention of drugs on the nasal mucus due to its gel-forming property (80).

The aqueous interaction of the sodium salt of ibuprofen with the cellulose ethers ethyl hydroxyethylcellulose (EHEC) and HPMC has been investigated in the concentration range 0–500 mM ibuprofen and 0.1–1% (w/w) polymer by cloud point, capillary viscometry, equilibrium dialysis, and fluorescence probe techniques (81). A combination of time-resolved and static fluorescence quenching shows that micellelike ibuprofen aggregates are formed in the solution. The average aggregation number of pure ibuprofen micelles in water is about 40.

#### IV. CURDLAN

Harada et al. (82) and Saito et al. (83) showed that more than 99% of the linkages in curdlan are (1 → 3)- $\beta$ -D-glyco-

side linkages. Very few (1 → 6)- $\beta$ -D-glycoside linkages seem to occur in this polysaccharide by the chemical (83) and enzymatic (84) methods. Curdlan is insoluble but swells in water.

#### A. Clinical Application of Curdlan

Maeda and Chihara (85) and Sasaki et al. (86) reported that curdlan, lentinan, and other similar polysaccharides inhibited the growth of Sarcoma-180. Moreover, Sasaki et al. (87) found that a serum factor is involved in the tumor inhibition by curdlan. When peritoneal macrophages from normal untreated mice were incubated in vitro with serum of mice treated with curdlan, they become cytotoxic to tumor cells. This was attributed to two serum factors, a peptide (mw = 4500) and probably a peptidoglycan (mw = 9000) found in serum after administration of the polysaccharide.

Morikawa et al. (88) showed that when curdlan is given i.p. to mice, it produces a high and persistent level of both polymorphonuclear (PMN) leukocytes and macrophages. The activated PMN leukocytes were spontaneously cytotoxic to mammary carcinoma cells in vitro.

Cellulose sulfate, curdlan sulphate, and sulfopropyl curdlan have been found to exhibit strong anti-human immunodeficiency virus (anti-HIV) activity (89,90). Yoshida et al. (91) showed that curdlan sulfate with a sulfur content of 14.4% at concentrations as low as 3.3  $\mu$ g/mL completely inhibited infection by HIV.

Antitumor active polysaccharide against Sarcoma-180 was isolated by DEAE-Sepharose CL-6B and Sepharose 4B column chromatography from the hot water-soluble fraction of the mycelium of liquid-cultured *Agaricus blazei* mill (92). This polysaccharide did not react with antibodies of antitumor polysaccharides such as lentinan, gliforan, and FIII-2-b, which is one of the antitumor polysaccharides from *A. blazei*. Moreover, the analyses of  $^{13}$ C-NMR and GC-MS suggested that this polysaccharide was preliminary glucomannan with a main chain of  $\beta$ -1,2-linked D-mannopyranosyl residues and  $\beta$ -D-glucopyranosyl-3-O- $\beta$ -D-glucopyranosyl residues as a side chain. This polysaccharide was completely different from the antitumor polysaccharide obtained from fruiting body of *A. blazei*,  $\beta$ -1,6-glucan.

#### V. GUAR GUM

Targeting of drugs to the colon, following oral administration, can be accomplished by the use of modified biodegradable polysaccharides as vehicles. Guar gum (GG) was crosslinked with increasing amounts of trisodium trimeta-

phosphate (STMP) to reduce its swelling properties for use as a vehicle in oral delivery formulations, especially drug delivery systems aimed at localizing drugs in the distal portions of the small bowel (93). Swelling of GG in artificial gastrointestinal fluids was reduced from 100- to 120-fold (native GG) to 10- to 35-fold depending on the amount of crosslinker used, showing a bell shape dependency. As a result of the crosslinking procedure GG lost its nonionic nature and became negatively charged.

Functionalizing of GG crosslinked products (GGP) as possible colon-specific drug carriers was analyzed by studying (1) the release kinetics of preloaded hydrocortisone from GGP hydrogels into buffer solutions with or without GG-degrading enzymes ( $\alpha$ -galactosidase and  $\beta$ -mannanase) and (2) direct measurements of the polymer's degradation in the cecum of conscious rats (94). The effect of a GG diet on  $\alpha$ -galactosidase and  $\beta$ -mannanase activity in the cecum of the rat and GGP degradation was also measured. It was found that the product GGP-0.1 (loosely crosslinked with 0.1 equivalents of STMP) was able to prevent the release of 80% of its hydrocortisone load for at least 6 h in PBS, pH 6.4. In vivo degradation studies in the rat cecum showed that, despite the chemical modification of GG, it retained its enzyme-degrading properties in a crosslinker concentration-dependent manner. Eight days of GG diet prior to the study increased  $\alpha$ -galactosidase activity in the cecum of the rat threefold compared to its activity without the diet.

A novel tablet formulation for oral administration using guar gum as the carrier and indomethacin as a model drug has been investigated for colon-specific drug delivery using in vitro methods (95). Drug release studies under conditions mimicking mouth-to-colon transit have shown that guar gum protects the drug from being released completely in the physiological environment of stomach and small intestine (95). Studies in pH 6.8 phosphate-buffered saline (PBS) containing rat cecal contents have demonstrated the susceptibility of guar gum to the colonic bacterial enzyme action with consequent drug release.

Also, it has been shown that the swelling of guar gum is affected by concentration of the drug and viscosity grade of the polymer. This study examines the mechanism of behavior of guar gum in a polymer-drug matrix (96). The swelling action of guar gum, in turn, is controlled by the rate of water uptake into the matrices. An inverse relationship exists between the drug concentration in the gel and matrix swelling. This implies that guar gum swelling is one of the factors affecting drug release. The swelling behavior of guar gum is therefore useful in predicting drug release.

Poly(vinyl alcohol)-guar gum interpenetrating network

microspheres were prepared by crosslinking with glutaraldehyde. Nifedipine was loaded into these matrices before and after crosslinking in order to study its release patterns (97). The mean particle size of the microspheres was found to be around 300  $\mu\text{m}$ . The molecular transport phenomenon, as studied by the dynamic swelling experiments, indicated that an increase in crosslinking affected the transport mechanism from Fickian to non-Fickian. The in vitro release study indicated that the release from these microspheres is not only dependent upon the extent of crosslinking, but also on the amount of the drug loaded as well as the method of drug loading (97).

Guar gum tablet formulations were prepared and evaluated under a variety of in vitro dissolution conditions. The formulations, along with Dilacor XR (diltiazem), were administered to a group of eight fasted, healthy volunteers in a four period crossover study (98). Dissolution of diltiazem from guar gum tablets was essentially independent of stir speed under normal conditions (USP Apparatus II).

## VI. PULLULAN

Although many fungi are known to produce exopolysaccharides with an interesting range of chemical and physical properties (99), most of the research effort has been directed to the  $\alpha$ -glucan pullulan, produced by *Aureobasidium pullulans* (100). Bernier (101) first described the production of two exopolysaccharides by Pullularia (*A. pullulans*), a heteropolysaccharide and a neutral glucan. These contain  $\alpha$ -(1-4) and  $\alpha$ -(1-6) glucosidic linkages.

Pullulan is a polysaccharide with high liver affinity. Considering this property, interferon-pullulan conjugation was promising for interferon (IFN) targeting to the liver with efficient exertion of its antiviral activity therein (102). The cyanuric chloride method enabled the preparation of an IFN-pullulan conjugate that retained approximately 7-9% of the biological activity of IFN. Pullulan conjugation enhanced the liver accumulation of IFN and the retention period with the results being reproducible. When injected intravenously to mice, the IFN-pullulan conjugate enhanced the activity of 2-5A synthetase in the liver. The activity could be induced at IFN doses much lower than those of free IFN injection. In addition, the liver 2-5A synthetase induced by conjugate injection was retained for 3 days, whereas it was lost within the first day for the free IFN-injected mice.

A chelating residue [diethylenetriamine pentaacetic acid (DTPA)] was introduced to pullulan (103). This DTPA-pullulan could conjugate with IFN through  $\text{Zn}^{2+}$

coordination on mixing these three components. Intravenous injection of the IFN–DTPA–pullulan conjugate with  $Zn^{2+}$  coordination induced activity in the liver of an antiviral enzyme (103). Liver targeting of IFN by this conjugation technique based on  $Zn^{2+}$  coordination opens a new method of IFN therapy.

Gu et al. (104) and Wang et al. (105) reported a novel formula of hydrophobized polysaccharide nanoparticles which can deliver a HER2 oncoprotein containing an epitope peptide to the MHC class I pathway. A protein consisting of the 147 amino-terminal amino acids of oncogene erbB-2/neu/HER2 (HER2) was complexed with two kinds of hydrophobized polysaccharides, cholesteryl group-bearing mannan (CHM) and cholesteryl group-bearing pullulan (CHP), to form nanoparticles (CHM-HER2 and CHP-HER2). CHM-HER2 and CHP-HER2 were able to induce CD3+/CD8+ CTLs against HER2-transfected syngeneic fibrosarcoma cell lines. In addition, vaccination by CHM-HER2 complexes led to a strongly enhanced production of IgG antibodies against HER2, whereas vaccination with HER2 proteins alone resulted in a production of antibodies at a marginal level. Mice immunized with CHM-HER2 or CHP-HER2 before tumor challenge successfully rejected HER2-transfected tumors. The complete rejection of tumors also occurred when CHM-HER2 was applied not later than 3 days after tumor implantation.

The effect of liposomal adriamycin with tumor recognition molecule, 1-aminolactose (1-AL), on AH66 hepatoma transplanted into nude mice was investigated by Ichinose et al. (106). Adriamycin (ADM) was encapsulated in liposome coating with CHP to increase the stability in the blood stream. 1-Aminolactose (1-AL) was assembled to the outer layer of CHP-coated liposomal ADM as a tumor recognition molecule. In an *in vivo* therapeutic study, 1-AL/CHP-coated liposomal ADM restrained tumor growth more when compared with CHP-coated liposomal ADM. Thus, 1-AL/CHP-coated liposome seems to be a carrier of ADM to tumor cells.

Yamamoto et al. (107) synthesized CHP bearing 1-aminolactose and introduced a saccharide, cholesteryl pullulan bearing 1-aminolactose (1-AL/CHP), to an outer layer of the conventional liposome as a cell recognition element. Lectin recognized the  $\beta$ -galactose by aggregation of 1-AL/CHP-coated liposome (1-AL/CHP liposome). The uptake of this liposome to AH66 rat hepatoma cells was greater than in liposomes without 1-aminolactose *in vitro*. Furthermore, 1-AL/CHP liposomal adriamycin showed a stronger antitumor effect in comparison with other types of liposomal adriamycin *in vitro*. When *in vivo* tumor-targeting efficacy was investigated in AH66 tumor-

transplanted mice using 3H-liposome, the tumor/serum radioactivity ratio in mice injected with 1-AL/CHP liposome was higher than that of mice injected with other liposomes. These observations suggest that 1-AL is effective as a cell recognition element. As a result, 1-AL/CHP liposome is considered to be a good carrier of anticancer drugs for the active targeting of tumor cells (107).

Insulin spontaneously and easily complexed with the hydrogel nanoparticle of CHP in water (108). The complexed nanoparticles (diameter 20–30 nm) thus obtained formed a very stable colloid (108). The original physiological activity of complexed insulin was preserved *in vivo* after *i.v.* injection.

Suzuki and Sunada (109) have investigated the influence of water-soluble polymers on the dissolution behavior of nifedipine from solid dispersions with combined carriers. All the solid dispersions of nifedipine were prepared by the fusion method using nicotinamide and four different water-soluble polymers: hydroxypropylmethylcellulose (HPMC), polyvinylpyrrolidone (PVP), partially hydrolyzed polyvinyl alcohol (PVA), and pullulan. HPMC, PVP, and PVA dissolved in the fused liquid of nicotinamide and operated efficiently on the amorphous formation of nifedipine in solid dispersions. In dissolution studies, the drug concentration for these dispersions increased to more than twice the intrinsic drug solubility. The rank order of the drug concentration was HPMC > PVP > PVA. However, since pullulan did not dissolve in the fused nicotinamide, nifedipine was present as a crystalline state in the solid dispersion; the supersaturation behavior of the drug was scarcely observed (109).

## VII. DEXTRIN AND CYCLODEXTRIN

Dextrin consist of an  $\alpha$ -(1→6)-linked glucan with branches attached to O-3 of the backbone chain units. The degree of branching is approximately 5%. Recently, enzymatic hydrolysis combined with chemical and nuclear magnetic resonance studies have enabled the ratio of single to multiple branches to be elegantly elucidated (110).

The molecular size is a pivotal importance for each of the pharmacological properties of dextrin, for example, colloid osmotic pressure, viscosity, cell surface adsorption, and steric exclusion principles (111,112).

The effects of dextrin on hemostasis have been reviewed (113,114). Although it is generally agreed that the coagulation mechanism remains normal after infusion of a standard clinical dose of dextrin (115,116). Dextran appears to be adsorbed to the surfaces of the vascular endothelium and various cells (117,118).

Whereas native dextrin is immunogenic in humans (119), lower molecular weight fractions in the clinical range were not found to be immunogenic (120,121). The antigenic determinants on the dextrin chain appear to correspond to segments of two to seven glucose units (121,122).

pH-sensitive dextran hydrogels were prepared by activation of dextran (T-70) with 4-nitrophenyl chloroformate, followed by conjugation of the activated dextran with 4-aminobutyric acid and crosslinking with 1,10-diaminodecane (123). The crosslinking efficiencies determined by mechanical measurements were in the range of 52–63%. Incorporation of carboxylpropyl groups in dextran hydrogels led to a higher equilibrium and faster swelling under high pH conditions. The swelling reversibility of hydrogels was also observed after repeated changes in buffers between pH 2.0 and 7.4 (123).

Cyclodextrin (CDs) are naturally occurring homochiral oligosaccharides composed of from 6 to 13  $\alpha$ -1,4-linked D-glucopyranose units. They possess annular structures whose wide and narrow hydrophilic ends are delineated by OH (2) and OH (3) secondary and OH (6) primary hydroxyl groups, respectively, whereas their hydrophobic annular interiors are lined with methyl and methylene groups and ether oxygens. Interest in CDs stems from their ability to partially or completely include a wide range of guest species within their annuli to form inclusion complexes, also referred to as host–guest complexes (124–130). The bonding between the CDs and guests is solely secondary in nature; nevertheless, the inclusion complexes can exhibit considerable thermodynamic stability (131).

Cyclodextrins are potentially very interesting as the formulator in pharmaceutical technology. These cyclic oligosaccharides have the ability to form noncovalent complexes with a number of drugs and in so doing alter their physicochemical properties. In addition, the primary and secondary hydroxyl group of the native ( $\alpha$ ,  $\beta$ ,  $\gamma$ ) cyclodextrins are potential sites for chemical modifications (132). Cyclodextrins have remarkable properties in improving stability, solubility, and bioavailability of drugs after oral administration (133,134). Natural CDs undergo enzymatic degradation along the gastrointestinal tract, which probably occurs mainly in the colon (135). No definitive results of acute toxicity have been published because the highest doses administered to animals do not result in any mortality (133). Because CDs are most often used to enhance the solubility and consequently the bioavailability of poorly water-soluble active ingredients, intravenous administration is among the most interesting parenteral routes. Inclusion of a guest molecule in the cavity of CDs constitutes a protected state of the included molecule. This protection is especially effective in the solid state, with respect to the oxygen from ambient air (136).

Cyclodextrins have the potential to enhance drug release by increasing the concentration of diffusible species within matrix. Guo and Cooklock (137) used a range of additives including CDs to increase the solubility of the poorly water-soluble opioid analgesic, buprenorphine, and modify its release from buccal patches composed of poly(acrylic acid), poly(isobutylene), and poly(isoprene).

By inclusion of guest molecule inside the cavity of CDs, side effects decreased. Inclusion in CDs can reduce the bitterness of femoxetine (138), reduce the local irritation of pirofen (139), and decrease the ulcerous effect of phenylbutazone (140) or indomethacin (141). In the case of active ingredients exhibiting a poor bioavailability due to water nonsolubility or low solubility, but without absorption problems, the improvement in apparent solubility can improve the bioavailability (142,143). Other examples of using CDs to promote drug release through dissolution-erosion mechanisms are given by Giunchedi et al. (144) and Song et al. (145).

Because of their ability to enhance the stability, solubility, or bioavailability of drugs, CDs have been the subject of studies concerning every administration route: oral (146–158); rectal (159–163); dermal (164–178); ocular (179–182); nasal (183–188); pulmonary (189–191); parenteral (192–196); intracerebral (197); intrathecal (198), and epidural (199,200) administration. Recently, modified CDs (201–212) were prepared either to allow the direct formation of targeting agents (213–217) or to enable them to be targeting agents.

## VIII. STARCH

### A. Microspheres and Microcapsules

Starch, in its native and modified form, has been subjected to extensive study over the past 40 years. Early interest in starch was associated with the food and paper industry, textile manufacture, and medicine. Crosslinked starch and starch networks have both the required biodegradability and a relatively high mechanical and chemical stability. Starch microspheres were prepared using epichlorohydrin as a crosslinking agent. Recently the need for three-dimensional matrices with controlled release properties for pharmaceutical and agrochemical uses has increased interest in starch gelation (218–223).

The condensation mechanism of epichlorohydrin with amylose involves epoxide ring opening, mediated by the nucleophilic attack of the alkali amylose, and subsequent chlorine displacement and epoxidation (224,225). The starch–epichlorohydrin reaction follows second order kinetics, first order with respect to epichlorohydrin as well

as starch. The activation energy for the reaction is 38 kJ/mol and the temperature coefficient  $K_{323}/K_{303}$  is 2 (226).

The crosslinking of starch with epichlorohydrin under homogeneous and heterogeneous condition was studied with a particular view of measuring the extent of the side reaction, where starch was substituted to give a monoether derivative (227). The extent of this reaction was strongly dependent on the reaction conditions (temperature, time, molar ratio of all reactants). Depending on these conditions, 5–25% epichlorohydrin was bound as glycerol monoether substituent by starch. The degree of swelling of the crosslinked starch was linearly dependent on the water/starch molar ratio in the reaction mixture (227). The crosslinking of starch proceeded with remarkable efficiency when epichlorohydrin was applied in the vapor phase.

An interfacial crosslinking process was applied to hydro-soluble starch derivatives: hydroxyethyl starch and carboxymethyl starch (223). All crosslinked polysaccharide microcapsules were characterized by a total resistance to digestive media.

Shefer et al. (224) characterized the structure and morphology of starch networks formed by two distinct methods using cross-polarization magic angle-spinning  $^{13}\text{C}$ -NMR spectroscopy (CP-MAS  $^{13}\text{C}$ -NMR) combined with wide angle x-ray diffraction measurements. The first step in the process involves the gelatinization of amylose using sodium hydroxide. After the addition of NaOH solution (6.6% w/w) the resonance lines of the amylose were broadened. Broadening can be caused by distribution of isotropic chemical shifts due to the loss of crystallinity (224). The loss of crystallinity during this process is also observed in the wide angle x-ray diffractogram of a sample following treatment with NaOH.

The amorphous nature of the networks formed following the reaction of amylose with epichlorohydrin is also supported by x-ray diffraction analysis. The resonance of the C6 carbon in the network formed is of weaker intensity and is shifted downfield by about 1 ppm from about 61.4 ppm in the native amylose molecule to 60.4 ppm in the crosslinked network. The secondary OH(2) and OH(3) of the native amylose at 5.0–5.4 ppm appear in the cross-linked network spectrum. This indicates that both crosslink points as well as glycolic functional group (4.7 ppm) are formed (224). These observations suggest that epichlorohydrin crosslinks and reacts monofunctionally at C2, C3, and C6 (224). Their swelling degree, reflecting the number of glycerol diether bridges in the polymeric network, and the number of noncrosslinking monoglycerol ether groups corresponding to a side reaction of epichlorohydrin with starch were determined (228). Degradation by  $\alpha$ -amylase was surface controlled and could be modulated by the introduction in the polymeric network of (1) nonhydrolyz-

able  $\alpha$ -1,6 bonds related to the presence of amylopectin in the raw starch, (2) glycerol diether, and (3) monoether groups, all of these being likely to block the activity of  $\alpha$ -amylase.

A novel silicone polymer-grafted starch microparticle—starch microparticles (MPs) grafted with 3-(triethoxysilyl)-propyl-terminated polydimethylsiloxane (TS-PDMS)—was developed that is efficacious both orally and intranasally (229,230). Unlike most other microparticle systems, this novel system does not appear to retard the release of antigen or to protect antigen from degradation. The results indicate that a unique physicochemical relationship occurs between protein antigen and silicone in a starch matrix that facilitates the mucosal immunogenicity of antigen. This leads to predominance of Th2 antibody response (229,230).

The efficacy of temporary arterial embolization using degradable starch microspheres combined with hyperthermia was investigated in rabbits bearing VX2 tumors (231). Microsphere injection caused a marked decrease of tumor blood flow and pH. During heating, there was a marked increase of the maximum temperature in tumor tissue compared with normal muscle. Tumor growth was suppressed 330% times at 3 weeks after hyperthermia alone and 270% times following combined treatment with microspheres and hyperthermia. Damage to normal muscle tissue was mild (231).

Evaluation of reticular endothelial system-specific magnetic starch microspheres (MSMs) as an i.v. contrast agent for MR imaging in a model of experimental liver metastases has been studied. A loss of liver signal intensity was obtained at all MSM dose levels. No metastases were detected in the precontrast images. The optimal detection rate of hepatic metastases was reached with the T1-weighted spin-echo (SE) sequence at a dose of 1.0 mg Fe/kg b.w. MSM and the diameters of the smallest lesions depicted were 1 mm (232). The use of MSM dramatically increased the detection of experimental hepatic metastases.

## B. Starch Derivatives

### 1. Hydroxyethyl Starch

Hydroxyethyl starches (HES) are high-polymeric compounds obtained via hydrolysis and subsequent hydroxyethylation from the highly branched amylopectin contained in maize. The glucose units can be substituted at carbon 2, 3, and 6 leading to various substitution patterns. This pattern is described by the C2/C6 hydroxyethylation ratio. The higher the degree of substitution and the C2/C6 ratio, the less the starch is metabolized. The *in vitro* molecular weight, the degree of substitution, and the C2/C6 ratio are the main determinants of the *in vivo* molecular weight,

which is clinically relevant. Hemorrhagic complications that occur after infusing larger volumes of HES can be avoided with a starch of low in vivo molecular weight (233). Furthermore high molecular weight HES macromolecules lead to a distinctive decrease in fibronectin concentration that reflects saturation of the reticuloendothelial system (RES). Another advantage of low in vivo molecular weight HES is its rather short half-life. Patients with an increased bleeding risk, microcirculatory disturbance, or affected RES should receive HES with low in vivo molecular weight. In the future, HES should be mainly characterized by the in vivo and not the in vitro molecular weight.

Artificial colloids affect hemostasis. Particularly, HES solutions may have detrimental effects on hemostatic mechanisms (234).

Hydroxyethyl starch is frequently used as a volume expander in critically ill patients. Hofbauer et al. (235) investigated whether HES influences the chemotaxis of polymorphonuclear leukocytes (PMNs) through endothelial cell monolayers by using a test system that allows the simultaneous treatment of both cell types; HES was shown to significantly reduce the chemotaxis of PMNs through endothelial cell monolayers.

The effects of HES on blood coagulation were investigated in 20 patients undergoing surgery to determine whether its use places recipients at risk of hemorrhage or thrombosis (236). The partial thromboplastin times are significantly prolonged; factor VIII activities and fibrinogen levels are decreased. After infusion of HES, no significant differences were detected in platelet count or prothrombin time. A decreased platelet aggregation was also found after the infusion of HES (236).

Jamnicky et al. (237,238) compared the effects of progressive in vitro hemodilution (30 and 60%) on blood coagulation in 80 patients receiving one of two different 6% HES solutions using thrombelastography (TEG). The newly developed solution has a mean molecular weight of 130 kD and a degree of substitution, defined as the average number of hydroxyethyl groups per glucose moiety, of 0.4 (HES 130/0.4); the conventional solution has a mean molecular weight of 200 kD and a degree of substitution of 0.5 (HES 200/0.5). Both HES solutions significantly compromised blood coagulation, as seen by an increase in reaction time and coagulation time and a decrease in angle alpha, maximal amplitude, and coagulation index (all  $p < 0.05$ ).

## 2. Acetyl Starch

Acetyl starch (ACS) is a new synthetic colloid solution for plasma volume expansion and is now undergoing phase 2 clinical trials. Behne et al. (239) compared the pharmaco-

kinetics of ACS with those of HES in 32 patients (ASA physical status I and II) undergoing elective surgery. In contrast to hydroxyethyl starch, this new agent undergoes rapid and nearly complete enzymatic degradation.

## 3. Carboxymethyl Starch

Claudius et al. (240) determined effects of sodium carboxymethyl starch (CMS) on the antimicrobial activity of vancomycin. In particular, the in vitro activity of vancomycin against two clinically relevant bacteria, *Staphylococcus aureus* and *Enterococcus faecalis*, was studied in the presence of varying concentrations of sodium CMS. From two independent studies conducted using an agar dilution method, it appeared that the binding of vancomycin to sodium carboxymethyl starch had no effect on the in vitro antimicrobial activity of vancomycin.

## IX. FUCAN SULFATES

Marine algal sulfated polysaccharides have been found to possess various pharmacological activities, i.e., antibacterial, antiviral, antitumor (241,242), immunosuppressive, antilipemic, antihemostatic, and anticoagulant (243). Fucan sulfates are a type of sulfated polysaccharide occurring in brown marine algae.

The anticoagulant activity of fucan sulfates (244) was mainly assayed by activated partial thromboplastin time, which expresses the intrinsic pathway of blood anticoagulation; prothrombin time, which explores the extrinsic pathway; thrombin clotting time; and reptilase clotting time methods (245). The anticoagulant components of brown, red, and green algae are found in fucan sulfates. They all comprise a family of polydisperse heteromolecules based on fucose, xylose, glucuronic acid, galactose, mannose, and half ester sulfate. They differ in sugar composition and sulfate content, and thus in structure (246–249).

The correlation between the sulfate and uronic acid contents and the anticoagulant activity of fucan sulfates was confirmed by a study on fucan sulfate from *Ecklenia kurume* (250). It has also been reported that fucoidans (pure fucans) from *F. vesiculosus* (251), *Eisenia bicyclis* (252), *Hizikia fusiforme* (253), *Laminaria angustata* (254), and *P. canaliculata* (255) showed antithrombin activity.

## X. LECTINS

Lectins are proteins or glycoproteins of nonimmune origin capable of binding to one or more specific sugar residues and mediating a variety of biological processes, such as cell–cell and host–pathogen interactions, serum glycopro-

tein, and innate immune responses. Currently, over 200 three-dimensional structures of lectins from plants, animals, bacteria, and viruses and their complexes are available (256–262).

Excellent recent reviews on the structure and interactions of lectins are available (263–272). Thus, lectins possess various specificities that are associated with their ability to interact with acetylamino-carbohydrates, amino-carbohydrates, sialic acid, hexoses, pentose, and many other carbohydrates (258,273). Lectins from plant sources were the first proteins of this class to be studied (274–277). Human foods of both plant and animal origin contain a variety of simple and complex carbohydrates as well as lectins. Both saccharides and lectins have the capacity to interfere with bacterial and viral attachment to epithelial cell surfaces within the alimentary canal, as has the major mucosal immunoglobulin, secretory IgA. It is well known that the lectin from jack fruits can bind to serum IgA1, but secretory IgA also possesses oligosaccharide receptors for bacterial lectins in fimbriae and can agglutinate *E. coli* by this antigen nonspecific mechanism (264).

Membrane lectins of certain cells are capable of internalization of their ligands, and hence glycoconjugates specifically recognized by these lectins can be used as carriers of metabolite inhibitors and drugs (278). Galactose-terminated glycoproteins and neoglycoproteins have been used to carry antiparasitic (279) and antiviral drugs (280,281).

The potential for using lectins as a means of “anchoring” a drug delivery system to the mucosal surfaces of the eye has been investigated (282). In this study the acute local dermal irritancy of these lectins, in terms of their potential to cause inflammation and tissue necrosis, was investigated. There was no evidence of tissue necrosis, edema, or Evans blue infiltration with any of the lectin solutions administered. The rabbits did not display any signs of discomfort such as scratching or continued grooming throughout the experiment. Histological examination of the injection sites revealed little sign of any inflammation, such as heterophil migration, edema, or tissue damage. It was concluded that these lectins demonstrate minimal acute irritancy, and will therefore be taken forward for formulation and in vivo studies.

## XI. HYALURONIC ACID, HYALURONAN, AND HYALURONAN DERIVATIVES

Hyaluronic acid (HA) is a natural mucopolysaccharide which consists of alternating residues of D-glucuronic acid and N-acetyl-D-glucosamine. Hyaluronic acid functions as the backbone of the proteoglycan aggregates necessary for the functional integrity of articulate cartilage of the knee.

Hyaluronan (sodium hyaluronate) and hyaluronan derivatives (hylans) have been developed as topical, injectable, and implantable vehicles for the controlled and localized delivery of biologically active molecules (283). Hyaluronan is the original lastoviscous, biocompatible polysaccharide developed for use in eye surgery and viscosurgery, orthopedic surgery, rheumatology, otology, plastic surgery, and veterinary medicine (284,285). Hyaluronic acid, either by itself or mixed with fibronectin, may be a potentially optimal bioimplant for the surgical management of vocal fold mucosal defects and lamina propria deficiencies (e.g., scarring) from a biomechanical standpoint (286).

Hyaluronic acid in the range of Mw 1300 kD may prove beneficial in minimizing bacterial contamination of surgical wounds when used in guided tissue regeneration surgery (287). The 1.0 mg/mL concentration of high molecular weight HA had the greatest overall bacteriostatic effect, inhibiting the growth of all six bacterial strains tested. Among the bacterial strains studied, HA was found to have no bactericidal effects, regardless of concentration or molecular weight.

An animal model study was conducted to compare the efficacy of recurrent topical applications of hyaluronic acid and gentamicin ointment for the treatment of noninfected, mechanical corneal erosions (288). Rabbit eyes treated with hyaluronic acid showed a significantly enhanced rate of epithelial defect closure compared with untreated eyes and a similar rate to that achieved with gentamicin ointment. In the eyes treated with hyaluronic acid a normal, multilayered epithelium was observed 48 h after complete healing, whereas the gentamicin-treated eyes showed an imperfectly layered epithelium, with irregularity of the cuboidal cells.

Through the esterification of the carboxyl group of the glucuronic acid moiety, polymeric prodrugs of hyaluronic acid have been prepared by several groups (289–291). Two drugs made up of HA derivatives have recently become available for patients in whom simple analgesics and conservative nonpharmacological therapy have failed. Leslie (292) reviews the epidemiology, pathogenesis, diagnosis, and medical management of osteoarthritis of the knee, with an emphasis on the physiologic and pharmacological mechanisms of HA. Health care providers may administer HA via intra-articular injection in primary care and rheumatologic or orthopedic settings or they may refer their patients to specialists for consultation.

Hyaluronic acid grafted with poly(ethylene glycol) (PEG) (PEG-g-HA) were synthesized. The materials characterization, enzymatic degradability, and peptide (insulin) release from solutions of the copolymers were examined (293). Insulin was preferentially partitioned into the PEG

phase in a PEG/HA solution system. Leakage of insulin from the copolymers was dependent upon the PEG content. Leakage rate of insulin from copolymer containing between 7 and 39% by weight of PEG were similar. The conformational change of insulin was effectively prevented in PEG-g-HA solutions, although insulin was denatured in storage of both phosphate buffered solution and HA solution. Such a heterogeneous-structured polymeric solution may be advantageous as an injectable therapeutic formulation for ophthalmic or arthritis treatment.

To increase the availability of sodium butyrate over a longer period of time. Coradini et al. (294) covalently linked isodium butyrate to HA (a component of the extracellular matrix). Its major advantages as a drug carrier consist of its high biocompatibility and its ability to bind CD44, a specific membrane receptor frequently overexpressed on the tumor cell surface (294). The biological activity of hyaluronic acid–butyric ester derivatives was evaluated in terms of the inhibition of the growth of the MCF7 cell line and compared with that of sodium butyrate. After 6 days of treatment, we observed a progressive improvement of the antiproliferative activity up to  $DS = 0.20$ ; thereafter, the antiproliferative effect of the ester derivatives decreased (294). Fluorescence microscopy showed that after 2 h of treatment fluorescein-labelled compounds appeared to be almost completely internalized into MCF7 cells, expressing CD44 standard and variant isoforms.

Two biomaterials based on hyaluronic acid modified by esterification of the carboxyl groups of the glucuronic acid (HYAFF 11 and ACP sponges) were tested as osteogenic or chondrogenic delivery vehicles for rabbit mesenchymal progenitor cells and compared with a well-characterized porous calcium phosphate ceramic delivery vehicle (295). The hyaluronic acid–based delivery vehicles are superior to porous calcium phosphate ceramic with respect to the number of cells loaded per unit volume of implant, and HYAFF 11 sponges are superior to the ceramics with regard to the amount of bone and cartilage formed. Additionally, hyaluronic acid–based vehicles have the advantage of degradation/resorption characteristics that allow complete replacement of the implant with newly formed tissue.

The tolerability and safety of hyaluronan-based three-dimensional scaffolds as a culture vehicle for mesenchymal progenitor cells was investigated (296). The proliferation patterns and extracellular matrix production of rabbit and human mesenchymal, bone marrow–derived progenitors first were characterized *in vitro*. Subsequently rabbit autologous cells were cultured in this hyaluronan-based scaffold and implanted in a full thickness osteochondral lesion. *In vitro* histologic findings showed that mesenchymal progenitor cells adhered and proliferated onto the hyaluronan-derived scaffold. *In vivo* data demonstrated

that the biomaterial, with or without mesenchymal progenitors, did not elicit any inflammatory response and was completely degraded within 4 months after implantation (296).

The new composite biomaterial made from hydroxyapatite and collagen conjugated with hyaluronic acid has been studied (297). The structure evaluation of the composite showed more dense arrangement due to the formation of collagen hyaluronic acid conjugate, and particles of inorganic component are closely anchored in the structure (297). The test of contact cytotoxicity showed a very good biocompatibility of the biomaterial.

The adsorption of glycosaminoglycans (heparin, heparan sulfate, dermatan sulfate, highly sulfated chondroitin sulfate, chondroitin sulfate, and hyaluronan) onto coral has been investigated (298). Granules of natural coral of specific diameter, between 100 and 500  $\mu\text{m}$ , having high content of calcium ( $>98\%$ ) and a homogeneous surface adsorb glycosaminoglycans with different capacity. Heparin (maximum adsorption  $1.29 \pm 0.10$  mg/20 mg of coral, 6.45% w/w) is adsorbed more than highly sulfated chondroitin sulfate species (maximum adsorption  $0.90 \pm 0.06$  mg/20 mg of coral, 4.50% w/w), chondroitin sulfate (maximum adsorption of  $0.72 \pm 0.06$  mg/20 mg of coral, 3.60% w/w), dermatan sulfate (maximum adsorption of  $0.70 \pm 0.06$  mg/20 mg of coral, 3.50% w/w), and heparan sulfate (maximum adsorption of  $0.72 \pm 0.07$  mg/20 mg of coral, 3.60% w/w) (298). Hyaluronan is not adsorbed onto granules of coral. The percentage adsorption of polyanions onto coral depends mainly on their charge density, with sulfate groups being more important than carboxyl groups. The adsorption of glycosaminoglycans is driven by electrostatic interactions with calcium sites of coral that are dependent on pH and blocked in the presence of large amounts of salt. Due to these peculiar properties, the combination of granules of natural coral with glycosaminoglycans makes this material potentially useful in osseointegration in bone metabolism or periodontal therapy (298).

Several biomaterials are available for the purpose of soft tissue augmentation, but none of them has all the properties of the ideal filler material. The recent development of HA gels for dermal implantation give the physician new possibilities of effective treatment in this field (299). Stabilized, nonanimal hyaluronic acid gel is well tolerated and effective in augmentation therapy of soft tissues of the face. This material presents several advantages in comparison to previously used injectable biomaterials and expands the arsenal of therapeutic tools in the field of soft tissue augmentation.

With the aim of producing a biomaterial for surgical applications, the alginate–hyaluronate association has been investigated (300). Crossed techniques were used to

assess the existence of polymer interactions in aqueous solutions up to 20 mg/mL.

## XII. ALGINATE

The alginates is a copolymer composed of D-mannuronic acid (M) and L-guluronic acid (G) arranged in MM and GG blocks interrupted by regions of more random distribution of M and G units. Due to the presence of carboxylate groups, alginate is a polyelectrolyte at neutral pH, with one charge per repeating unit in the coil conformation (301).

### A. Alginate Hydrogel

Interactions of alginate with univalent cations in solution have been investigated by circular dichroism (c.d.) (302) and rheological measurements. Poly-L-guluronate chain segments show substantial enhancement (approximately 50%) of c.d. ellipticity in the presence of excess of  $K^+$ , with smaller changes for other univalent cations:  $Li^+ < Na^+ < K^+ > Rb^+ > Cs^+ > NH_4^+$  (302). Pass and Hales (303) have investigated the effect of the cation on the enthalpy of dilution of alkali metal salts of alginate.

Calcium alginate has been one of the most extensively investigated biopolymers for binding heavy metals from dilute aqueous solutions (304–307). Alginate forms gels in the presence of divalent ions at concentration of  $>0.1\%$  w/w (308). The gels are not thermoreversible. The ratio of calcium to alginate over which thixotropic gels are formed depends on the alginate type, the pH, and the solids content of the system (309). Previous studies of alginate gelation by c.d. and other techniques (310–312) have shown that the primary event in network formation is dimerization of poly-L-guluronate chain sequences, in a regular 2(1) conformation (313,314) with specific chelation of  $Ca^{2+}$  ions between the participating chains (315).

For high M alginates (high D-mannuronic acid alginate), thixotropic gels exist at calcium levels that, in an alginate with a high proportion of L-guluronic acid blocks, would be holding the alginate chains in a permanent gel structure. Specific intermolecular cooperative interactions occur between calcium and glucuronate blocks owing to the buckled ribbon structure of the polyguluronic acid. This observation has led to the well-known proposal of “egg-box” junction zones (308,316).  $^{13}C$ -NMR spectroscopic studies have been made on alginate solutions undergoing sol–gel transition induced by four different divalent cations: Ca, Cu, Co, and Mn (317).

The rigid structure and large pore size of these gels are useful for the encapsulation of enzymes, proteins, drugs, liposomes, and living cells. Oral administration of calcium

alginate hydrogels without buffering of stomach acid may result in desegregation of the calcium alginate complex. Several antacids can buffer gastric fluid at pH 4.5, which is an appropriate pH for pancreatic buffering in the duodenum. An increase in enteric pH to 6.5 will occur in the ileum. Buffering of gastric fluid with antacids would be necessary in order to facilitate release of drugs from calcium alginate into small intestine—the most appropriate application of this system.

The sodium alginate from *Sarassum fulvellum* showed a considerable antitumor activity against various murine tumors, such as Sarcoma-180, Ehrlich ascites carcinoma and IMC carcinoma (318).

With the aim of producing a biomaterial for surgical applications, the alginate–hyaluronate association has been investigated (319). Crossed techniques were used to assess the existence of polymer interactions in aqueous solutions up to 20 mg/mL. Viscometry measurements using the capillary technique or the Couette flow, together with circular dichroism investigations, evidenced the moderate significance of interactions between the two polysaccharides in dilute solutions. In addition, the case of more concentrated solutions and containing 20 mg/mL alginate was approached by rheological measurements in the flow mode; the behavior of the polymer associations appeared as a compromise between those of individual polysaccharides (319).

### B. Alginate–Polyelectrolyte Complexation

Irreversible hydrogels are insoluble in water, as well as in other solvents, in a wide range of temperatures and dilutions. Due to their solubility profiles, irreversible hydrogels have found multiple applications as food additives, in cosmetics, in medicine, and in biotechnology (320–326).

The complexation of complementary polymers has been modeled theoretically (327,328). In this analysis the total free energy of complexation was divided into two contributions: one arising from the specific interactions between complexing functional groups and a second arising from configurational changes of the system upon complexation. Several authors have modeled the association of biological polymers (329–332).

The interactions of alginates of various compositions with basic polypeptides, namely, poly(L-lysine) and poly(Lys-Ala-Ala), have been studied by means of circular dichroism (333). The alginates used differ from each other in the content of L-guluronate and mixed sequences. The content of D-mannuronate sequences in all alginates is almost identical. The lower complexation efficiency with alginate II (MM 33%, GG 30%, MG 37%) than with alginate I (MM 30%, GG 20%, MG 50%) and the nearly zero effi-

ciency with alginate III (MM 33%, GG 47%, MG 20%) are due to the presence of considerable amounts of non-complexing L-guluronate sequences in the alginate structure (333). On the basis of the results of complexation achieved in this study (333), it may be suggested that the L-guluronan chain is more rigid, i.e., less adaptable to the changes in the surrounding medium than the D-galacturonan chain.

The influence of charge density of a polycation on complexation was studied with the sequentially regular poly(Lys-Ala-Ala), which is characterized by a charge density one-third that of poly(L-lysine) (333). Alginates interacted with poly(Lys-Ala-Ala) rather intensively. The difference in efficiency of interaction of L-guluronan and D-galacturonan with poly(L-lysine) results from the difference in the conformational flexibility of their polyanionic chains in solution. L-Guluronan maintains the rigid twofold symmetry in solution, and D-galacturonan is conformationally adaptable in the course of interaction.

Many of the present controlled-release devices for *in vivo* delivery of drugs involve elaborate preparations, often employing either harsh chemicals, such as organic solvent, or extreme conditions, such as elevated temperatures. These conditions have the potential to destroy the activity of sensitive macromolecule drugs, such as proteins or oligopeptides.

Drug delivery particulates were prepared using alginate, polylysine, and pectin. Theophylline, chlorothiazide, and indomethacin were used as the model drugs for *in vitro* assessments, and mannitol was the model for assessing paracellular drug absorption across Caco-2 cell monolayers. Alginate and pectin served as the core polymers, and polylysine helped to strengthen the particulates. Use of pectin specially helped in forming a more robust particulate that was more resistant in acidic pH and modulated the release profiles of the encapsulated model drugs in the alkaline pH. Alginate and pectin were also found to enhance the paracellular absorption of mannitol across Caco-2 cell monolayers by about three times. The release rate could be described as a first-order or square-root time process depending on the drug load. Use of alginate-polylysine-pectin particulates is expected to combine the advantages of bioadhesion, absorption enhancement, and sustained release. This particulate system may have potential use as a carrier for drugs that are poorly absorbed after oral administration (334).

The polyionic complex based on alginate were used to include the animal cells (335). Microencapsulation of islets of Langerhans in alginate-poly(L-lysine) capsules provides an effective protection against cell-mediated immune destruction, and ideally should allow the transplanta-

tion of islets in the absence of immunosuppression. It has previously been suggested that alginate rich in mannuronic acid (high M) is more immunogenic than alginate rich in guluronic acid (high G). The ability of these alginates to induce an antibody response in the recipient or act as an adjuvant to antibody responses against antigens leaked from the capsule was investigated (335). High G-alginate capsules are less immunogenic than high M capsules. Because encapsulation did not protect against the generation of antibodies against islet-like cell clusters (ICC), it can be assumed that antigen leakage from the capsules occurs, as no evidence was found for capsules breaking *in vivo*.

Alginate and proteins were also used in polyionic complexation (336). Freshly prepared gels of gelatine with alginate or pectate below the isoelectric point of gelatine (e.g., at pH 3.9) melt over the same temperature range as gelatine (30–40°C), but on aging they become thermostable (336). The gels are also stable in 7M urea, arguing against hydrogen bonding or hydrophobic interactions, but the enhanced thermal stability can be eliminated by high salt (e.g., 0.3M NaCl) or by raising the pH to above the isoelectric point of gelatine, as expected for an ionic network (336).

A systematic study of the alginate-polycation microencapsulation process, as applied to encapsulation of bioactive macromolecules such as protein, was conducted by Wheatly et al. (337). When protein drugs (myoglobin) were suspended in sodium alginate solution and sprayed into buffered calcium chloride solution to form crosslinked microcapsules. The drug-loaded capsules were coated with a final layer of poly(L-lysine).

### C. Calcium Alginate as a Matrix for Delivery of Nucleic Acids

Advances in the design of genetically targeted agents offer new opportunities for drug therapy (338–340). Accordingly, the encapsulation of DNA and its derivatives may be useful for enteric targeting of nucleic acids as gene transfer agents, carriers for DNA intercalaters, and modified oligonucleotides (341).

The biodegradable microspheres based on sodium alginate were used to encapsulate plasmid DNA containing the bacterial  $\beta$ -galactosidase (LacZ) gene under the control of either the cytomegalovirus (CMV) immediate-early promoter or the Rous sarcoma virus (RSV) early promoter. Mice inoculated orally with microspheres containing plasmid DNA expressed LacZ in the intestine, spleen, and liver. Inoculation of mice with microspheres containing both the plasmid DNA and bovine adenovirus type 3 (BA3) resulted in a significant increase in LacZ expres-

sion compared to those inoculated with microspheres containing only the plasmid DNA. Our results suggest that adenoviruses are capable of augmenting transgene expression by plasmid DNA both *in vitro* and *in vivo* (342).

Chitosan and poly(L-lysine) membranes, coating alginate beads, were almost totally inert to the enzymatic hydrolysis by lysozyme; chitosanase; and trypsin, chymotrypsin, or proteinase (343). Less than 2% of the membrane weight was hydrolyzed. It appears that either membrane material would be stable for *in vivo* application, and in particular in the protection of DNA during gastrointestinal transit. At chitosanase concentrations of 1.4 mg/mL and in the presence of sodium ions, 20% of the total double-stranded DNA was released from chitosan coated beads. An exchange of calcium for sodium within the bead liquefied the alginate core releasing DNA. The presence of calcium stabilized the alginate bead, retaining all the DNA. Highly pure DNA was recovered from beads through mechanical membrane disruption, core liquefaction in citrate, and use of DNA spin columns to separate DNA/alginate mixtures in a citrate buffer. DNA recovery efficiencies as high as 94% were achieved when the initial alginate/DNA weight ratio was 1000 (343).

Alginate gels produced by an external or internal gelation technique were studied so as to determine the optimal bead matrix within which DNA can be immobilized for *in vivo* application. The encapsulation yield of double-stranded DNA was over 97 and 80%, respectively, for beads formed using external and internal calcium gelation methods, regardless of the composition of alginate. Homogeneous gels formed by internal gelation absorbed half as much DNase as compared with heterogeneous gels formed by external gelation. Testing of bead weight changes during formation, storage, and simulated gastrointestinal (GI) conditions (pH 1.2 and 7.0) showed that high alginate concentration, high G content, and homogeneous gels (internal gelation) result in the lowest bead shrinkage and alginate leakage. These characteristics appear best suited for stabilizing DNA during GI transit (344).

Co-guanidine membranes were shown to form intact, ionically complexed membranes on alginate beads, serving as an alternative to the commonly used polymers, poly(L-lysine) and chitosan. DNA was encapsulated (345). The level of DNA protection from nuclease diffusion and the degree of DNA complexation with co-guanidine membranes were all shown to be dependent on both polymer concentration and coating time. The highest level of DNase exclusion was possible within beads coated with a polymer concentration of 5 mg/mL. Recovery of double-stranded DNA after nuclease exposure for 60 min reached 90% of that initially encapsulated. The level of DNA pro-

tection was found to be comparable to high molecular weight poly(L-lysine) membranes (197.1 kDa) (345). Co-guanidine membranes coating alginate result in a molecular weight cutoff sufficient to retain DNA and exclude 31-kDa DNase, while providing access to the low molecular weight carcinogen, ethidium bromide.

Somatic gene therapy using nonautologous recombinant cells immunologically protected with alginate microcapsules has been successfully used to treat rodent genetic diseases. Ross et al. (346) have reported the delivery of recombinant gene products to the brain in rodents by implanting microencapsulated cells for the purpose of eventually treating neurodegenerative diseases with this technology. Alginate–poly(L-lysine)–alginate microcapsules enclosing mouse C2C12 myoblasts expressing the marker gene human growth hormone (hGH) at  $95 \pm 20$  ng per million cells per hour were implanted into the right lateral ventricles of mice under stereotaxic guidance. Control mice were implanted similarly with nontransfected but encapsulated cells. Delivery of hGH to the different regions of the brain at various times postimplantation was examined. At 7, 28, 56, and 112 days postimplantation, hGH was detected at high levels around the implantation site and also at lower levels in the surrounding regions, while control mice showed no signal. Immunohistochemical staining of the implanted brains showed that on days 7, 56, and 112 postimplantation, hGH was localized in the tissues around the implantation site.

#### D. Calcium Alginate as Microparticles for Drug and Drug Proteins Delivery Systems

Present and future applications of alginates are mainly linked to the most striking feature of the alginate molecule, i.e., a sol–gel transition in the presence of multivalent cations, e.g.,  $\text{Ca}^{2+}$ . The properties of alginate gels suggest biomedical and pharmaceutical uses. Calcium alginate has been extensively studied and employed in a number of pharmaceutical applications (347,348), especially in controlled drug release (349). For many drug candidates a modified *in vivo* drug release is desired to improve efficacy, sustain effect, or minimize toxicity. Polymeric delivery systems, such as microspheres, nanospheres, and polymeric films, have been extensively researched in an attempt to achieve modified drug release (350). Calcium alginate offer an alternative approach.

The release rate of nifedipine HCl from various alginate microparticles was investigated (351,352). The effect of drug/polymer weight ratio,  $\text{CaCl}_2$  concentration, and curing time on parameters such as the time for 50% of the drug to be released ( $t_{50\%}$ ) and the drug entrapment

efficiency were evaluated with analysis of variance. The release of drug from alginate microparticles took place by both diffusion through the swollen matrix and relaxation of the polymer at pH 1.2–4.5. However, the release was due to diffusion and erosion mechanisms at pH 7–7.5.

Pellets of calcium–alginate, calcium–pectinate, and calcium–alginate–pectinate were produced via crosslinking in an aqueous medium for site-specific drug delivery in the gastrointestinal tract (353). In general, texture analysis of various pellets indicated that both strength and resilience profiles were in the order of calcium–alginate  $\geq$  calcium–alginate–pectinate  $>$  calcium–pectinate. Calcium–alginate pellets were found to be viscoelastic, while calcium–pectinate was highly brittle.

Alginate gel beads containing tiaramide (TAM) were prepared (354) using a gelation of alginate with calcium cations. Bead performance was evaluated *in vitro* for different dissolution media, and beads were also subjected to coating. Tiaramide release was dependent both on its solubility in dissolution medium and the guluronate residue content of the alginate used. The release rate was in the following order: in pH 1.2  $>$  pH 6.8  $>$  water. The fast release rate in pH 1.2 is the result of the high solubility of TAM in acidic medium (354). Beads with high guluronate content gave the best controlled results.

Calcium-induced alginate gel beads containing chitosan salt (Alg-CS) were prepared using nicotinic acid (NA), a drug for hyperlipidemia, and investigated its two functions in gastrointestinal tract: (1) NA release from Alg-CS and (2) uptake of bile acids into Alg-CS. The amount of NA incorporated in Alg-CS increased according to increment of CS content. Nicotinic acid was rapidly released from Alg-CS in diluted HCl solution (pH 1.2) or physiological saline without disintegration of the beads. When Alg-CS was placed in bile acid solution it took bile acid into itself. About 80% of taurocholic acid dissolved in the medium was taken into Alg-CS. According to increment of bile acid concentration the uptake amount increased, and an approximately linear relationship existed among them (355).

Calcium alginate beads containing ampicillin were prepared (356). Morphological studies and drug contents, *in vitro* release, and erosion tests were carried out for the characterization of the prepared beads. The dried particles were characterized by irregular shape and a smooth or rough surface, depending on the viscosity grade of the alginate used. The control of the drug for different time intervals depended on the molecular weight of the polymer used; however, the pH change test showed that this capacity was much lower in the case of acid-treated particles. The results obtained show that the ampicillin beads prepared are suitable for intramammary therapy.

Ionotropic gelation by divalent metal interaction was employed of indomethacin–sodium alginate dispersion with calcium ions to induce the spontaneous formation of indomethacin–calcium alginate gel discs (357). A three-phase approach was developed to establish the critical curing parameters. Since curing involved crosslinking of the sodium alginate with calcium ions, an optimal concentration of calcium chloride (phase one) and crosslinking reaction time (phase two) had to be determined. Furthermore, the third phase involved the optimization of the air drying time of the gel discs. In phases one and two, stabilization of *in vitro* drug release characteristics was used as the marker of optimal crosslinking efficiency. Phase three was based on achieving fully dried gel discs by drying to constant weight at 21°C under an extractor. The study revealed that optimal crosslinking efficiency was achieved in 1% w/v calcium chloride solution for 24 h and air dried at 21°C under an extractor for 48 h (357).

Growth and progression of malignant brain tumors occurs in a micromilieu consisting of both tumor and normal cells. Several proteins have been identified with the potential of interfering directly with tumor cells or with the neovascularization process, thereby inhibiting tumor growth. A continuous delivery of such inhibitory proteins to the tumor microenvironment by genetically engineered cells could theoretically be of considerable therapeutic importance. Read et al. (358) have investigated the growth characteristics of cells encapsulated in alginate, which represents a potential delivery system for recombinant proteins that may have antitumor effects. Three different cell lines, NHI 3T3, 293, and BT4C, were encapsulated in alginate, which is an immunisolating substance extracted from brown seaweed. Morphological studies showed that encapsulated cells proliferated and formed spheroids within the alginate in the *in vitro* cultures and after implantation into the brain. Even after 4 months *in vivo* a substantial amount of living cells were observed within the alginate beads. A vigorous infiltration of mononuclear cells was observed in the brain bordering the alginate beads 1 week after implantation (358).

The insecticide/nematicide carbofuran was incorporated in alginate-based granules to obtain controlled release (CR) properties (359). The basic formulation (sodium alginate 1.61%, carbofuran 0.59%, water) was modified by addition of sorbents. The effect on carbofuran release rate, caused by the incorporation of natural and acid-treated bentonite in alginate formulation, was studied by immersion of the granules in water under shaking (359). The use of alginate-based CR formulations resulted in a reduction of the leached amount of carbofuran compared with the total amount of pesticide leached using the technical product (50 and 75% for CR granules containing natu-

ral and acid-treated bentonite, respectively). Alginate–bentonite CR formulations might be efficient systems for reducing carbofuran leaching in clay soils, which would reduce the risk of groundwater pollution.

### E. Calcium Alginate Wound Dressing

It is commonly accepted that the ideal wound covering should mimic many properties of human skin. It should be adhesive, elastic, durable, impermeable to bacteria, and occlusive. Alginates are highly absorbent, gel-forming materials with hemostatic properties, and it has long been known that more rapid wound healing occurs when a gel is formed at the wound surface and dehydration is prevented (306). Because of the biocompatibility, exudate absorbability, and film-forming properties of calcium alginate product, they are good candidates for burn and wound management uses.

Ueng et al. (360) investigated the calcium alginate dressing as a drug delivery system for the treatment of various surgical infections. Cytotoxicity of the calcium alginate dressing to fibroblasts and HeLa cells was evaluated by the 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2H tetrazolium bromide colorimetric assay. The calcium alginate dressing was mixed with vancomycin, and lyophilized or not lyophilized to form two types of antibiotic dressings. The results suggested that the antibiotic dressings present no obvious toxic risk to their use as a drug delivery system. All antibiotic dressings released bactericidal concentrations of the antibiotics in vitro for the period of time needed to treat surgical infections. This study offers a convenient method to meet the specific antibiotic requirement for different infections.

The healing of cutaneous ulcers requires the development of a vascularized granular tissue bed, filling of large tissue defects by dermal regeneration, and the restoration of a continuous epidermal keratinocyte layer. These processes were modelled in vitro in the present study, utilizing human dermal fibroblast, microvascular endothelial cell (HMEC), and keratinocyte cultures to examine the effect of calcium alginate on the proliferation and motility of these cultures, and the formation of capillarylike structures by HMEC (361). This study demonstrates that the calcium alginate tested increased the proliferation of fibroblasts but decreased the proliferation of HMEC and keratinocytes. In contrast, the calcium alginate decreased fibroblast motility but had no effect on keratinocyte motility. There was no significant effect of calcium alginate on the formation of capillarylike structures by HMEC. The effects of calcium alginate on cell proliferation and migration may have been mediated by released calcium ions. These results suggest

that the calcium alginate tested may improve some cellular aspects of normal wound healing but not others (361).

Drug-impregnated polyelectrolyte complex (PEC) sponge composed of chitosan and sodium alginate was prepared for wound dressing application (362). Equilibrium water content and release of silver sulfadiazine (AgSD) could be controlled by the number of repeated in situ PEC reactions between chitosan and sodium alginate. The release of AgSD from AgSD-impregnated PEC wound dressing in PBS buffer (pH = 7.4) was dependent on the number of repeated in situ complex formations for the wound dressing (362). In vivo tests showed that granulation tissue formation and wound contraction for the AgSD plus dihydroepiandrosterone (DHEA)–impregnated PEC wound dressing were faster than any other groups.

Control of hemorrhage during excision and grafting is difficult and postoperative hematoma may reduce graft take. Kneafsey et al. (363) have found calcium alginate dressings can be of immense help in minimizing these technical problems. Calcium alginate dressings following hemorrhoidectomy effectively reduce postoperative pain compared to more bulky anal packs (364).

A prospective controlled trial was carried out to assess the healing efficacy of calcium alginate and paraffin gauze on split skin graft donor sites (365). Calcium alginate dressings provide a significant improvement in healing split skin graft donor sites.

### F. Calcium Alginate as Tissue Engineering

New cartilage formation has been successfully achieved by technology referred to as tissue engineering. Recent advances in tissue engineering permit us to focus on production of larger amounts of cartilaginous tissue, such as might be needed for reconstructive surgery of the entire auricle.

Polymers and hydrogels such as poly(glycolic acid), calcium alginate, and poly(ethylene) and poly(propylene) hydrogels have been used as cell carriers to regenerate cartilage in the nude mouse model. This study compared the suitability of three polymers for generating tissue engineered elastic cartilage using autologous cells in an immunocompetent porcine animal model (366). When using pluronics as scaffold, histologic features resemble those of native elastic cartilage, showing a more organized arrangement of the cells, which seems to correlate to functional properties as elastin presence in the tissue.

Transplantation of isolated chondrocytes has long been acknowledged as a potential method for rebuilding small defects in damaged or deformed cartilages. Chalain et al. (367) describe modification of the basic techniques that lead to production of a large amount of elastic cartilage

originated from porcine and human isolated chondrocytes. Small fragments of auricular cartilage were harvested from children undergoing ear reconstruction for microtia or excision of preauricular tags and from ears of juvenile pigs. Enzymatically isolated elastic chondrocytes were then agitated in suspension to form the chondronlike aggregates, which were further embedded in molded hydrogel constructs made of alginate and type I collagen augmented with  $\kappa$ -elastin. The constructs were then implanted in nude mice and harvested 4 and 12 weeks after heterotransplantation. The resulting neocartilage closely resembled native auricular cartilage at the gross, microscopic, and ultrastructural levels (367).

In vitro multiplication of isolated autologous chondrocytes is required to obtain an adequate number of cells to generate neocartilage, but is known to induce cell dedifferentiation. Marijnissen et al. (368) and Demoor-Fossard et al. (369) investigated whether multiplied chondrocytes can be used to generate neocartilage in vivo. Adult bovine articular chondrocytes were suspended in alginate at densities of 10 or 50 million/mL, or after multiplication in monolayer for one (P1) or three passages (P3). Alginate with cells was seeded in demineralized bovine bone matrix (DBM) or a fleece of polylactic/polyglycolic acid (E210) and implanted in nude mice for 8 weeks. The newly formed tissue was evaluated. Structural homogeneity of the tissue, composed of freshly isolated as well as serially passaged cells, was found to be enhanced by high-density seeding (50 million/mL) and the use of E210 as a carrier. The percentage of collagen type II, positive-staining P3 cells was generally higher when E210 was used as a carrier. Furthermore, seeding P3 chondrocytes at the higher density (50 million/mL) enhanced collagen type II expression.

Chondrocytes from 21-day-old rat fetal nasal cartilage were cultured in alginate beads for up to 20 days (370). It was found that chondrocytes retained their spherical shape and typical chondrocytic appearance. During the culture time, chondrocytes underwent differentiation, as demonstrated by the alkaline phosphatase-specific activity and rate of proteoglycan synthesis. Morphological data confirmed chondrocyte differentiation with the appearance of hypertrophic chondrocytes scattered in the alginate gel and a dense extracellular matrix containing filamentous structures and matrix vesicles (370). These results indicate that the alginate system represents a relevant model for studies of chondrogenesis and endochondral ossification. Furthermore, the encapsulation method could prove useful for studies of tissue-biomaterial interactions in an in vitro environment which more closely mirrors the cartilage matrix than other culture methods.

A potential approach to facilitate the performance of implanted hepatocytes is to enable their aggregation and

re-expression of their differentiated function prior to implantation. Glicklis et al. (371) have examined the behavior of freshly isolated rat adult hepatocytes seeded within a novel three-dimensional (3-D) scaffold based on alginate. The attractive features of this scaffold include a highly porous structure (spongelike) with interconnecting pores, and pore sizes with diameters of 100–150  $\mu\text{m}$ . Due to their hydrophilic nature, seeding hepatocytes onto the alginate sponges was efficient. DNA measurements showed that the total cell number within the sponges did not change over 2 weeks, indicating that hepatocytes do not proliferate under these culture conditions. More than 90% of the seeded cells participated in the aggregation; the high efficiency is attributed to the nonadherent nature of alginate. The 3-D arrangement of hepatocytes within the alginate sponges promoted their functional expression; within a week the cells secreted the maximal albumin secretion rate of 60 microg albumin/10(6) cells/day (371).

Tissue engineering, a field that combines polymer scaffolds with isolated cell populations to create new tissue, may be applied to soft tissue augmentation—an area in which polymers and cell populations have been injected independently. Marler et al. (372) have developed an inbred rat model in which the subcutaneous injection of a hydrogel, a form of polymer, under vacuum permits direct comparison of different materials in terms of both histologic behavior and their ability to maintain the specific shape and volume of a construct. Using this model, three forms of calcium alginate, (a synthetic hydrogel) were compared over an 8-week period: a standard alginate that was gelled following injection into animals (alginate postgel); a standard alginate that was gelled before injection into animals (alginate pregel); and alginate-RGD, to which the cell adhesion tripeptide RGD was linked covalently (RGD postgel). Parallel groups that included cultured syngeneic fibroblasts suspended within each of these three gels were also evaluated (alginate postgel plus cells, alginate pregel plus cells, and RGD postgel plus cells). Histologically, the gel remained a uniform sheet surrounded by a fibrous capsule in the alginate postgel groups. In the alginate pregel and RGD postgel groups, there was significant ingrowth of a fibrovascular stroma into the gel with fragmentation of the construct. In constructs in which syngeneic fibroblasts were included, cells were visualized throughout the gel but did not extend processes or appear to contribute to new tissue formation. Material compression testing indicated that the alginate and RGD postgel constructs became stiffer over a 12-week period, particularly in the cell-containing groups (372).

Bone morphogenetic proteins (BMPs) are unique molecules with a specific biological activity for inducing ectopic bone formation when implanted with a suitable carrier matrix. A novel BMP-2-derived oligopeptide,

NSVNSKIPKACCVPTLSAI, was coupled covalently to alginate. Then NSVNSKIPKACCVPTLSAI-linked alginate hydrogel composites were implanted into the calf muscle of rats and harvested 3 or 8 weeks after surgery. Ectopic bone formation was observed in alginate hydrogel linked with BMP-2-derived peptide. It is suggested that alginate hydrogel linked with an oligopeptide derived from BMP-2 might provide an alternative system for topical delivery of the morphogenetic signal of BMP-2 (373).

Alginate membrane was proposed as a self-setting barrier membrane that can be used for guided tissue regeneration. The alginate membrane can be prepared and placed at the bone defect during the surgical procedure. The procedure consists of two simple steps. First, the bone defect is filled with sodium alginate (Na-Alg) aqueous solution. Then calcium chloride aqueous solution is dropped on the surface of the Na-Alg aqueous solution. An alginate membrane is formed on the bone defect, keeping the inside of the bone defect filled with unreacted Na-Alg aqueous solution (374).

Many materials have been used for artificial tubular prostheses to assist peripheral nerve gap reconstruction. However, the clinical use of these devices has been restricted because a microsurgical procedure requires specialized techniques and expensive equipment, such as operating microscope systems. Therefore Suzuki et al., (375) developed a new gluing method, without sutures, that uses freeze-dried alginate gel. A 7-mm gap in the sciatic nerve of rats was bridged with freeze-dried alginate gel. Regeneration was evaluated by electrophysiologic testing and histologic study. Eighteen weeks after surgery, functional reinnervation of motor and sensory nerves had occurred, as demonstrated by recovery of compound muscle action potentials (CMAPs), compound nerve action potentials (CNAPs), and somatosensory-evoked potentials (SEPs). Histologically, many regenerated nerve fasciculi, including myelinated and unmyelinated fibers, were observed and the implanted alginate gel had disappeared. In conclusion, a gluing technique using alginate gel is a potential alternative to the conventional nerve autograph technique. Advantages include simple application and rapid repair. Freeze-dried alginate gel is a promising material for artificial nerve guides for peripheral nerves and also could be used for repair of disrupted pathways in central nervous tissue that is amorphous and cannot be sutured (375).

### XIII. XANTHAN GUM

Xanthan gum is a widely used thickening agent in foods and is a recent addition to the hydrophilic matrix carrier list (376). The primary structure is a (1 → 4)-linked β-D-glucan backbone (cellulose) substituted through position 3

on alternate glucose residues with a charged trisaccharide side chain (377). Xanthans secondary structure has been studied by x-ray fiber diffraction (378) and analyzed by molecular modeling (379). Addition of the side chain causes the backbone to change from a twofold ribbonlike cellulose conformation to a fivefold helix (380–383). A single helix stabilized by backbone–sidechain bonding has been proposed, but double helical models cannot be excluded (378,379).

The majority of studies of xanthan in the literature have been “molecular,” including optical rotation, NMR, DSC, and circular dichroism (381–385), but the interpretation of some of these have been complicated by the nature of the macromolecule. The order–disorder transition has first order kinetics, is fully reversible, and shows no thermal hysteresis. From this evidence Morris et al. (380) suggested a single helix stabilized intramolecularly by ordered packing of side chains along the polymer backbone.

#### A. Xanthan Gels

A number of polysaccharides interact with galactomannans resulting in synergistic viscosity increases or gel formation, which have been extensively investigated by Dea et al. (386,387) and other groups (388–398). Synergistic interactions of polysaccharides in binary mixtures have often been considered to be synonymous with intermolecular binding of the two polysaccharides. The synergisms between plant galactomannans (carob, tara, or enzymatically modified guar gum) and xanthan or certain algal polysaccharides (κ-carrageenan, furcellaran, or agarose) have been attributed to intermolecular binding of the backbone of the galactomannan and the helix of the order polysaccharide (386,390). The evidence for this and for similar (388,389) well-accepted such intermolecular models. The structural similarity of galacturonic acid and glucuronic acid blocks favors the formation networks between pectin and alginate (387). The crosslinking of cellulose fibrils by galactomannans has indeed been demonstrated by electron microscopy (391). Cairns et al. (392,393) have proposed a different model for the gelation of xanthan and galactomannans, based on x-ray fiber diffraction studies on stretched gels. Mixed junction zones were formed by interaction between the xanthan and galactomannan backbones, with the relative positions of xanthan side chains on either side of a sandwiched galactomannan molecule being staggered. The x-ray results indicate a repeat distance of 0.52 nm (393). Xanthan is widely used in foodstuffs in the form of synergistic gels with gluco- and galactomannans (394); these two types of polysaccharide per se and xanthan alone will not form gels, whereas mixtures of xanthan with either of the plant polysaccharides, when heated and allowed to cool, form thermoreversible gels (395,396).

The influence of the galactomannan characteristic ratios (M/G) on the temperature of gelation (T<sub>g</sub>) and the gel strength of mixtures of galactomannan with xanthan is reported (397). Two galactomannans were investigated: one highly substituted from the seeds of *Mimosa scabrella* (M/G = 11) and the other, less substituted, from the endosperm of *Schizolobium parahybae* (M/G = 30). The xanthan/galactomannan systems (4:2 g l<sup>-1</sup>), in 5 mM NaCl showed a T<sub>g</sub> of 24°C for that of *S. parahybae* (398) and 20°C for the galactomannan of *M. scabrella*, determined by viscoelastic measurements and microcalorimetry. A T<sub>g</sub> of 40–50°C was found by Shatwell et al. (399) for locust bean gum (LBG) (M/G = 43). Lundin and Hermansson (400) reported a difference of 13°C T<sub>g</sub> of two LBG samples, with M/G = 3 (40°C) and 5 (53°C), in mixtures with xanthan. It appears that the more substituted galactomannans have lower temperatures of gelation in the presence of xanthan. The mechanism of gelation depends also on the M/G ratio. For the lower values it involves only disordered xanthan chains in contrast to M/G ratios higher than 3. In addition, the presence of the galactomannan from *M. scabrella* increased slightly the temperature of the conformational change (T<sub>m</sub>) of xanthan, probably due to the ionic strength contribution of proteins (3.9%) present in the galactomannan. On the other hand, the galactomannans from *S. parahybae*, with 1.5% of proteins, and *M. scabrella*, with 2.4% of protein, did not show this effect, the T<sub>m</sub> of xanthan alone or in a mixture being practically unchanged (397).

Examples of current or potential applications of xanthan in pharmaceuticals (401,402) or biomedical uses are as excipients in tablets or clear blood fluid substitutes. The function of xanthan in tablets is similar to other polysaccharides used in the same way, namely, to erode or dissolve slowly and thereby yield a delayed release of active ingredients compared to formulations not containing hydrocolloids. Recently reported is that xanthan used in tablets yields a comparable kinetics in the release of drugs to those of formulations containing N-CMC or carrageenan (403).

Oral candidiasis frequently occurs in individuals with dry mouth syndrome (xerostomia), in immunocompromised patients, and in denture wearers. Russien et al. (401) developed a formulation which will prolong the retention time of antimicrobial agents at the site of application. The activity against *Candida albicans* of a synthetic cationic peptide dhvar 1, based on the human fungicidal salivary peptide histatin 5, was tested in a mixture with the bioadhesive. Coupling caused a reduction of the viscosity and elasticity of the xanthan solution related to the applied concentration of the coupling agent. Incubation of the peptide with clarified human whole saliva resulted in proteolytic degradation of the peptide. In the presence of xanthan the

degradation occurred more slowly. It was concluded that xanthan is an appropriate vehicle for antimicrobial peptides in a retention-increasing formulation.

#### XIV. PECTIN

Pectin is a general term for a group of natural polymers that occur as structural materials in all land-growing plants. Polymerized galacturonic acid partially esterified with methanol accounts for the major part of any commercial pectin. Commercial pectins are divided into low-ester pectin and high-ester pectins. Pectin is not degraded by enzymes secreted in the upper gastrointestinal tract and passes intact through the small intestine. Pectin has been used as fiber source in numerous studies of the effects on gastric emptying, gastric ulcer, glucose and insulin level, bile acid binding, gallstone, binding of divalent and trivalent cations, influence on the enzymatic activity of the upper digestive tract, lowering serum cholesterol level, healing intestinal wounds, colon cancer, colonic cell proliferation, and as source of volatile fatty acids in the colon (404–409). Pectin influences the viscosity of the meal, and its short-term effect on the rate of gastric emptying may be explained in this way. A sustained effect of pectin consumption in the studies by Schwartz et al. (410), however, cannot be explained by increased viscosity of the stomach content. Apparently, pectin delays absorption of glucose in two ways: by delaying gastric emptying and by increasing the intestinal barrier layer (407).

Kohen et al. (411) demonstrated a protective effect of pectin against oxidative damages of the jejunal mucosa in rats. Protection against radicals is important because the mucosa is exposed to oxidative stress from the diet.

The antidiarrhea effect of pectin (in the form of dried citrus peels or waste from potato starch manufacturing) in cattle is enhanced by mixing with lecithin from soy oil refining. The positive effect of lecithin supplementation is explained by increased adhesion of pathogenic bacteria to the pectin–lecithin complex (412).

The pectin-based raft-forming antireflux agent Aflurax (Idoflux) was examined, first regarding reduction of esophageal acid exposure and also as to its efficacy as maintenance treatment in patients with healed esophagitis (413). The median (interquartile range) acid exposure times in the upright position were 3.1% (1.6–13.0%) on Aflurax versus 6.7% (2.5–14.9%) on placebo (p = 0.10). In the supine position no difference was found (Aflurax 13.7%, placebo 13.2%). The time to recurrence of heartburn with Aflurax treatment was prolonged significantly; after 6 months the life table estimates were 48% of patients in remission on Aflurax versus 8% on placebo (p = 0.01).

Following treatment, erosive esophagitis was found in 17/34 on Aflurax versus 28/38 on placebo ( $p < 0.05$ ). Aflurax significantly delays recurrence of moderate or severe heartburn and erosive esophagitis, when used as maintenance treatment. The acid exposure was not significantly reduced with pH monitoring (413).

Lowering the serum cholesterol level is, without doubt, the most studied physiological effect of pectin and other soluble dietary fibers. Numerous studies in hypercholesterolemic and normolipidemic humans, rats, and other experimental animals have proven the serum cholesterol lowering effect of pectin (404–408,414–417). The conclusion from the last 25 years' studies is that a pectin dosage of 10–15 g/day leads to a decrease in the serum cholesterol level of 10%.

The dietary effect of the water-soluble dietary fibers (WSDF) guar gum, partially hydrolyzed guar gum (PHGG), glucomannan, and highly methoxylated (HM) pectin on the serum lipid level and immunoglobulin (Ig) production of Sprague–Dawley rats was compared with that of water-insoluble cellulose (418). Although serum total cholesterol and triglyceride levels were significantly lower in the rats fed with WSDF than in those fed with cellulose, a decrease in the level of phospholipids was only observed in the rats that had been fed on guar gum or glucomannan. In addition, all WSDF feeding enhanced IgA productivity in the spleen and mesenteric lymph node lymphocytes, although the increase in serum IgA level was only observed in the rats fed on WSDF, and not on PHGG. When mesenteric lymph node lymphocytes were cultured in the presence of various concentrations of guar gum or glucomannan, no significant increase in Ig production was apparent. These data suggest that WSDF indirectly enhanced the Ig production of lymphocytes, and that serum lipid reduction and IgA production–enhancing activities of WSDF were dependent on their molecular sizes (418).

Experimental hypercholesterolemia and its modulation by some natural dietary supplements (pectin, garlic, and ginseng) and by the drug gemfibrozil were studied (419). Results of the study demonstrated that feeding the cholesterol-enriched diet caused a significant increase in total, LDL, and HDL cholesterol; plasma MDA and post-heparin total; and hepatic lipase activities. On the other hand, serum Tg and erythrocyte superoxide dismutase were not changed. Histopathological examination revealed marked alteration in the aortic wall with the appearance of large multiple atheromatous plaques. Both garlic and pectin were successful in a significant reduction of the hypercholesterolemia in a way comparable to gemfibrozil. Garlic was the only treatment that has antilipid peroxidative property (419).

To investigate the effects of pectin on cholesterol metabolism, normal rats were fed for 3 weeks a diet con-

taining 2.5 or 5% apple or orange pectin or without pectin (control) (420). Cholesterol concentrations were determined in feces after 1, 2, and 3 weeks of treatment, and in liver and serum at the end of the experimental trials. Cholesterol concentration in feces showed a significant increase by week 3 in rats fed 5% orange or apple pectin. Hepatic cholesterol concentration declined significantly in all pectin-fed groups. Serum cholesterol only declined significantly in apple-fed groups. The decrease of cholesterol levels in liver and serum and its increase in feces could explain the beneficial effect of including these fibers in the diet to prevent some currently very frequent diseases (420).

Because a high daily consumption of polysaccharide-containing food is assessed to decrease the risk of cancer of the gastrointestinal system, different types of carbohydrates were investigated for their antimutagenic activity against different standard mutagens. Within the screening pronounced antimutagenic effects were found for xyloglucan and different pectins and pectinlike rhamnolacturonans against 1-nitropyrene–induced mutagenicity. Inhibition rates were dose-dependent and varied between 20 and 50%. Concerning the mode of action, a direct interaction of the polymers with the cells is claimed, protecting the organisms from the mutagenic attack (421).

Anticarcinogenic and tumor growth–inhibiting effects of nonsoluble fibers have been described (422). In a preliminary study on methylnitrosourea-induced mammary carcinogenesis in female Sprague–Dawley rats, 15% oligofructose added to the basal diet modulated this carcinogenesis in a negative manner (423). There was a lower number of tumor-bearing rats and a lower total number of mammary tumors in oligofructose-fed rats than in the group fed the basal diet alone.

The effect of dietary nondigestible carbohydrates (15% oligofructose, inulin, or pectin incorporated into the basal diet) on the growth of intramuscularly transplanted mouse tumors, belonging to two tumor lines (TLT and EMT6), was also investigated (424). The results were evaluated by regular tumor measurements with a vernier caliper. The mean tumor surface in the experimental groups was compared with that in animals of the control group fed the basal diet containing starch as the only carbohydrate. The growth of both tumor lines was significantly inhibited by supplementing the diet with nondigestible carbohydrates. Such nontoxic dietary treatment appears to be easy and risk free for patients, applicable as an adjuvant factor in the classical protocols of human cancer therapy (424).

Among pectin, apple pectin exerts stronger bacteriostatic action on *Staphylococcus aureus*, *Streptococcus faecalis*, *Pseudomonas aeruginosa*, and *Escherichia coli* in comparison with citrus pectin. In this study, we used water-

soluble methoxylated pectin from apple. The diet, supplemented by 20% apple pectin, significantly decreased the number of tumors and the incidence of colon tumors. PGE2 level in distal colonic mucus in 20% apple pectin-fed rats were lower than those in basal diet fed rats. Fecal  $\beta$ -glucuronidase activities in the apple pectin-fed group, which has been considered a key enzyme for the final activation of dimethylhydrazine metabolism to carcinogens in the colonic lumen, were significantly lower than those in control group at initiation stage of carcinogenesis. The concentrations of  $\beta$ -glucosidase and azoreductase were also decreased. The effect of apple pectin on the colon carcinogenesis may partially depend on PGE, concentration decrease in colonic mucus, and on the type of pectin, also related to fecal enzyme activities.

The resistance of pectin to degradation in the upper GI tract and its complete dissolution in the colon makes pectin an ideal ingredient for colon-specific delivery. The solubility in the GI fluids is suppressed by crosslinking with calcium or by chemical means. Coacervate with gelatine permits the formation of microglobules suitable for controlled-release products (425–427).

To develop an enzymatically controlled pulsatile drug release system based on an impermeable capsule body, which contains the drug and is enclosed by an erodible pectin/pectinase plug have been studied (428). The plug was prepared by direct compression of pectin and pectinase in different ratios. In addition to the disintegration times of the plugs, the lag times and the release profiles of the pulsatile system were determined as a function of pectin/enzyme ratio, the pH of the surrounding medium, and the addition of buffering or chelating agents. The drug release was controlled by the enzymatic degradation and dissolution of pectin (429).

The use of pectin in tablet formulations have been studied by Meshali and Gabr (430) using a blend of pectin and chitosan. Ashford et al. (431,432) protected a core tablet with a coat of HM pectin. It was shown that the tablets disintegrated in the colon. Coprecipitation of cationic drugs with pectin was shown to be applicable for sustained release of water-soluble drugs (433). Encapsulation of liver cells by coacervation of carboxymethylcellulose, chondroitin sulfate, chitosan, and polygalacturonic acid gave viable cells that could be used for extracorporeal liver support (434).

## XV. HEPARIN

Heparin is the most biologically reactive member of the family of sulfated glycosaminoglycans (GAGs), which are

widespread in animal tissue (435). Heparin and chondroitin sulfates, which are the most abundant sulfated glycosaminoglycans, contribute an enormously important role in the successful development of open heart surgery. Due to its antithrombotic and anticoagulant properties, heparin is extensively used in the management of cardiovascular diseases (436–438). Long-term treatments with heparin, as well as short-term ones in the case of patients susceptible to hemorrhage, involve risk of bleeding. Another unwanted side effect of heparin is its interaction with platelet function, which may lead to depletion of these blood components (thrombocytopenia, HIT). During the last decade, fundamental aspects of the pathogenesis of HIT have been resolved. The understanding of some the mechanisms underlying the development of new, paradox thromboembolic complications in HIT led to the concept that thrombin generation plays a key role in clinically manifest HIT. Consequently new therapeutic concepts imply the use of drugs with either indirect or direct antithrombin activity, such as donaparoid sodium and the recombinant hirudin lepirudin. In recent years results of the first prospective studies assessing various treatment regimens in HIT became available. Although data of randomized trials are still missing, some treatment recommendations can already be drawn from these studies (439).

The discovery of new activities of heparin, relating to inhibition of growth of smooth muscle cells (440), angiogenesis (441), the human immunodeficiency virus (HIV) (442), and tissue engineering (443), has widened the scope of potential uses of this GAG. Incorporation of heparin-binding peptides into fibrin gels enhances neurite extension, an example of designer matrices in tissue engineering.

Kratz et al. (444) have recently shown that heparin in combination with chitosan stimulates re-epithelialization in an in vitro model of human wound healing. The chitosan–heparin membrane stimulated the increased stabilization and concentration of growth factors in the wound area, which stimulated healing.

Some of the biological properties of heparin can be simulated by other GAGs or by chemically sulfated vegetal, algal, or microbial polysaccharides. However, the type of carbohydrate backbone and the sulfation pattern of the polysaccharide are important for the emergence and level of specific activities (445). As the prophylactic use of heparin continues to increase, nurses must be aware that heparin use may cause heparin-induced skin necrosis—a rare but serious complication. Although even more severe complications may occur from heparin use, this discussion will focus on skin necrosis caused by subcutaneous heparin. Should heparin-induced skin necrosis develop, heparin

therapy must be discontinued immediately. Reports of one patient's reaction to this complication have been presented (446,447).

Angiogenesis is a prerequisite for tumor expansion and metastasis. The angiogenic potential of the heparin-binding growth factors acidic fibroblast growth factor (FGF) and basic FGF has been demonstrated in various publications. Zugmaier et al. (448) have studied the inhibitory effects of suramin and the polysulfated heparinoids pentosan polysulfate, dextran sulfate, and fucoidan on the action of FGF. Polysulfated heparinoids exert a selective inhibitory effect on heparin-binding angiogenesis factors at an IC<sub>50</sub>, which is 100 times below the IC<sub>50</sub> of suramin. Therefore, the administration of polysulfated heparinoids might become a novel approach to tumor therapy based on blocking angiogenesis.

Aspirin, a potent antiplatelet drug, and heparin, an anticoagulant, are commonly used for postimplant complications such as thrombosis and thromboembolism. Aspirin and heparin were embedded in chitosan-polyethylene vinylacetate comatrix to develop a prolonged release form (449). The effect of these drugs toward the bioprosthetic calcification was investigated by *in vitro* and *in vivo* models (449). *In vitro* and *in vivo* evaluation suggest that the released aspirin-heparin from the comatrix had a synergistic effect in inhibiting glutaraldehyde pretreated bovine pericardium calcification. Biochemical, histological, and scanning electron microscopic evaluation of retrieved samples demonstrated a significant reduction in calcium deposition.

Many of the acute coronary ischemic syndromes are triggered by spontaneous or mechanical disruption of atherosclerotic plaques with resultant activation of platelets and coagulation. Given the central role of platelets and thrombin in arterial thrombosis, current strategies for its prevention and treatment focus on both inhibition of platelet aggregation and control of thrombin generation and activity. Although aspirin and unfractionated heparin are the cornerstones of current treatment strategies, both have limitations (450).

Among the biomedical applications of synthetic polymers, the development of blood-handling equipment (e.g., the hemodialysis and cardiopulmonary bypass, angiographic catheters, intra-aortic balloon pumps, cardiovascular prostheses, artificial heart devices) has been one of the most investigated areas in the past two decades. Biomaterial thrombogenicity remains the single most important concern preventing even more widespread application.

In recent years, low molecular weight heparins (LMWH) have been tested in the prevention and treatment of deep vein thrombosis and pulmonary embolism, as well

as in the treatment of stroke and unstable angina. In all these situations, LMWH had a similar or even a better risk/benefit ratio than unfractionated heparin (UH) (451). Acute myocardial infarction and coronary angioplasty are among the new targets presently under investigation with various LMWH. Patients with mechanical heart valves require life-long anticoagulation. Therefore, the anticoagulation with LMWH after mechanical heart valve replacement were studied (451). Anticoagulation activity with LMWH after mechanical heart valve replacement appears feasible, provides adequate biological anticoagulation, and compares favorably with UH anticoagulation. Randomized studies are now needed to further evaluate this new therapeutic approach.

Albumin has also been utilized with heparin preadsorption of both molecules or by their covalent coupling, which results in heparin-albumin conjugates. Albumin preadsorbed onto surface reduce platelet adhesion, while heparin is able to interact with antithrombin III, preventing thrombus formation (452-456). Crosslinked gels of albumin as well as heparinized albumin gels, potential sealant of prosthetic vascular grafts, were studied with regard to *in vitro* stability, binding of basic fibroblast growth factor, and cellular interactions (457). It can be concluded that crosslinked gels of albumin to which heparin is immobilized, are candidate sealants for prosthetic vascular grafts and suitable substrates for endothelial cell seeding.

Inhibitory effects of heparin coupling on calcification of bioprosthetic vascular grafts of different origin were studied. Heparin-bonded and 0.625% glutaraldehyde crosslinked (GA) segments of porcine thoracic aorta (AO), pulmonary artery (PA), jugular vein (JV) and rabbit aorta (RA) were implanted subcutaneously in weanling rats for 5 months (458). Heparin bonding was ineffective in prevention of calcification of JV and RA. Calcium content of heparin-coupled PA and AO was significantly less when compared with their GA-treated counterparts. Calcification inhibition was achieved to a greater extent in heparin-bonded PA than in the AO coupled to heparin. Heparin-bonded porcine pulmonary artery seemed to be the best among all vascular bioprostheses in this study.

Clinical procedures involving extracorporeal blood circulation are potentially complicated by the interaction of various blood systems with foreign surfaces. In cardiopulmonary bypass, exposure of blood to synthetic surfaces generally leads to activation of cellular and humoral blood systems with activation of complement cascade. This reaction can be associated with a variety of postoperation clinical complications, such as increased pulmonary capillary permeability, anaphylactic reactions, and various degrees of organ failure which contribute to mortality in routine

cardiac operations. Application of biocompatible materials in an extracorporeal circuit modifies the normal pattern of blood activation, and therefore may potentially reduce clinical complications in routine cardiac surgery (459). The use of heparin-coated circuits resulted in reduction of systemic leukocyte activation of cardiopulmonary bypass reflected by reduced leukocyte and neutrophil counts 24 h after operation ( $p < 0.05$ ).

Various sugar-carrying polystyrenes (PS), which consist of synthetic styrene and sugar moieties, are glycoconjugates that are able to attach to polymeric surfaces. Heparin-carrying PS (HCPS) is especially able to retain the binding of heparin-binding growth factors (GFs) such as vascular endothelial GF 165 or fibroblast GF 2. Human skin fibroblast cells, human coronary smooth muscle cells, and human coronary endothelial cells have good adherence to the HCPS-coated plate. These results indicate that growth of various cells can be controlled by the HCPS coating, thereby retaining the bioactivity of molecules such as heparin-binding GFs. Thus, HCPS-coated surfaces control selective growth of various cells (460).

Using polystyrene microspheres coated with heparin or heparan sulfate, it was shown that coated microspheres specifically bound eukaryotic cells and were endocytosed by nonprofessional phagocytic cells. Coated microspheres displayed properties of binding to eukaryotic cells that were similar to those of *Chlamydiae*, and the microspheres were competitively inhibited by chlamydial organisms. Endocytosis of heparin-coated beads resulted in the tyrosine phosphorylation of a similar set of host proteins, as did endocytosis of *Chlamydiae*; however, unlike viable chlamydial organisms, which prevent phagolysosomal fusion, endocytosed beads were trafficked to a lysosomal compartment. These findings suggest that heparin-coated beads and *Chlamydia trachomatis* enter eukaryotic cells by similar pathways (461).

Poly(ethylene terephthalate) (PET) film was exposed to oxygen plasma glow discharge to produce peroxides on its surfaces. These peroxides were then used as catalysts for the polymerization of acrylic acid (AA) in order to prepare a carboxylic acid group-introduced PET (PET-AA). Insulin and heparin coimmobilized PET (PET-I-H) was prepared by the grafting of poly(ethylene oxide) to PET-AA, followed by reaction first with insulin and then heparin (462). The blood compatibility of the surface-modified PETs were examined using in vitro thrombus formation, plasma recalcification time, activated partial thromboplastin time, and platelet adhesion and activation.

The growing importance of polymer membrane-based potentiometric polyion sensors in biomedical research and clinical measurements has brought up the question of how

accurate and reproducible these sensors are. Polymer membrane-based potentiometric sensors were developed earlier to provide a rapid and direct method of analysis for polyions such as heparin. These heparin sensors are irreversible, requiring a membrane renewal procedure between measurements which currently prevents the sensors from being used for continuous monitoring of blood heparin. Indeed, recent research has revealed that these sensors behave quite differently than classical ion-selective electrodes. Mathison and Bakker (463,464) explored ways to improve measurement reproducibility and long-term potential stability by considering the unique pseudo-steady state response mechanism of the polyion sensors developed so far. Heparin may be stripped out of the phase boundary membrane surface with a high sample NaCl concentration, and this characteristic is used to modify the calibration procedure in order to avoid memory effects. It is also attempted to reduce long-term potential drifts by continuously stripping heparin out of the membrane at the membrane inner filling solution side. A theoretical model is presented to explain the experimental results (464).

## XVI. CHITOSAN

Chitosan is a polysaccharide comprising copolymers of glucosamine and N-acetylglucosamine. Chitosan is usually prepared from chitin (2-acetamido-2-deoxy  $\beta$ -1,4-D-glucan), and chitin has been found in a wide range of natural sources (crustaceans, fungi, insects, annelids, mollusks, coelenterate, etc.). However chitosan is only manufactured from crustaceans (crab and crayfish), primarily because a large amount of the crustacean exoskeleton is available as a byproduct of food processing. It is a natural, nontoxic, biodegradable polysaccharide available as solution, flake, fine powder, bead, and fiber. Due to the fact that chitosan has a large molecular weight, exhibits a positive charge, and demonstrates film-forming ability and gelation characteristics, the material has been extensively used in the industry, foremost as a flocculant in the clarification of wastewater (465,466), as a chelating agent for harmful metals for the detoxification of hazardous waste (467,468), for the clarification of beverages, such as fruit juices and beers (469), and for agricultural purposes such as fungicides (470). In addition chitosan has been exploited in the cosmetic industry, in the dental industry, for hair care products, and for ophthalmic applications, such as for contact lens coatings or the contact lens material itself (471–473). It has been extensively used as a biomaterial (474) due to its immunostimulatory activities, anticoagulant properties (475), antibacterial and antifungal action (476–481), and

also as a promoter of wound healing in the field of surgery (482–484). Chitosan caused leakage of glucose and lactate dehydrogenase from *E. coli* cells. These data support the hypothesis that the mechanism of chitosan antibacterial action involves a crosslinkage between the polycations of chitosan and the anions on the bacterial surface that changes the membrane permeability.

Recently, Artursson et al. (485) and Schipper et al. (486) reported that the structural properties of chitosans, such as degree of acetylation and molecular weight, are very important for its absorption enhancement of hydrophilic drugs. They found that a low degree of acetylation and/or a high molecular weight appear to be necessary for chitosans to increase the epithelial permeability.

Chitosan ingestion effectively lowers serum cholesterol (487–489). Oligosaccharides of chain length less than five residues are ineffective. Orally administered chitosan binds fat in the intestine, blocking absorption, and has been shown to lower blood cholesterol in animals and humans. As a result it has been proposed that dietary supplementation with chitosan may inhibit the formation of atherosclerotic plaque (490,491). Animals were fed for 20 weeks on a diet containing 5% chitosan or on a control diet. Blood cholesterol levels were significantly lower in the chitosan-fed animals throughout the study, and at 20 weeks were 64% of control levels. When the area of aortic plaque in the two groups was compared, a highly significant inhibition of atherogenesis in both the whole aorta and the aortic arch was observed in the chitosan-fed animals—42 and 50%, respectively. Body growth was significantly greater in the chitosan-fed animals. This study shows a direct correlation between lowering of serum cholesterol with chitosan and inhibition of atherogenesis, and suggests that the agent could be used to inhibit the development of atherosclerosis in individuals with hypercholesterolemia.

The effects of chitosan have been investigated on 80 patients with renal failure undergoing long-term stable hemodialysis treatment (492). The patients were tested after a control treatment period of 1 week. Half were fed 30 chitosan tablets (45 mg chitosan per tablet) three times a day. Ingestion of chitosan effectively reduced total serum cholesterol levels (from  $10.14 \pm 4.40$  to  $5.82 \pm 2.19$  mM) and increased serum hemoglobin levels (from  $58.2 \pm 12.1$  to  $68 \pm 9.0$  g L<sup>-1</sup>). Significant reductions in urea and creatinine levels in serum were observed after 4 weeks of chitosan ingestion (492). During the treatment period, no clinically problematic symptoms were observed. These data suggest that chitosan might be an ineffective treatment for renal failure patients, although the mechanism of the effect should be investigated further.

New silica–chitosan hybrid biomaterials were produced

using biopolymer chitosan and its heparinlike derivative as the organic species to be incorporated into the silicon alkoxide–based network (493). These hybrid materials displayed good blood compatibility in comparison with their single component systems.

#### A. Biocompatibility and Bioadhesivity of Chitosan

Chitin and chitosan are substrate for lysozyme, an enzyme found in various mammalian tissues (494,495). The enzymatic hydrolysis of chitin and chitosan leads to the production of N-acetyl-D-glucosamine and D-glucosamine. It is believed that the glucosamine plays an important physiological role in in vivo biochemical processes. It is known that glucosamine takes part in detoxification functions of liver and kidney and possesses anti-inflammatory, hepatoprotective, antireactive, and antihypoxic qualities (496–498).

Chitosan lacks irritant or allergic effect and is biocompatible with both healthy and infected human skin (499). When chitosan was administered orally in mice, the LD<sub>50</sub> was found to be in excess of 126 g/kg, which is higher than that of sucrose (500).

Chitosan has been proposed for the development of membranes and fibers for hemodialysis and blood oxygenators, skin substitute, and wound dressing materials (501–503). Chitosan as hemodialysis membranes promotes surface-induced thrombosis and embolization (501). When blood comes in contact with biomaterial surfaces like chitosan, there is an initial adsorption of plasma proteins, followed by adhesion and activation of platelets (504).

To improve blood compatibility, chitosan surface was modified by the complexation–interpenetration method using an anionic derivative of poly(ethylene glycol), methoxypropyl(ethylene glycol) sulfonate (505). The result of this study shows that chitosan surface can be permanently modified by complexation–interpenetration of anionic poly(ethylene glycol) derivative to improve blood compatibility of chitosan. When in contact with blood, the modified surface can resist plasma protein adsorption and cell adhesion by the steric repulsion mechanism (505).

Mucoadhesive properties of three viscosity grades of chitosan were investigated to assess the suitability of this polymer for gastroadhesive formulations. The influence of the pH, ionic strength, and temperature of the hydration medium on the rheological properties were studied. The mucoadhesive performance was assessed in vitro by means of rheological synergism and tensile stress testing (506). It was found that the interaction of chitosan with mucin decreases on increasing molecular weight.

Toxicity of chitosan also depends on its high charge density but appears to be less affected by the molecular weight (507,508).

### **B. Chitosan and Its Derivatives as Biomaterials for Wound Healing**

It is commonly accepted that the ideal wound covering should mimic many properties of human skin. Because of the biocompatibility, exudate absorbability, and film-forming properties of chitosan products, they are good candidates for burn and wound management uses (509). Chitosan may be used to inhibit fibroplasia in wound healing and promote tissue growth and differentiation in tissue culture. Chitosan also shows a biological aptitude to stimulate cell proliferation and histoarchitectural tissue organization (510).

Earlier, Prudden (511) and Allen and Prudden (512) had investigated the tricking effect of cartilage preparations in accelerating wound healing. The phenomenon was later attributed to the presence of N-acetyl-D-glucosamine.

Chitosan has been reported as a wound healing accelerator (513). Cotton fiber type chitosan (DA = 18%) was applied on open skin wounds for 15 days, and the process of wound healing was evaluated histologically and immunohistochemically. On day 3 postwounding, the chitosan-treated wounds showed histologically severe infiltration of polymorphonuclear cells. Granulation was more pronounced on day 9 and 15. Immunohistochemical typing of collagen I, III, and IV showed increase of the production of type III collagen in the chitosan group. The appearance of mitotic cells occurred numerously in the control on postwounding day 3 and in the chitosan group on postwounding day 6. These results suggest chitosan has a function in the acceleration of infiltration of polymorphonuclear cells at the early stage of wound healing, followed by the production of collagen by fibroblasts (513).

Chitosan acetate films, which were tough and protective, had the advantages of good oxygen permeability, high water absorptivity, and slow lysozyme degradation (514).

Loke et al. (515) have prepared wound dressing consisting of two layers: the upper layer a carboxymethyl-chitin hydrogel material, while the lower layer is an antimicrobial impregnated biomaterial. The hydrogel layer acts as a mechanical and microbial barrier and is capable of absorbing wound exudate. From the *in vitro* release studies, the loading concentration was optimized to deliver sufficient antimicrobial drug into the wound area to sustain the antimicrobial activity for 24 h.

Chitosan may facilitate wound healing by stimulating granulation tissue formation and re-epithelialization (516,517). The 3M company has marketed TEGASORB,

a wound healing product for human use containing chitosan as an excipient.

A photocrosslinkable chitosan to which both azide and lactose moieties were introduced (Az-CH-LA) was prepared as a biological adhesive for soft tissues, and its effectiveness was compared with that of fibrin glue. Introduction of the lactose moieties resulted in a much more water-soluble chitosan at neutral pH. Application of ultraviolet light irradiation to photocrosslinkable Az-CH-LA produced an insoluble hydrogel within 60 s (518). The binding strength of the chitosan hydrogel prepared from 30–50 mg/mL of Az-CH-LA was similar to that of fibrin glue. Compared to the fibrin glue, the chitosan hydrogel more effectively sealed air leakage from pinholes on isolated small intestine and aorta and from incisions on isolated trachea. Neither Az-CH-LA nor its hydrogel showed any cytotoxicity in cell culture tests of human skin fibroblasts, coronar endothelial cells, and smooth muscle cells. These results suggest that the photocrosslinkable chitosan developed here has the potential of serving as a new tissue adhesive in medical use.

Water-soluble chitin was prepared by controlling degree of deacetylation and molecular weight of chitin through alkaline and ultrasonic treatment (519). Its accelerating effect on wound healing in rats was compared with those of chitin and chitosan. The water-soluble chitin was found to be more efficient than chitin or chitosan as a wound-healing accelerator. The wound treated with water-soluble chitin solution was completely re-epithelialized, granulation tissues in the wound were nearly replaced by fibrosis, and hair follicles were almost healed at 7 days after initial wounding.

### **C. Chitosan Use as a Matrix for Drug Delivery Systems**

As a pharmaceutical excipient, chitosan has been added for sustained release (520–522) and to improve dissolution of poorly soluble drugs (523). The applications of chitosan as an excipient in pharmaceutical products are listed in Table 3.

Kotze et al. (524) showed that chitosan hydrochloride and chitosan glutamate are potent absorption enhancers in acidic environments. It was concluded that there is a need for chitosan derivatives with increased solubility, especially at neutral and basic pH values, for use as absorption enhancers aimed at the delivery of therapeutic compounds in the more basic environment of the large intestine and colon.

The efficiency of chitosan in tablets was dependent on chitosan crystallinity, degree of deacetylation, molecular weight, and particle size (525,526).

**Table 3** Chitosan as a Pharmaceutical Excipient

Conventional formulations:
Gels
Films
Emulsions
Direct compression tablets
Wetting agent
Coating agent
Controlled release matrix tablets:
Microspheres and microcapsules
Transmucosal drug delivery
Vaccine delivery
DNA delivery

Sabnis et al. (527) studied the potential utility of chitosan (I) in inhibiting diclofenac sodium (II) release in the gastric environment from a directly compressible tablet formulation. Analyses of variance model was tested using SAS® (SAS Institute, Inc., NC) indicated that the degree of N-deacetylation of chitosan significantly affected drug release at pH 1.2 and 6.8 ( $p < 0.0001$ ). An increase in the pH of the dissolution medium resulted in an increase in drug release ( $p < 0.0001$ ). The ionic strength of the dissolution medium did not significantly affect drug release at any of the pHs studied ( $p > 0.198$ ).

Using chitosan solution ( $pH < 6$ ), gel formation will occur with a number of different multivalent anionic counterions. By adding a chitosan solution dropwise into a crosslinking solution having  $pH < 6$ , a real ionotropic gel is formed (528). The  $NH_2$  groups of chitosan are protonated and an ionic crosslinking occurs.

Chitosan crosslinked with high molecular weight counterions (529–531) results in capsules (Table 4), while crosslinking with low molecular weight counterions results

**Table 4** Possible Counterions for the Ionotropic Gelation of Chitosan

Polycation	Counterions
Chitosan– $NH_2$	Low molecular weight
	Pyrophosphate
	Triphosphate
	Tetraphosphate
	Octaphosphate
	Hexametaphosphate
	$[Fe(CN)_6]^{4-}$ , $[Fe(CN)_6]^{3-}$
	High molecular weight
	Poly(1-hydroxy-1-sulfonate-2-propene)
	Poly(aldehydicarbonic acid)
	Xanthane
	Pectin

**Table 5** Hydrophobic Counterions for the Ionotropic Gelation of Chitosan

Polycation	Hydrophobic counterions
Chitosan– $NH_2$	Octyl sulfate
	Lauryl sulfate
	Hexadecyl sulfate
	Cetylstearyl sulfate

in globules (Table 4) (528). Using more hydrophobic counterions (Table 5) it is possible to prepare hydrophobic carriers (532).

#### D. Microspheres and Microcapsules

Over the past decade, several microsphere drug formulations have matured beyond the stage of promising investigational agents in preclinical and clinical trials to become viable pharmaceutical products approved for widespread human use. Chitosan microspheres are produced, either by an emulsification–crosslinking process or by use of complexation between oppositely charged macromolecules. The resulting crosslinked chitosan microspheres were characterized by being smooth, spherical, and in the size range of 45–300  $\mu m$ .

Influence of chitosan molecular weight on drug loading and drug release of drug-loaded chitosan microspheres was studied (533). Chitosans of 70,000, 750,000, and 2,000,000 molecular weight were employed. Ketoprofen (ket) was chosen as the model drug to be encapsulated. Prepared chitosan microparticle delivery systems can modulate ket release within 48 h.

A new microparticulate of chitosan controlled-release system, consisting of hydrophilic chitosan microcores entrapped in a hydrophobic cellulosic polymer, such as cellulose acetate butyrate (CAB) or ethyl cellulose (EC), was proposed (534). These microparticles were obtained with different types of chitosan and various core/coat ratios, with the particle size in all cases being smaller than 70  $\mu m$ . Using sodium diclofenac (SD) and fluorescein isothiocyanate-labeled bovine serum albumin (FITC-BSA) as model compounds, the properties of these new microparticles for the entrapment and controlled release of drugs and proteins were investigated. The microparticles were stable at low pH and thus suitable for oral delivery without requiring any harmful crosslinkage treatment.

A new system which combines specific biodegradability and pH-dependent release is presented. The system consists of chitosan (CS) microcores entrapped within acrylic microspheres. Sodium diclofenac (SD), used as a model drug, was efficiently entrapped within CS microcores us-

ing spray-drying and then microencapsulated into Eudragit L-100 and Eudragit S-100 using an oil-in-oil solvent evaporation method (535). The size of the CS microcores was small (1.8–2.9  $\mu\text{m}$ ) and they were encapsulated within Eudragit microspheres (size between 152 and 233  $\mu\text{m}$ ) forming a multireservoir system. A combined mechanism of release is proposed, which considers the dissolution of the Eudragit coating, the swelling of the CS microcores and the dissolution of SD and its further diffusion through the CS gel cores.

Novel CS and CS/ethylene oxide–propylene oxide block copolymer (PEO-PPO) nanoparticles and their potential for the association and controlled release of proteins and vaccines were studied by Calvo et al. (536). The mechanism of protein association was elucidated using several proteins, bovine serum albumin, and tetanus and diphtheria toxoids, and varying the formulation conditions (different pH values and concentrations of PEO-PPO) and the stage of protein incorporation into the nanoparticle formation medium.

### 1. Microspheres and Microcapsules with Insulin

As a consequence of poor oral bioavailability and the current lack of alternative delivery routes, insulin is presently administered parenterally. The difficulties in achieving a normal physiological profile of insulin by injectable therapy has led to the investigation of alternative, nonparenteral routes for the delivery of insulin in an attempt to improve glycemic control. An insulin delivery system has been widely investigated as an alternative to subcutaneous injection for the treatment of diabetes.

Bugamelli et al. (537) investigated the production of chitosan microparticles containing insulin by interfacial crosslinkage of chitosan solution in the aqueous phase of a water/oil dispersion in the presence of ascorbil palmitate, thus permitting covalent bond formation with the amino group of chitosan when its oxidation to dehydroascorbyl palmitate takes place during microparticle preparation. This preparation method produced microparticles characterized by high loading levels of insulin, completely releasing the drug in about 80 h at an almost constant release rate.

Tozaki et al. (538) studied the colon-specific insulin delivery with chitosan capsules. A marked absorption of insulin and a corresponding decrease in plasma glucose levels was observed following the oral administration of these capsules that contain 20 IU of insulin and sodium glycocholate (PA% = 3.49%), as compared with the capsules containing only lactose or only 20 IU of insulin (PA% = 1.62%). The hypoglycemic effect started from 8 h after the administration of chitosan capsules when the capsules

entered the colon, as evaluated by the transit time experiments with chitosan capsules. These findings suggest that chitosan capsules may be useful carriers for the colon-specific delivery of peptides including insulin.

### 2. Microspheres and Microcapsules for Cancer Therapy

Intravenously administered anticancer drugs are distributed throughout the body as a function of the physicochemical properties of the molecule. A pharmacologically active concentration is reached in the tumor tissue at the expense of massive contamination of the rest of the body. The use of microsphere drug carriers could represent a more rational approach to specific cancer therapy.

Kawashima et al. (539) have developed a novel mucoadhesive DL-lactide/glycolide copolymer (PLGA) nanosphere system to improve peptide absorption and prolong the physiological activity following oral administration. The desired PLGA nanospheres with elcatonin were prepared by the emulsion solvent diffusion method to coat the surface of the resultant nanospheres with a mucoadhesive polymer such as chitosan, poly (acrylic acid), and sodium alginate. The chitosan-coated nanospheres showed higher mucoadhesion to the everted intestinal tract in saline than the other polymer-coated nanospheres.

Nishioka et al. (540) produced glutaraldehyde cross-linked chitosan microspheres that contained cisplatin. Similar microspheres were prepared by Jameela and Jayakrishnan (541) containing mitoxantrone. Drug release was found to be effectively controlled by the degree of crosslinking. Wang et al. (542) described an orthogonal experimental design to optimize the formulation of cisplatin (CDDP)-loaded chitosan microspheres (namely, CDDP-DAC-MS), which were produced by an emulsion-chemical crosslinking technique. Seven factors and three levels for each factor that might affect the formulation of microspheres were selected and arranged in an L27(3(13)) orthogonal experimental table.

Chitosan nanoparticles, readily prepared without the use of organic solvents, are a suitable vehicle for the delivery of these immunostimulants from *Mycobacterium vaccae* (PS4A); the formulations might find application as antitumor agents (543).

The fate of  $^{166}\text{Ho}$ -chitosan complex, a radiopharmaceutical drug for cancer therapy, was determined by studying its absorption, distribution, and excretion in rats and mice (544). To determine the effects of chitosan in  $^{166}\text{Ho}$ -chitosan complex,  $^{166}\text{Ho}$  alone (0.75 mg of  $\text{Ho}(\text{NO}_3)_3 \times 5\text{H}_2\text{O}/\text{head}$ ) was intrahepatically administered to male rats; and radioactive concentrations in blood,

urinary and fecal excretion, and radioactive distribution were examined. The radioactive concentrations in tissues and the whole-body autoradiography images showed that most of the administered radioactivity was localized at the administration site, and only slight radioactivity was detected from the liver, spleen, lungs, and bones. These results strongly suggest that  $^{166}\text{Ho}$  is retained at the administration site only when it forms a chelate complex with chitosan. Autoradiographs after intratumoral administration of  $^{166}\text{Ho}$ -chitosan complex showed that radioactivity was localized at the site of administration without distribution to the other organs and tissues. These results strongly suggest that  $^{166}\text{Ho}$  is retained at the administration site only when it forms a chelate complex with chitosan. Autoradiographs after intratumoral administration of  $^{166}\text{Ho}$ -chitosan complex showed that radioactivity was localized at the site of administration without distribution to the other organs and tissues (544).

The potential of gadolinium neutron-capture therapy (Gd-NCT) for cancer was evaluated using chitosan nanoparticles as a novel gadolinium device (545). The nanoparticles, incorporating 1200  $\mu\text{g}$  of natural gadolinium, were administered intratumorally twice in mice bearing subcutaneous B16F10 melanoma. The thermal neutron irradiation was performed for the tumor site, with the fluence of  $6.32 \times 10^{12}$  neutrons/cm<sup>2</sup> 8 h after the second gadolinium administration. After the irradiation, the tumor growth in the nanoparticle-administered group was significantly suppressed compared to that in the gadopentetate solution-administered group, despite radioresistance of melanoma and the smaller Gd dose than that administered in past Gd-NCT trials. This study demonstrated the potential usefulness of Gd-NCT using gadolinium-loaded nanoparticles (545).

Hojo et al. (546) have prepared a hybrid of a water-soluble chitosan and a laminin-related peptide, and have examined its inhibitory effect on experimental metastasis in mice. Four methods were tried to achieve a coupling reaction, the diphenylphosphoryl azide method, the diisopropylcarbodiimide/1-hydroxybenzotriazole method, the water-soluble carbodiimide, and the 2-(1H-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium tetrafluoroborate (TBTU) method, but all four methods were unsuccessful. Therefore, a small spacer, tert-butyloxycarbonyl-Gly, was intercalated in chitosan by the TBTU method to facilitate its coupling with the peptide. Conjugation of the peptide with the larger chitosan molecule did not reduce the inhibitory effect of the peptide on experimental metastasis in mice, it actually potentiated the antimetastatic effect, demonstrating that chitosan may be effective as a drug carrier for peptides.

DNA was immobilized within alginate matrix using

an external or an internal calcium source, and then membrane coated with chitosan or poly-L-lysine. Membrane thickness increased with decreasing polymer molecular weight and increasing degree of deacetylation of chitosan (547,548). Less than 1% of total double-stranded DNA remained unhydrolyzed within chitosan- or poly-L-lysine-coated beads, corresponding with an increase in DNA residuals (i.e., double- and single-stranded DNA, polynucleotides, bases). Chitosan membranes did not offer sufficient DNA protection from DNase diffusion since all of the double-stranded DNA was hydrolyzed after 40 min of exposure.

### 3. Microspheres and Microcapsules with Antiinflammatory Drugs

An inclusion complex composed of hydrocortisone acetate (HC) and hydroxypropyl- $\beta$ -cyclodextrin (HP $\beta$ CD) was prepared by the spray-drying method (549). Hydrocortisone acetate alone, HC inclusion complex, or HC with HP $\beta$ CD as a physical mixture were incorporated into chitosan microspheres by spray-drying (549). The HC release rates from chitosan microspheres were influenced by the drug/polymer ratio in the manner that an increase in the release rate was observed when the drug loading was decreased. However, release data from all samples showed significant improvement of the dissolution rate for HC, with 25–40% of the drug being released in the first hour compared with about 5% for pure HC.

Mooren et al. (550) investigated the influence of chitosan microspheres on transport of the hydrophilic, antiinflammatory drug prednisolone sodium phosphate (PSP) across the epithelial barrier. The effect is dependent on the integrity of the intercellular cell contact zones and the microparticles are able to pass the epithelial layer. Their potential benefit under inflammatory conditions like in inflammatory bowel disease, in order to establish high drug doses at the region of interest, remains to be shown.

Chitosan microspheres were also used as support for the antiinflammatory drugs in order to assure the gastrointestinal tract protection. In this way the chitosan microspheres covalently linked with citric acid and loaded with indomethacin are prepared (551). Also, a pharmacokinetic model of colon-specific drug has been validated by use of 5-aminosalicylic acid (5-ASA) as a model antiinflammatory drug (552). The simulation curves obtained from the pharmacokinetic model were in good agreement with experimental data obtained after oral administration of 5-ASA-containing chitosan capsules. The concentrations of 5-ASA in the large intestinal mucus after drug administration were higher than after administration of the drug in carmellose suspension. These findings suggest that

our pharmacokinetic model of colon-specific drug delivery can accurately evaluate this colon-specific delivery system and that 5-ASA-containing chitosan capsules are more effective than other 5-ASA formulations for treatment of colitis in rats.

#### 4. Microspheres and Microcapsules as Local Injection

Local implantation or injection of microspheres containing bisphosphonates for site-specific therapy may aid in treating several pathological conditions associated with bone destruction. Chitosan microspheres containing two antiresorption and anticalcification agents, pamidronate and suberoylbisphosphonate, were prepared from a water-in-oil emulsion. Various formulation variables were studied for their effect on the release rate profile of these bone-seeking agents (553). Polymer coating of micromatrices yielded microspheres with the most retarded release rate, and the drug delivery system was found biocompatible in endothelial cell culture. Bisphosphonate released from chitosan microspheres effectively inhibited bioprosthetic tissue calcification in the rat subdermal model.

The formation of microcapsules which contain rosemary oil is herewith described (554). The process is based on two steps: (1) formation of oil-in-water emulsions using lecithin as emulsifier, thus imparting negative charges on the oil droplets and (2) addition of a cationic biopolymer, chitosan, in conditions that favor the formation of an insoluble chitosan-lecithin complex.

#### E. Gels

Hydrogels formed from chitosan are usually covalently crosslinked. Crosslinking agents such as glutaraldehyde (555–557), glyoxal (558), and diethyl squarate (559) have been employed in the fabrication of chitosan hydrogels. Chitosan has also been covalently crosslinked with the carbohydrate scleroglucandialdehyde (560). In addition semi-interpenetrating polymer network hydrogels have been produced between chitosan-polyethylene oxide diacrylate crosslinked by UV irradiation (561), glyoxal crosslinked chitosan-polyethylene oxide (562), and glutaraldehyde crosslinked chitosan combined with silk fibroin (563) or polyacrylic acid (564).

Noncovalent crosslinking has been used to prepare chitosan-based gels by the O- and N-acetylation of chitosan (565) and the attachment of C10-alkyl glycosides to chitosan (566). By the attachment of hydrophobic palmitoyl groups to glycol chitosan, a water-soluble chitosan derivative has been produced (567).

Thin films of a biopolymer chitosan (CHIT) were cast on glassy carbon electrodes, modified by grafting Lucifer Yellow VS dye (LYVS) onto chitosan chains, and crosslinked with glutaric dialdehyde (GDI) (568). The ion transport and ion exchange properties of such polymeric structures (CHIT, CHIT-LYVS, CHIT-LYVS-GDI) were studied using cyclic voltammetry, rotating disk electrode, and flow injection analysis. The results showed that the chitosan matrix supported a fast ion transport as demonstrated by aqueous-like values of the apparent diffusion coefficients of  $\text{Ru}(\text{NH}_3)_6(3)^+$  and dopamine in the films (568). The results indicate that the chemically modified chitosan is an attractive new coating for the development of fast, selective, and reversible sensors.

Miyazaki et al. (569) and Kristl et al. (565) investigated the suitability of dried chitosan gels as vehicles for the sustained release of the poorly soluble drugs such as indomethacin, papaverine hydrochloride, and lidocaine. The gel showed zero order release into pH 7.4 buffer at 24 h. It was found that the degree of deacetylation and the chitosan content were important for the release properties.

The influence of the acid type used to dissolve chitosan on the resulting sponge, physical properties, and the consequent effect on the drug liberation were investigated (570). Chitosan was dissolved in different acid solutions and chitosan-gelatine sponges were produced by frothing up the polymer solution and then freeze-drying the foam. Prednisolone was used as a model drug. Using tartaric or citric acid resulted in unstable, soft, elastic, and disintegrating sponges with fast drug release. Elastic but harder sponges from stable foams were obtained when hydrochloric or lactic acid were used. The use of acetic or formic acid enabled the production of stable foams and soft and elastic sponges, allowing low drug release. The rate of drug release was decreased by crosslinking the polymers with glutaraldehyde. Therefore, it is possible to manipulate the mechanical properties and the drug liberation rate by using different acids to dissolve chitosan (570).

A biodegradable drug delivery system of a gentamicin-loaded chitosan bar with sustained antibiotic effect is described (571). Combined crosslinking, solvent evaporation, and a cylinder model cutting technique was used to prepare the chitosan bar. Sustained diffusion of gentamicin into the surrounding medium was seen using a release test *in vitro*. Approximately 11% gentamicin was released from the bar in the first 24 h. The gentamicin released from the bar showed significant antibacterial activity. The bar implanted in the proximal portion of the rabbit tibia produced a low blood concentration of gentamicin, but a much higher concentration was produced in local bone and in the hematoma. In all bone tissue around the bar, the genta-

micin concentration exceeded the minimum inhibitory concentration for the common causative organisms of osteomyelitis for approximately 8 weeks (571). Based on these test results together with the chitosan characteristics of biodegradable, antibiotic, and immunologic activity, the gentamicin-loaded chitosan bar seems to be a clinically useful method for the treatment of bone infection. This system has an advantage over other systems in that it avoids a second operation for removal of the carrier.

Chitosan–ethylene diamine tetracetic acid (EDTA) conjugate gels have also been reported in which the carboxylic acid group of EDTA are covalently linked to the amino groups of chitosan (572,573). A recently developed chitosan–EDTA conjugate, neutralized with sodium hydroxide (NaChito-EDTA), has been tested for possible topical use (571). This antimicrobial activity of NaChito-EDTA can be explained by its highest binding affinity toward magnesium, which stabilizes the outer membrane of gram-negative bacteria.

New mucoadhesive polymers, exhibiting a high capacity to bind bivalent cations that are essential cofactors for intestinal proteolytic enzymes, were synthesized (574). Under the formation of amide bonds, the complexing agent EDTA was covalently bound to the primary amino groups of chitosan (574,575). Whereas proteolytic activity of the serine proteases trypsin,  $\alpha$ -chymotrypsin, and elastase could not be inhibited, proteolytic activity of the zinc proteases carboxypeptidase A and aminopeptidase N was strongly inhibited by the chitosan–EDTA conjugate. The adhesive force of the conjugate was even higher than of chitosan HCl.

Berberine (the main ingredient of *Coptis* spp.) was incorporated into chitosan hydrogel to prepare ointments. The physicochemical properties of the ointments and the release profile of berberine were investigated. The results indicated that the viscosity of chitosan hydrogel increased with an increasing amount of lactic acid or EDTA (576). The release rate of berberine was inversely proportional to ointment viscosity.

The effect of heparin ionically linked to chitosan on the stimulation of re-epithelialization of full thickness wounds in human skin was investigated in an *in vitro* model (577). After 7 days of incubation, heparin–chitosan gel stimulated 9/10 of the full thickness wounds to re-epithelialize compared with only 3/10 of the wounds that were covered with chitosan gel or membrane; and none of the wounds incubated without gel or membrane or with heparin solution alone.

One approach taken by Hoffman et al. (578) was to synthesize hybrid copolymers by grafting temperature-responsive polymers (Pluronic) to chitosan backbones. The

polymers gelled as the temperature was raised from 4 to 37°C and provided significant extension of drug release.

## F. Chitosan–Polyelectrolyte Complexation

Polymer complexes are formed by the association of two or more complementary polymers and may arise from electrostatic forces, hydrophobic interactions, hydrogen bonding, van der Waals forces, or combinations of these interactions (579–583). The formation of complexes may strongly affect the polymer solubility, rheology, conductivity, and turbidity of polymer solutions (583). Hydrogen bonds are distinctly directional and specific and are more localized than any other type of weak intermolecular interaction (584). Many polymer complexes form as a result of electrostatic forces. Polymeric acids may form complexes by proton transfer to complementary polymeric bases, resulting in poly(cation)/poly(anion) pairs. In addition to the interpolymer complexes, intrapolymer complexes of polyampholytes have been studied (585–587). In these systems complexes may be formed between oppositely charged moieties on the same polymer chain, or even on the same monomer units. Finally, simple polyelectrolytes in solution may be linked together by multivalent ions to form gels or coacervates (588,589). The complex stability is dependent upon such variables as charge density, solvent, ionic strength, pH, and temperature. Polyelectrolytes of high charge density may form relatively insoluble complexes. Characteristics of the macromolecule complexes are largely based on their higher molecular weight, which are called polymer effects, such as cooperative interactions, concerted interactions, steric compatibility, and microenvironmental effects (590).

Gel technology based on ionic crosslinked polysaccharides is currently in use and of considerable interest for potential application in the extraction with solvents (591), as controlled release systems (592,593), as mechanochemical devices (594), in the oil industry (595–597), and also in several other biomedical applications (598,599).

The binding of chitosan to alginate beads was studied quantitatively by using radioactive-labelled fractions of chitosan (600). The binding of chitosan was markedly increased by reducing the number average molecular weight of chitosan below 20,000 Da and by increasing the porosity of the alginate gel. The porosity was increased by producing homogeneous gels, and by adding calcium chloride to the chitosan solution during the membrane-forming stage. The binding of chitosan was also found to increase with decreasing fraction of N-acetylations (FA) on chitosan, in the range of FA = 0.3 to FA = 0, and with increasing pH, in the range of pH 4 to 6. Capsules with a diameter of 500

$\mu\text{m}$  had a higher weight ratio of chitosan to alginate after 24 h of binding than the capsules with the larger diameter of 1500  $\mu\text{m}$ .

To prepare spray-dried composite particles containing alginate–chitosan complex [SD(L/AL-CS)], an aqueous solution of lactose and sodium alginate and the acetic acid solution of chitosan were concomitantly fed into the rotary atomizer of a spray-dryer (601). The drug release profiles of dry-coated tablet with SD(L/AL-CS) indicated a long induction period followed by a rapid drug release phase in the artificial intestinal fluid. The induction period for drug release to occur was increased with an increase in the degree of deacetylation of chitosan and in the amount of chitosan in the formulation. The prolongation of induction period was attributed to the formation of an insoluble ion complex between sodium alginate and chitosan in the composite particles, which could form a rigid gel structure on the tablet surface.

The stability of alginate–chitosan capsules was shown to depend strongly on the amount of chitosan bound to the capsules. When the capsules were made by dropping a solution of sodium alginate into a chitosan solution (one-stage procedure), all the chitosan was located in a thin alginate–chitosan membrane on the surface. These capsules were much weaker than the capsules made by reacting calcium alginate beads in an aqueous solution of chitosan and calcium chloride (two-stage procedure). Cap-

sules with high mechanical strength were obtained after shorter reaction times when the number average molecular weight of the chitosan was reduced to around 15,000 Da, when the capsules were made more homogeneous, and when the capsule diameter was reduced to around 300  $\mu\text{m}$  (602).

Noncovalent crosslinked chitosan gel mixtures can be prepared by the use of polyelectrolyte complexes of chitosan and polyanions such as carboxymethylcellulose (603) and xanthan (604,605).

Gelatine forms polyionic complexes with chitosan at the suitable pH value (606). These complexes show a slower rate of dissolution than chitosan at the corresponding pH. Therefore a combination of chitosan and gelatine in a sponge will first lead to an absorption of the wound fluid and second slowly release a wound-treating drug (607,608). The release profile and biodegradability of both polymers can be effectively controlled by glutaraldehyde crosslinking (609,610).

The complexation reaction between the polyions leads to structural changes in both polymers, xanthan and chitosan. A water-insoluble hydrogel is formed by blocking the hydrophilic functions ( $\text{R}-\text{COOH}$  in case of polyanions and  $\text{R}'-\text{NH}_2$  for the polycations) and by the interaction between the macromolecular chains (Fig. 1). The latter effect created an ‘‘ionic’’ reticular network that immobilized the polymers. The hydrogel has the property of incorporat-

**Figure 1.1** The complexation reaction between xanthan and chitosan.

ing a significant amount of structural water as well as the capacity of stabilizing, in its matrix, biological products (611–615).

Recently, we have studied the complexation reaction between xanthan and chitosan by determining the yields and the structure of the complex as well as its swelling capacity. The complexation efficiency readily reaches 90% of the available chitosan and the less deacetylated chitosan (DA = 34%) forms a stable hydrogel having the highest chitosan/xanthan ratio. In fact, the lower the DA, the higher the amount of xanthan needed to form a stable hydrogel. Additionally, we have studied the influence of the pH of the chitosan solution on the yield of complexation with xanthan. The results are shown in Table 6. We notice a poor complexation at low pH due to strong ionization of the amine groups, which impedes its reaction with the carboxylic groups present in the xanthan. Similar results have been reported for the complexation of chitosan with carboxymethyl cellulose (CMC) and alginic acid (616,617).

The decomposition of the chitosan–xanthan hydrogel depends on the pH and the ionic concentration of the buffer solution. In the pH range between 1.2 and 9.2 the hydrogel is stable no matter the ionic concentration present (Fig. 2).

The swelling characteristics and the water content of the hydrogel are shown in Table 7, from which we can notice that water constitutes, in all cases, the largest weight concentration of the hydrogel. The large swelling capacity of these hydrogels does not lead to their disintegration when prepared as microspheres, as in the case for the xanthan–CMC complex (616).

Scanning electron microscope (SEM) images of the hydrogels are shown in Fig. 3 for typical gel samples (24.25% chitosan, 75.75% xanthan). The images convey the mes-

**Figure 1.2** Evaluation of chitosan–xanthan complex stability at different pH conditions. Time: 48 h; buffer solution concentration: 0.2M.

sage that the gels are quite porous and that formation of fibrillar structures takes place. The channels present in the gels have a pore size between  $10^{-7}$  and  $10^{-6}$  m (0.1–1  $\mu$ m), whereas the fibrils have a typical dimension of  $10^{-7}$  m (100 nm). The surface of the microsphere has a homogeneous porous structure (Fig. 3b), which allows the passage of polymeric substrates to the regions where the immobilized enzymes are lodged.

Transmission electron microscope (TEM) images of the hydrogels are shown in Fig. 4. Since the preparation of the samples for TEM inevitably leads to modifications of the sample, care has to be exercised in the interpretation of the micrographs. Figure 4 shows the presence of loose aggregates of fibrils probably resulting from the rupture of the elaborate network, observed via scanning electron microscopy (SEM), due to the drying and cutting procedures used. The aggregates are formed of fiber fragments having typical diameters of 50 to 100 nm in agreement

**Table 6** Influence of the pH of the Chitosan Solution on the Yield of Its Complexation with Xanthan

pH	Xanthan complexation yield (%)

with the SEM observations. A concentration of material near the external surface of the sample is also evident. The “open spaces” (pores) are quite developed toward the center of the sample.

Evaluation of their biocompatibility was carried out with L929 fibroblasts cell line to determine the cytotoxicity and with J774 macrophages cell line to assess the inflammatory response. Cytokines and nitric oxide (NO) are also secreted by the macrophages as indicators of the inflammatory response, and they are known to induce other cells such as T lymphocytes to proliferate and synthesize proteins and additional factors which, in turn, enhance macrophage activation (618–621). Nitric oxide production and efficacy as

**Figure 1.4** Transmission electron microscope images of typical gels (24.25% chitosan, 75.75% xanthan) 48,000 $\times$ .

an immune effector molecule has been also demonstrated in murine models (622). The TNF- $\alpha$ , IL- $\beta$ , and NO secretion as markers for macrophages activation were assessed.

The CH-X complex did not show a cytotoxic effect regardless of degradation time periods and concentration used (Fig. 5) (623).

Production of TNF- $\alpha$  by macrophages was stimulated by CH-X particles for the concentration of 1 mg/mL. This effect was more evident at higher concentration (10 mg/mL). Production of IL-1 $\beta$  was enhanced after macrophage incubation with CH-X particles, while the concentration did not affect the secretion level (Fig. 6). Our study demonstrated clearly that macrophages incubated with

**Figure 1.5** Effect of CH-X particles on L-929 cell viability particles (direct contact).

Figure 1.6 Effect of CH-X particles on IL-1 $\beta$  secretion.

CH-X particles were activated to produce IL-1 $\beta$ . The size of the particles could be not phagocytosable.

Secretion of TNF- $\alpha$  and NO (Fig. 7) is influenced in the same way by CH-X extract products with a slight sensitivity for TNF- $\alpha$  secretion.

Macrophages also play an important role in the phagocytosis of the material and its degradation in vivo. The inflammatory reaction is essential for preparing the wound for the production of a new extracellular matrix. Cytokines and growth factors released by the inflammatory cells attract the fibroblasts into the wound to initiate the reconstruction process. In vivo studies based on light microscopy observations showed a recruitment of specific cell populations responsible for the preparation of wound repair and deposition of new matrices. Their presence is shown in Fig. 8, and the presence of collagen attests to the healing process (Fig. 9). Degradation study on the animal

Figure 1.7 Effects of CH-X extract products on NO<sub>2</sub><sup>-</sup> secretion by J-774 macrophages.

Figure 1.8 TEM micrograph showing fibroblast adhering along CH-X particles (P) after 8 weeks of implantation in rat subcutaneous tissue.

model used indicated a phagocytosis of the CH-X particles by macrophages, which can lead to the entire resorption of the hydrogel.

Shioya et al. (616) developed the encapsulation method using chitosan. The encapsulation is based on the electrostatic interactions of chitosan as a polycation with sodium carboxymethyl cellulose as a polyanion. The objective of this investigation was to identify the factors which control the transmembrane permeability of the capsules prepared with chitosan and CMC (616). The permeability slightly decreases with time. Longer reaction times did not improve

Figure 1.9 LM micrograph (156  $\times$ ) showing dense fibrosis formation with blood vessels (arrows) and inflammatory reaction around CH-X particles (P) after 2 weeks implantation in rat subcutaneous tissue.

the capsule membrane (616). The permeability increases with an increase in the salt concentration. Adding salt may cause a reduction in the effective charge by a shielding effect (623) and then prevent the chitosan from reacting with CMC. In parallel with permeability, the capsule membranes formed by chitosan with salt also have lower mechanical strengths because of a lower density of interpolymer bridge. The lower molecular weight of chitosan may give a more compact membrane structure, thus lower permeability.

The equilibrium adsorption rates of chitosan on oxidized cellulose substrates were determined and are plotted as a function of carboxylic acid group content (624). The increase in absorption with increase in carboxyl group content may arise from two effects (624):

1. Increased electrostatic interaction between polyanion (oxidized cellulose) and polycation (chitosan)
2. Increased substrate surface area due to increased swelling on immersion in water because of increase in the hydrophilic character of the substrate (oxidized cellulose) with increase in the extent of modification

The addition of NaCl has two opposing effects on the absorption of chitosan on oxidized cellulose (624). At low sodium chloride concentration, the dominant effect is reduction of the hydrodynamic volume of the chitosan molecules leading to an increase in the equilibrium adsorption. At higher sodium chloride concentration, competition between  $\text{Na}^+$  ions and cationic groups on the chitosan for the carboxylic acid groups on the cellulose predominates, leading to a gradual decrease in the equilibrium adsorption of chitosan (624).

Remunan-Lopez and Bodmeier (625) investigated optimal conditions for the complex between chitosan and gelatine. All of the optimal conditions—pH, polymer ratio, polymer concentration, temperature, reaction time, and ionic strength—were essentially coincident with chitosan–polysaccharide complexes.

Glycol chitosan (GC) and methyl glycol chitosan (MGC) were, individually, reacted with potassium metaphosphate (MPK) to form a series of water-insoluble macromolecular complexes (MC) in aqueous solution at different hydrogen ion concentration (GC-MPK and MGC-MPK) systems (626). These coagulation curves indicate the dependence of hydrogen ion concentration on the mole ratio of the reacting group of MPK to that of GC, GC +  $\text{CaCl}_2$ , or MGC in the reaction mixture at the beginning and end of the coagulation.

Enzymatic-hydrolyzed chitosan was employed to prepare chitosan–tripolyphosphate and chitosan–polyphos-

phoric acid gel beads using a polyelectrolyte complexation method for the sustained release of anticancer agent, 6-mercaptopurine (627). The complexation mechanism of chitosan beads gelled in pentasodium tripolyphosphate or polyphosphoric acid solution was ionotropic crosslinking or interpolymer complexation, respectively. The drug release patterns of all chitosan gel beads in pH 6.8 seemed to be diffusional based, whereas release profiles in pH 1.2 medium seemed to be non-Fickian diffusion controlled due to the swelling or matrix erosion.

Insulin-loaded chitosan nanoparticles were prepared by ionotropic gelation of chitosan with tripolyphosphate anions (628). The ability of chitosan nanoparticles to enhance the nasal absorption of insulin was investigated in a conscious rabbit model by monitoring the plasma glucose levels. Chitosan nanoparticles enhanced the nasal absorption of insulin to a greater extent than an aqueous solution of chitosan. The amount and molecular weight of chitosan did not have a significant effect on insulin response. In vivo absorption studies in animals have been carried out to evaluate the nasal absorption–promoting activity of chitosan using insulin as a model peptide (629–630).

## F. Chitosan as Scaffolds

It is known that glycosaminoglycans are involved in cell–cell and cell–matrix interactions, and probably act as modulators of cell morphology, differentiation, movement, synthesis, and function (631–633). Chitosan, having structural similarity to glucosaminoglycans, was modified using several proteins (collagen, albumin, and gelatin) to increase surface area and improve biocompatibility. In vitro, collagen-blended chitosan matrices were found to attach more readily to chromaffin cells than gelatin- or albumin-blended matrices (634). Morphological evidence showed that the chromaffin cells attached to collagen-blended chitosan substrate integrated well with the hydrogel matrix and survived for at least 2 weeks under in vivo conditions. Collagen-blended chitosan substrates produce significantly improved bovine adrenal medullary chromaffin cell attachment characteristics, which can be considered for neural tissue engineering studies. Morphological examinations revealed that the chromaffin cells survived for at least 2 weeks with collagen–chitosan scaffolds.

The effectiveness of chitosan as a scaffold of hepatocyte attachment was examined (635). Since chitosan gel was too fragile to use for cell culture, its free amino groups were crosslinked by glutaraldehyde to increase its strength. Rat hepatocytes seeded onto glutaraldehyde-crosslinked chitosan (GA–chitosan) gel could attach with stability to the surface, retaining its spherical form, the same as in vivo, and then release a very small amount of lactate dehy-

drogenase during the 5-day culture period. By contrast, hepatocytes on a collagen-coated surface spread flat, and they released much more lactate dehydrogenase than those on the GA–chitosan gel. Hepatocytes on GA–chitosan also retained higher urea synthesis activity, a liver-specific function, than those on the collagen-coated surface. These results indicate that chitosan is a promising biopolymer as a scaffold of hepatocyte attachment which can be applied to an effective bioartificial liver support system.

The quality of articulate cartilage engineered using a cell–polymer construct depends, in part, on the chemical composition of the biomaterial and whether that biomaterial can support the chondrocytic phenotype. Acknowledging the supportive influence of tissue-specific matrix molecules on the chondrocytic phenotype, Sechriest et al. (636) combined chondroitin sulphate-A (CSA) and chitosan, a glycosaminoglycan (GAG) analog, to develop a novel biomaterial to support chondrogenesis. Chitosan may be combined with the polyanionic CSA such that ionic crosslinking results in hydrogel formation. Bovine primary articular chondrocytes, when seeded onto a thin layer of CSA–chitosan, form discrete, focal adhesions to the material and maintain many characteristics of the differentiated chondrocytic phenotype, including round morphology, limited mitosis, and collagen type II and proteoglycan production.

With an aim of improving bone regeneration, chitosan sponge containing platelet-derived growth factor-BB (PDGF-BB) was developed. For fabrication of chitosan sponge, chitosan solution was freeze-dried, crosslinked, and freeze-dried again. PDGF-BB was incorporated into the chitosan sponge by soaking chitosan sponge into the PDGF-BB solution. Release kinetics of PDGF-BB, cell attachment, proliferation capacity, and bony regenerative potentials of PDGF-BB–loaded chitosan sponge were investigated (637). Release rate of PDGF-BB could be controlled by varying initial loading content of PDGF-BB to obtain optimal therapeutic efficacy. PDGF-BB–loaded chitosan sponge induced significantly high cell attachment and proliferation levels, which indicated good cellular adaptability. PDGF-BB–loaded chitosan sponge demonstrated marked increase in new bone formation and rapid calcification. Degradation of the chitosan sponge was proceeded at defect site and subsequently replaced with new bone. Histomorphometric analysis confirmed that PDGF-BB–loaded chitosan sponge significantly induced new bone formation. These results suggested that chitosan sponge and PDGF-BB–loaded chitosan sponge may be beneficial to enhance periodontal bone regeneration (637).

The ability of cultured human foreskin fibroblasts to bind and to contract lattices of collagen, collagen–chitosan, and collagen–chitosan sulfate was determined (638).

Scanning electron microscopy of the cellular lattices showed fibers of the collagen–chitosan mixture to be the thickest and with altered organization. These results show that chitosan sulfation markedly enhances fibroblast adhesion and promotes contraction of a collagen lattice compared to the unsulfated material. By analogy to the *in vivo* sequence of hyaluronan followed by sulfated glycosaminoglycans in wounds, the results suggest that glycosaminoglycan sulfation may be a contributing signal for phenotypic transformation during wound healing (638).

### G. Chitosan-Based Vector–DNA Complexes for Gene Delivery

Chitosan is a candidate nonviral vector for gene delivery. Therefore, formation of DNA particles with chitosan (639) or chemically modified chitosan (640), such as N,N,N-trimethylchitosan, has been investigated for gene transfer. Successful chitosan-mediated transfection has been reported for a few cell types, such as HEK 293 cells (639). Erbacher et al. (641) have found chitosan presents some characteristics favorable for gene delivery, such as the ability to condense DNA and to form homogeneous population of complexes, smaller than 100 nm, in defined conditions. Moreover, chitosan could easily be chemically modified by coupling ligands, such as lactose, in order to target cells expressing a galactose-binding membrane lectin. With the aim of developing a chitosan-based vector system, various biophysical characteristics of chitosan-condensed DNA complexes were measured, and several transfection experiments mediated by chitosan and lactosylated chitosan were performed (642).

In order to achieve an efficient gene delivery via receptor-mediated endocytosis, the synthesis of a novel chitosan derivative having recognizable saccharide residues, N,N,N-trimethylchitosan–galactose conjugate, was performed (643). The formation of a polyelectrolyte complex with DNA and the cellular recognition of N,N,N-trimethylchitosan–galactose conjugate were tested, and then the possibility of its application as a gene delivery tool was investigated.

Chitosan is a polysaccharide that demonstrates much potential as a gene delivery system. The ability of a commercially available chitosan and depolymerized chitosan oligomers to condense plasmid was determined using TEM and microtitration calorimetry, while the diameter and stability of the resultant complexes were measured using laser light scattering (644). A selected complex containing a lytic peptide was administered in the upper small intestine and colon of rabbits, and reporter gene expression was measured in defined intestinal tissues. Reporter gene expression was enhanced in defined intestinal tissues, al-

though levels of expression remained low. The combination of strong complex stability and low *in vivo* expression levels suggest that uptake and/or decomplexation, but not endosomal release, may be the critical rate-limiting steps in the uptake process.

Many cationic polymers (645–649) have been explored as nonviral vectors. Highly purified chitosan fractions of  $\leq 5000$  Da (N1), 5000–10,000 Da (N2), and  $\geq 10,000$  Da (N3) were prepared and characterized in respect of their cytotoxicity, ability to cause hemolysis, ability to complex DNA, as well as ability to protect DNA from nuclease degradation (650). Chitosan–DNA interaction at a charge of 1:1 was much greater than seen for poly(L-lysine), and complexation resulted of DNA degradation by DNase II:  $99.9 \pm 0.1$ ,  $99.1 \pm 1.5$ , and  $98.5 \pm 2.0\%$  for N1, N2, and N3, respectively. After intravenous injection, all the chitosans showed rapid blood clearance. The observations that the highly purified chitosan fractions used were neither toxic nor hemolytic, that they have ability to complex DNA and protect against nuclease degradation and that low molecular weight chitosan can be administered intravenously without liver accumulation suggest there is potential to investigate further low molecular weight chitosans as components of a synthetic gene delivery system (650).

Hydrophobically modified chitosan containing 5.1 deoxycholic acid groups per 100 anhydroglucose units was synthesized by an EDC-mediated coupling reaction. Formation and characteristics of self-aggregates of hydrophobically modified chitosan were studied by fluorescence spectroscopy and dynamic light scattering method (651). Charge complex formation between self-aggregates and plasmid DNA was confirmed by electrophoresis on an agarose gel.

Mao et al. (652) describe a new immunoprophylactic strategy using oral allergen gene immunization to modulate peanut antigen-induced murine anaphylactic responses. Oral administration of DNA nanoparticles synthesized by complexing plasmid DNA with chitosan resulted in transduced gene expression in the intestinal epithelium. Oral allergen gene immunization with chitosan–DNA nanoparticles is effective in modulating murine anaphylactic responses, and indicates its prophylactic utility in treating food allergy.

## H. Chitosan Derivatives

In the 1990s chitosan turned out to be a useful excipient in various pharmaceutical formulations. By modifications of the primary amino group at the 2 position of this poly ( $\beta 1 \rightarrow 4$ -D-glucosamine), the features of chitosan can even be optimized according to a given task in drug delivery

systems. For peroral peptide delivery these tasks focus on overcoming the absorption (I) and enzymatic barrier (II) of the gut. On the one hand, even unmodified chitosan proved to display a permeation-enhancing effect for peptide drugs. On the other hand, a protective effect for polymer embedded peptides toward degradation by intestinal peptidases can be achieved by the immobilization of enzyme inhibitors on the polymer. Whereas serine proteases are inhibited by the covalent attachment of competitive inhibitors such as the Bowman-Birk inhibitor, metallopeptidases are inhibited by chitosan derivatives displaying complexing properties such as chitosan–EDTA conjugates. In addition, because of the mucoadhesive properties of chitosan and most of its derivatives, a presystemic metabolism of peptides on the path between the dosage form and the absorption membrane can be strongly reduced. Based on these unique features, the co-administration of chitosan and its derivatives leads to a strongly improved bioavailability of many perorally given peptide drugs such as insulin, calcitonin, and buserelin. These polymers are therefore useful excipients for the peroral administration of peptide drugs (653).

To increase chitosan's utility, it has been N-derivatized by phosphonomethylation (PM-chitosan) or by carboxymethylation (CM-chitosan). Both derivatives dissolve easily in water at neutral conditions. Moreover, these derivatives maintain the beneficial cosmetic properties of chitosan (654).

Chitosan succinate and phthalate matrices showed pH-dependent release profiles of the entrapped diclofenac sodium (655). Maximum drug release was observed under pH 7.4, in contrast to pH 2 at which the matrices resisted dissolution.

A simple carbohydrate polymer glycol chitosan (degree of polymerization approximately 800) has been investigated for its ability to form polymeric vesicle drug carriers. The attachment of hydrophobic groups to glycol chitosan should yield an amphiphilic polymer capable of self-assembly into vesicles. Chitosan is used because the membrane-penetration enhancement of chitosan polymers offers the possibility of fabricating a drug delivery system suitable for the oral and intranasal administration of gut-labile molecules. Glycol chitosan modified by attachment of a strategic number of fatty acid pendant groups (11–16 mol%) assembles into unilamellar polymeric vesicles in the presence of cholesterol. These polymeric vesicles are found to be biocompatible and hemocompatible and capable of entrapping water-soluble drugs (656). These polymeric vesicles efficiently entrap water-soluble drugs.

Investigations of chitosan citrate as a hydrocolloidal matrix material (657–659) and as the wall of a microcapsule (660) have been reported.

A chitosan with lauryl groups attached to amino groups to provide the hydrophobic moieties and carboxymethyl groups attached to hydroxy groups to provide the hydrophilic moieties [N-lauryl-carboxymethylchitosan (LCC)] was newly synthesized. The solubility of taxol in LCC micelles in aqueous solution was examined (661). It was found that LCC solubilized taxol by forming micelles with particle sizes less than 100 nm. This particle size was considered effective for passive targeting for tumors. The concentration of taxol in the micellar solution was very high, with a maximum of 2.37 mg/mL.

### I. Macromolecular Prodrugs Based on Chitosan

5-Fluorouracil (5FU) has remarkable antitumor activity. In order to provide a polymeric prodrug of 5FU with reduced side effects, having affinity for tumor cells, and exhibiting high antitumor activity, four kinds of chitosan derivatives were synthesized carrying 5FU through some kinds of spacers via ether, amide, ester, or carbamoyl bonds (662,663). Chitosan-fixing 5FU at the 2 position through a hexamethylene spacer and carbamoyl linkages exhibits a higher effect with respect to prolongation of life than free 5FU. Small-sized chitosan gel nanospheres, containing 5FU or immobilizing 5FU derivatives (aminophenyl-carbamoyl-5FU or aminopentyl-ester-methylene-5FU), were prepared by the glutaraldehyde crosslinking technique and the emulsion method (663). When chitosan was crosslinked with glutaraldehyde, these 5FU derivatives were simultaneously immobilized to chitosan by means of Schiff's base formation. The chitosan gel nanospheres were coated with anionic polysaccharides.

Covalently drug-pendant 6-O-carboxymethyl-chitin (CM-chitin) was synthesized, in which process the drug was coupled through an enzyme-susceptible bond (664). Chromophore-terminating peptides were coupled with CM-chitin as a model for a CM-chitin–drug conjugate. The amino acid composition of the spacer and the spacer length were found to be preliminary regulation factors for two-step hydrolysis of the polymeric drug.

The water-soluble conjugates of mitomycin C (MMC) with N-succinyl-chitosan (N-suc-chitosan) and glycol-chitosan (gly-chitosan), named N-suc-chitosan-glu-MMC and gly-chitosan-glu-MMC, respectively, were characterized mainly by the plasma concentration time profiles of MMC after intraperitoneal administration and their in vivo antitumor effect against P388 leukemia and Sarcoma-180. Before in vivo evaluation, polymer–drug binding characteristics were checked by gel chromatography (665). For the Sarcoma-180 solid tumor inoculated subcutaneously, the polymer characteristics affected the antitumor effect. That is, with the intravenous injection, gly-chitosan-

glu-MMC hardly exhibited any tumor growth inhibition, but N-suc-chitosan-glu-MMC showed significant tumor growth suppression. As to the intratumoral administration, the tendency to suppress tumor growth was observed in MMC and both the conjugates.

### J. Sterilization of Chitosan

Chitosan has potential biomedical applications that may require the final products to be sterilized before use. The gamma irradiation of purified and highly deacetylated chitosan fibers and films at sterilizing doses (up to 25 KGB) caused main chain scissions. The viscosity average molecular weight of the polymer decreased with increasing irradiation dose (666). Irradiation in anoxia did not affect film properties significantly.

# Biomimetics

**Weiyuan John Kao**

*University of Wisconsin, Madison, Wisconsin*

### I. INTRODUCTION

Current biomaterial research efforts mainly focus on elucidating the specific interaction among material physicochemical properties, proteins/enzymes and various biological molecules, observed cellular functions, and physiological parameters such as mechanical forces in vitro and in vivo (1–10). Based on these investigations, biomaterial developments have begun to utilize the diversity and uniqueness of biology for potential methods to control biological behavior of a myriad of tissue engineering and biomedical applications. As the result of this novel approach and new technology, the field of biomimetic materials emerges. However, the root of biomimetics can be traced to the early 1970s when functional artificial molecules were designed and synthesized by mimicking the functional structure and synthesis pathway of natural compounds. For example, biomimetic methodologies were employed to selectively synthesize antileukemic triptolides (11), cyclical polyenes such as racemic 11 $\alpha$ -hydroxyprogesterone (12–14), camptothecin chromophores (15), catechol estrogens (16), polyketone-derived phenols (17), D-glucose-derived (+)-biotin (18), and much more. In the 1980s and early 1990s, the field of biomimetics expanded dramatically to such areas as antitumor pharmaceuticals (19–21), the development of receptor agonists and antagonists (22,23), the study of functional structures and syntheses of proteins and nucleotides (24), and the elucidation of biological pathways such as enzyme catalysis (25). In the late 1990s and into the new millennium, biomimetic

methodologies have been employed as an engineering tool to develop novel material processing methods such as calcium phosphate coatings on metal alloys (26) and poly(L-lactic acid)-co-apatite composites (27), to formulate biofunctional materials for biomedicine and bioengineering such as synthetic peptide amphiphiles (28) and polymers derived from molecular and microbiology (29–31), and to continue to be utilized in probing the molecular fundamentals and mechanisms of biology.

Although the biomimetic approach has been employed by various scientific disciplines to develop novel molecules and materials, there is not a consensus in the definition of “biomimetics” that is accepted by various science communities, namely, engineering, chemistry, medicine, and life sciences. Nonetheless, the semantic definition is the ability to camouflage a substance with suitable contrivances similar to the environmental background with the aim to elude a hostile observer. However, such a definition is insufficient and narrow. Hence, the author argues that in the biological and engineering arena, the application of mimetism should be broad and hence dynamic and encompassing. The author will attempt to address the wide spectrum of biomimetics in this chapter by highlighting selected research investigations in which the knowledge of biological sciences has been adopted as a template in the study and development of novel molecules and materials. The author will emphasize the complementary interrelationship between biomimetic research and the pursuit of understanding the complex biological system. Biological systems fundamentally function at the angstrom scale of

molecular atoms, the nano scale of macromolecules, the micron scale of cells and protein matrices, and the macro scale of tissues, organs, and macroorganisms (32). The uniqueness of biological materials and systems is the metastable microstructure formed from the molecular to macroscale in order to attain a combination of required properties (i.e., physical, chemical, biological, structural, etc.) for optimal function. Hence, the intricate micro- and macroarchitecture and multifunctional properties of biological systems are utilized as foundations in the investigation of biomimetic materials. By studying the hierarchical structure of biological systems and biological constituents at all possible scales of spatial resolution, the fundamentals of the unique structural designs can be deduced and mimicked by currently available techniques. Alternatively, the molecular synthesis and processing mechanism of biological systems and biological components can be elucidated and applied to develop novel materials (32). Both strategies embody the principle and the dynamic nature of biomimeticism. Investigations adopting these broad research principles will be presented in this chapter as illustrative examples of biomimetic macromolecules and novel biomaterials with potential biomedical values.

## II. BIOFUNCTIONAL MOLECULAR BIOMIMETICS

From the beginning of biomimetic research in the field of chemistry, pharmaceutical sciences, and biochemistry, bioactive molecules have been synthesized by studying the native functional structure and natural synthesis pathways of model molecules. This approach continues to this day. Of particular interest to biomedicine is the investigation on superoxide dismutase (SOD) enzymes to catalyze oxygen radicals for the management of chronic inflammation, excessive oxidative metabolism, and tumor (19–21). For example, hemodialysis polymer membranes may activate the phagocyte oxidative metabolism resulting in the highly oxidized low-density lipoprotein found in uremic patients. Superoxide dismutase eliminates the highly reactive and hence destructive superoxide radicals and participates in the oxygen radical detoxification process. However, the native SOD molecule is highly unstable and has low bioavailability and high immunogenicity. The biomimetic approach to develop molecules with SOD activity was first pioneered by Yamamoto et al. (21) and continued by Ohse and Nagaoka, who demonstrated that the reaction of various metalloporphyrins and poly(styrene-co-maleic anhydride) copolymers resulted in the formulation of novel chimeras with pH sensible sites and SOD-like active sites (Fig. 1) (33). Using in vitro assay systems based on cyto-

chrome-*c*, the low molecular weight metalloporphyrins catalyzed the dismutation of  $O_2^-$  with a rate constant of  $10^7$ – $10^8$ /M/s. The  $k_{cat}$  value for the multifunctional chimera of metalloporphyrins and poly(styrene-co-maleic anhydride) was found to be  $1.1 \pm 0.1 \times 10^6$ /M/s at 8.1 pH in vitro. In vivo studies demonstrated that the chimera construct of metalloporphyrins and poly(styrene-co-maleic anhydride) bound to the warfarin site of albumin and showed an enhanced half-life circulation time; while the SOD activity was retained.

In the design of biofunctional molecules to study and modulate host cell behavior (34), Kao et al. have chosen a family of active proteins, i.e., interleukin-1 (IL1), as a model in the design of biofunctional molecules. IL1 $\beta$  is a potent proinflammatory cytokine that upregulates cellular function upon ligation with IL1 receptor type I (IL1RI) on the extracellular membrane (35). IL1 $\beta$ -activated macrophages (a primary class of phagocytic leukocytes) may release high levels of IL1 $\beta$ , tumor necrosis factor  $\alpha$ , and granulocyte/macrophage-colony stimulating factor (GM-CSF), which all have important roles in the healing process (1,4,9,36). Circulating IL1 receptor antagonist (IL1ra) is the natural antagonist for IL1 $\beta$ . IL1 $\beta$  ligates with Domain 1, 2, and 3 of IL1RI and initiates signaling pathways to upregulate cellular functions (37); whereas, IL1ra only binds with Domain 1 and 2 of IL1RI, resulting in no postligation signal transduction (38). It has been proposed that IL1 $\beta$  complexes with Domain 3 of IL1RI by a strong electrostatic interaction. Kao et al. designed macromolecules based on the functional architecture of IL1 $\beta$  and IL1ra. Antagonists were designed from known IL1 $\beta$  and IL1ra amino acid residues showing strong avidity toward Domain 1 and 2 of IL1RI (35,37–39). These residues are R<sup>(4)</sup> L<sup>(6)</sup> F<sup>(46)</sup> I<sup>(56)</sup> K<sup>(103)</sup> E<sup>(105)</sup> of IL1 $\beta$  and W<sup>(17)</sup> Q<sup>(21)</sup> Y<sup>(35)</sup> Q<sup>(37)</sup> Y<sup>(148)</sup> of IL1ra (35,37–40). Strong evidence suggests that these amino acids are essential in ligand–receptor interaction. The tertiary structures of the native IL1 $\beta$  and IL1ra molecule in solution were utilized as a guide in determining the spatial interrelationship between each residue. The minimum distance between each residue was approximated using the structural coordinates archived in the SwissProt Database<sup>®</sup>. Based on the measurement, a polyglycine sequence of approximately the same length was utilized to link each amino acid at all possible orientations. Kao et al. further hypothesized that the resulting antagonist sequences, which target Domains 1 and 2 of IL1RI, can be converted to agonists by coupling a strong electrostatic moiety (i.e., poly-lysine) to the terminal amino acid of the antagonist sequence, thus allowing the complexation between the peptide macromolecule and Domains 1, 2, and 3 of IL1RI to occur. To formulate agonists, a trimeric glycine linker was utilized to join the antagonist domain with

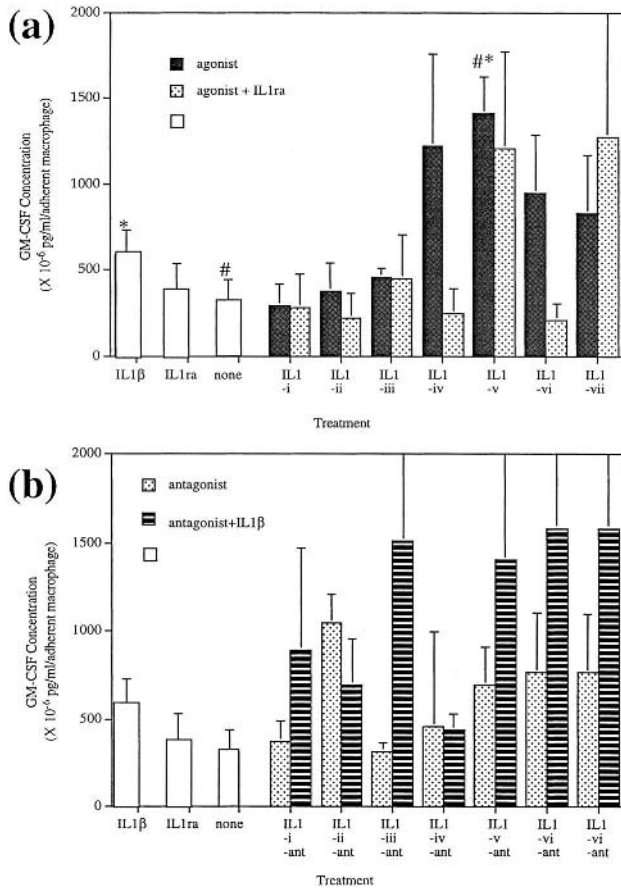

**Figure 2.1** Structure of poly(styrene-co-maleic anhydride)-co-metalloporphyrin derivatives with superoxide dismutase activity. (Adopted from Ref. 33.)

the poly-lysine domain. The trimeric glycine linker was designed to introduce spatial flexibility between the poly-lysine sequence and the antagonist oligopeptide domain since chain mobility may impact the dynamics of ligand-receptor association. Consequently, a library of linear oligopeptides were formulated and synthesized using solid-resin methods with standard 9-fluorenylmethyloxycarbonyl chemistry (41). Peptides thus formulated were designated as follows. Antagonists included those modeled after the IL1 $\beta$  molecule: (IL1iant) RGGLGGFGGIGKGGEG, (IL1iiant) FGRGGLGGGIGKGGEG, and (IL1iiiant) LGGRGFGGIGKGGEG; those modeled after the IL1ra molecule: (IL1ivant) WGGGQGGYGGQGGGYG and (IL1vant) WGGYGGQGGYGGQG; and that modeled after antagonists developed via combinatorial chemistry (40): (IL1viant) YWQPYALPL. Agonists included those modeled after the IL1 $\beta$  molecule: (IL1i) KKKGGGRGGLGGFGGIGKGGEG, (IL1ii) KKKGGGFGRGGLGGGIGKGGEG, and (IL1iii) KKKGGGLGGRGFGGIGKGGEG; those modeled after the IL1ra molecule: (IL1iv) KKKGGG WGGGQGGYGGQGGGYG and (IL1v) KKKGGGWGGYGGQGGYGGQG; and those modeled after antagonists developed via combinatorial chemistry (40): (IL1vi) KKKGGGYWQPYALPL and (IL1vii) YWQPYALPLGGGKK. Human blood monocyte-derived macrophages were allowed to adhere on tissue culture polystyrene for 2 h in

the presence of autologous serum in the culture medium. After 2 h, nonadherent cells were removed and adherent cells were challenged with free peptides at an optimal concentration of 50 pmol/mL that had been determined previously. Simultaneously, adherent cells were also challenged with or without recombinant human IL1 $\beta$  or IL1ra at 25 pmol/mL. Peptides with scrambled amino acid sequences were also employed as peptide controls. Cells were cultured thereafter in the presence of autologous serum and supernatants were collected at various time points for assay. At 4 h after the peptide challenge, no differences in GM-CSF release by adherent macrophages were observed among all test samples and controls. At 18 h after the free peptide challenge, IL1 $\beta$ -treated adherent macrophages on tissue-culture polystyrene (TCPS) showed a higher GM-CSF release than controls without treatment (Fig. 2a). Adherent macrophages treated with agonist IL1v showed a higher GM-CSF release than that treated with IL1 $\beta$ , IL1ra, none, and other agonists. It is known that IL1 $\beta$  upregulates GM-CSF release by human macrophages via the induction of AP-1 and NF $\kappa$ B gene expression factors. The result suggests that IL1v activates these gene expression factors resulting in an increased GM-CSF production. The GM-CSF level of cells treated with IL1v remained comparable when IL1ra was added simultaneously as the IL1v peptide indicating that the effect of IL1v in increasing GM-CSF release

**Figure 2.2** The release of GM-CSF by adherent human blood-derived macrophages (normalized to adherent macrophage density) on tissue-culture polystyrene after 18 h incubated with (a) biomimetic agonists derived from IL1-family proteins with or without recombinant human IL1ra (\* represents  $p < 0.05$  versus values of “none” control; # represents  $p < 0.05$  versus values of IL1 $\beta$  control; IL1v values were larger than that of IL1i, IL1ii, IL1iii, IL1vi, and IL1vii at  $p < 0.05$ ); or (b) biomimetic antagonists derived from IL1-family proteins with or without recombinant human IL1 $\beta$  (\* represents  $p < 0.05$  versus values of “none” control; # represents  $p < 0.05$  versus values of IL1 $\beta$  control; no differences at  $p > 0.95$  were found among each test group indicating that the GM-CSF release mediated by antagonists was not neutralized by the presence of IL1 $\beta$ ). All values mean  $\pm$  s.e.m.,  $n = 4$ .

by adherent macrophages was not neutralized in the presence of the natural IL1 $\beta$  antagonist, namely, IL1ra. No significant differences in the GM-CSF release were observed between macrophages without treatment and those treated with both IL1 $\beta$  and one of the antagonists (Fig. 2b). These results indicate that the IL1-derived biomimetic antagonists neutralized the ability of IL1 $\beta$  in increasing the re-

lease of GM-CSF by adherent macrophages. Recombinant IL1 $\beta$  and IL1ra proteins have been investigated for their potential therapeutic values. For example, IL1 $\beta$  augments hematopoiesis and increases wound healing; whereas, IL1ra attenuates host inflammatory reaction. However, the clinical value of these regimens has yet to be demonstrated due to high cost, low bioavailability, deleterious side effects of the high dosage that is often required, and the presence of natural agonists, antagonists, and serum proteases. Hence, IL1-derived agonists and antagonists are currently under extensive investigation by pharmaceutical companies and basic science research laboratories to improve the therapeutic value of native IL1 $\beta$  and IL1ra moieties (42–44). IL1-derived agonists have demonstrated potential in increasing hematopoietic stem cell proliferation, increasing B cell proliferation, enhancing local wound healing, and modulating collagenase production. IL1-derived antagonists have shown promise in decreasing the extent of acute and chronic inflammation in diseases such as rheumatoid arthritis, treating septic shock, suppressing chronic leukemia, and modulating bone resorption by osteoclasts. These two examples illustrate the uniqueness of a biomimetic approach to develop synthetic molecules derived from naturally occurring precursors such as SOD and IL1 family proteins. These biomimetic molecules demonstrate enhanced biochemical and physical properties that can be employed to study biological systems and potentially improve clinical medicine.

### III. NOVEL POLYMERIC MATERIALS CONTAINING PEPTIDE/PROTEIN BIOMIMETICS

Currently, several laboratories have taken the biomimetic approach to develop novel biomaterials containing biologically derived functional moieties to modulate specific cellular behavior in a variety of physiological systems such as cardiovascular, orthopedic, and nervous. The overall goal of these investigations is to obtain fundamental understanding of the complex biological–material interaction; the knowledge is necessary for the construction of tissue engineered devices and novel therapeutic biomedical products. Hubbell and West have focused on the study and development of enzymatically degradable hydrogels that are responsive to the local host environment (45,46). For example, West et al. utilized known protease substrate peptides (i.e., sequence LGPA from collagenase, sequence AAA from elastase, or sequence NRV from plasmin) copolymerized with polyethyleneglycols using dicyclohexylcarbodiimide-based chemistry to formulate BAB (peptide–polyethyleneglycol–peptide) block copolymers. The BAB

copolymers were reacted with acryloyl chloride to provide photopolymerizable end groups. ABA (polyethyleneglycol-peptide-polyethyleneglycol) block copolymers were formed by reacting the peptide with two amine groups such as lysine residues at the C terminus with polyethyleneglycol-N-hydroxysuccinimide monoacrylate. Cell adhesive peptides such as RGDs were also reacted with polyethyleneglycol-N-hydroxysuccinimide monoacrylate and were subsequently grafted into the photopolymerized ABA hydrogel network. Hydrogel networks were formulated via photopolymerization with block copolymers, triethanolamine, and 2,2-dimethoxy-2-phenyl acetophenone photoinitiator in 1-vinyl-2-pyrrolidone (47). After the BAB (peptide-polyethyleneglycol-peptide)-containing hydrogels were hydrated to equilibrium, type IV collagenase, porcine pancreatic elastase, or plasmin at various concentrations was added to the hydrogel to commence degradation. Hydrogels were found to degrade in a protease-specific and dose-dependent fashion that increased with increasing treatment time. When the ABA (polyethyleneglycol-peptide-polyethyleneglycol)-containing hydrogel network grafted with the RGDs cell adhesion mediating motif was cultured with human dermal fibroblasts, cells were found to adhere and migrate throughout the hydrogel matrix. Since the polymer construct degrades enzymatically in the presence of a specific enzyme substrate, the degradation path within the hydrogel can be controlled spatially and temporally by varying the hydrogel chemical composition. These bioresponsive materials allow the study of cell migration mechanisms and function. Similar methodologies are currently being utilized by Hubbell et al. to investigate and to partly control the biomolecular mechanism of neurite extension and migration within a similar polyethyleneglycol-containing, bioresponsive hydrogel system immobilized with enzymatically degradable peptides (48,49).

In the development of biofunctional materials by mimicking ligand-receptor interactions, a clear understanding of the function-structure relationship between target proteins and cell membrane receptors is crucial. Furthermore, the ultimate challenge of eliciting specific cellular function by utilizing biofunctional materials lies within the normal host foreign body response, which might overcome the bioactive functionalities in the material intended to modulate cellular function. The major function of blood-derived phagocytic monocytes and macrophages is to mediate the normal host immune and inflammatory response against foreign objects such as microorganisms and biomaterials (1). Several characteristic macrophage functions are identified as critical events in the foreign body response. Macrophages recognize adsorbed proteins on the foreign surface via several ligand-receptor superfamilies (4). The process

of adherent macrophage activation and fusion to form multinucleated foreign body giant cells (FBGC) is unique to the macrophage phenotype. The presence of FBGCs is utilized as a histopathology marker for chronic inflammation and the host foreign body reaction. Foreign body giant cells have been demonstrated on implanted biomaterials and the rate of material degradation underneath the giant cells has been shown to be markedly increased (50). However, the molecular mechanisms involved in FBGC formation remain unclear. Activated macrophages may release a variety of cytokines, growth factors, and other bioactive agents to modulate the function of other cell types in the inflammatory milieu (1). Several macrophage-derived cytokines and growth factors are utilized on a limited basis to alter the inflammatory response and promote the healing process. For example, IL1 $\beta$  and GM-CSF are given to injured patients and bone marrow transplant recipients to assist the recovery of hematopoiesis (42-44). Pharmaceuticals based on the property, function, and structure of anti-tumor necrosis factor  $\alpha$  are administered to patients suffering from chronic inflammation in order to enhance the wound healing process and attenuate inflammation (44). However, the long-term clinical efficacy of treatments involving the systemic administration of these bioactive agents has yet to be demonstrated. Hence, the localized delivery of selected cytokines and growth factors produced by endogenous inflammatory cells is desirable and may have potential therapeutic value in the fundamental processes of tissue healing, growth regulation, and biocompatibility.

Before the ability to control specific cellular function via biomaterials can be realized, a more detailed understanding of the interplay between material-bound ligands and receptors on the cell surface must be obtained. Furthermore, the redundancies that exist between receptors and target proteins must also be addressed. For instance, the tripeptide RGD sequence is found in several extracellular matrix proteins such as fibronectin, vitronectin, and fibrinogen. Several cell membrane receptors on different types of cells have been shown to complex with the RGD cell adhesion motif of these matrix proteins. For example, platelet surface glycoprotein IIb/IIIa recognizes the RGD sequence of fibrinogen, and integrin  $\alpha_5\beta_1$  and  $\alpha_{IIb}\beta_3$  receptors on macrophages also recognize the RGD motif of fibronectin. Other integrin receptors on a variety of cell types that recognize the RGD cell binding motif are  $\alpha_{(2,3,4,5,7,8,v)}\beta_1$  and  $\alpha_v\beta_{(1,3,5,6,8)}$ . Some of the current biomaterial development and research utilize the RGD sequence to provide bioactive sites for cell adhesion. However, it is apparent that such a design strategy to elicit a specific cellular function is limited by the redundancies that exist between receptors and target proteins.

A clear elucidation of the mechanism involved in the interaction among cells, proteins/enzymes, materials, and various physiological parameters such as mechanical forces is critical for the development of biomimetic materials with specific cellular activity in the new field of cellular engineering (Fig. 3). The author acknowledges the critical role of this type of fundamental research at the molecular level between cells and material surfaces in the development of novel enabling technologies. The resulting technologies and know-how are vital for the future of tissue engineered products, the improvement of clinical biomaterials, and the construction of biofunctional materials.

Several methodologies were utilized to examine the interrelationship between material chemistry and cellular behavior at protein and cellular levels under *in vitro* and *in vivo* environments (1–10). Based on these findings, Kao et al. designed methodologies to probe the molecular mechanism of receptor–ligand recognition and postligation cellular function (51,52). In one of the studies, Kao et al. designed and employed biomimetic oligopeptides to probe the effect of primary and tertiary structures of a model protein (*i.e.*, fibronectin) in ligand–receptor interaction (52). Synthetic peptides were formulated based on the primary and tertiary structures of human plasma fibronectin (53,54). Specifically, the amino acid sequences PHSRN

#### Current Research:

#### Future Research in “Cellular Engineering”:

**Figure 2.3** Current research focuses on elucidating the complex mechanisms in the interaction among cells, proteins/enzymes, materials, and various physiological parameters such as mechanical forces. Fundamental research at the molecular level results in the development of novel “enabling technologies” that are critical for the development of biomimetic materials with specific cellular activity in the new field of “cellular engineering.” Manipulation of cellular function is vital for the future of tissue-engineered products, the improvement of clinical biomaterials, and the pursuit of novel biofunctional materials.

(55) and RGD (56), which are located in the FIII-9 and the FIII-10 modules, respectively, of the central cell binding domain (Fig. 4) and the sequence PRRARV of the C terminal heparin binding domain of fibronectin (53) were chosen for exploration. RGD and PHSRN are present on adjacent loops of two connecting FIII modules and bind synergistically to the same integrin receptor (57). The heparin binding domain of fibronectin in which the sequence PRRARV resides also binds directly with integrin receptors (58,59); however, the precise mechanisms involved in this association remain unclear. The tertiary structure of fibronectin (60,61) was used as a guide in the design of peptides that included RGD and PHSRN. The distance between these sequences was approximated using the structural coordinates archived in the SwissProt Database (sequence FINC\_HUMAN P02751). Based on the measurement, a hexamer of glycine ( $G_6$ ) of approximately the same length was used to link the two bioactive sequences in both possible orientations. The combination of RGD and PRRARV was studied using a  $G_6$  linker; although in this case the  $G_6$  linker was not selected based on any structural considerations. A terminal trimeric glycine domain ( $G_3$ ) was employed as a spacer in all peptides. Oligopeptides were synthesized using solid-resin methods with standard 9-fluorenylmethyloxycarbonyl chemistry (41). The following oligopeptides were synthesized:  $G_3$ RGDG,  $G_3$ PHSRNG,  $G_3$ PRRARVG,  $G_3$ RGDG $_6$ PHSRNG,  $G_3$ PHSRNG $_6$ RGDG,  $G_3$ RGDG $_6$ PRRARVG, and  $G_3$ PRRARVG $_6$ RGDG. A cyclic RGD peptide with an amino acid sequence of LNQEQVSPD(cRGDGRN) was utilized for comparison. LNQEQVSPD is a leader sequence and the cyclical RGDGRN sequence has been shown to bind with  $\alpha_v\beta_3$  integrin with high specificity and affinity (62). Peptides were immobilized onto a polymer network terpolymerized with polyethyleneglycol, acrylic acid, and trimethylolpropane-triacrylate (51,52). The network had been shown to mediate low levels ( $<30$  cells/mm<sup>2</sup>) of adhesion by human macrophages, human neonatal foreskin dermal fibroblasts, and human umbilical vein endothelial cells in serum-containing culture medium up to 10 days. Macrophage ad-

hesion and FBGC formation in vitro assays (63) were performed. Under the FBGC culture condition described, FBGCs containing up to 50 nuclei/cell formed consistently on tissue-culture polystyrene control surfaces. Briefly, freshly isolated human blood-derived monocytes were incubated with samples in RPMI containing 20% autologous serum. At 96 and 168 h, the medium was changed to RPMI with heat-inactivated autologous serum + 10 ng/mL of recombinant human interleukin-4 + 5 ng/mL of recombinant human GM-CSF. Each adherent cell with three or more nuclei per cell was defined as a FBGC. Competitive inhibition studies utilizing soluble free peptides and neutralizing antibodies were performed to ascertain ligand–receptor specificity and identification. Kao et al. (52) found that serum fibronectin modulated macrophage adhesion and the extent (i.e., size) of FBGC formation on control surfaces in the presence of serum proteins. Macrophages adhered to all peptide-grafted polymer networks with relatively subtle differences between adhesion mediated by RGD, PHSRN, PRRARV, or combinations thereof (Table 1) (52).  $\beta_1$  integrin subunit was essential in macrophage adhesion to peptide-grafted networks in a receptor–peptide specific manner; whereas,  $\beta_3$  integrin subunit was less important. Macrophage adhesion to PRRARV was mediated primarily by the direct interaction with integrins. RGD or PHSRN alone did not provide an adequate substrate for macrophage fusion to form FBGCs. However, the PHSRN synergistic site and the RGD site in a single oligopeptide provided a substrate for FBGC formation that was statistically comparable to that on the positive control material

in the presence of serum proteins (Table 2) (52). This response was highly dependent upon the relative orientation between RGD and PHSRN. PRRARV alone or in tandem with RGD in a single peptide formulation did not support FBGC formation. Furthermore, neutralizing antibody was utilized in the FBGC culture assay to partly determine the role of integrins and fibronectin-derived oligopeptides in modulating the function of adherent macrophages to fuse and form FBGCs. Antibody isotype negative controls were also utilized for confirmation. Both integrin  $\beta_3$  and  $\beta_1$  subunits were found to play an importance role in mediating FBGC formation by macrophages adhered on peptide-grafted networks (Table 3) (52). Results showed that no antibody– and anti- $\beta_3$  neutralizing antibody–treated groups had a comparable FBGC density on TCPS (Table 3). On most of the peptide-grafted network, no FBGC formation was observed in the anti- $\beta_3$  antibody–treated group. One notable exception was the peptide that contains the PHSRN and the RGD domain in the optimal orientation, namely G<sub>3</sub>PHSRNG<sub>6</sub>RGDG, on which anti–integrin  $\beta_3$  reduced FBGC formation by about 70%. When anti- $\beta_1$  neutralizing antibody was utilized, no FBGC formation was observed on any sample. Macrophages and FBGCs express  $\alpha_2$ ,  $\alpha_4$ ,  $\beta_1$ , and  $\beta_3$  integrin subunits. It is also known that the first 160 amino acids of integrin  $\beta_1$ , specifically the  $\alpha$ -helix formed by residues 141 to 160, are critical in integrin–ligand recognition. These findings suggest that the association between this region of the integrin  $\beta_1$  receptor and G<sub>3</sub>PHSRNG<sub>6</sub>RGDG, but not G<sub>3</sub>RGDG<sub>6</sub>PHSRNG, results in the necessary binding characteristic that determine the subsequent cellular event leading to FBGC formation. Activated integrin  $\beta_1$  or  $\beta_3$  intracellular domains stimulate cell migration, modulate proliferation

and gene expression, induce the assembly of F-actin cytoskeleton, and localize the activity of focal adhesion kinase pp125<sup>FAK</sup>. These cellular events may contribute to the process of FBGC formation; however, the exact interrelationship between ligand–receptor architecture and association in activating intracellular signaling events resulting in the control of cellular behavior remains unclear.

To yield insights into the mechanisms coordinated by the interaction between integrins and fibronectin in mediating macrophage adhesion and FBGC formation, Kao et al. utilized the aforementioned biomimetic fibronectin-derived oligopeptides to probe the structure–function characteristic and signaling pathways of fibronectin–integrin association in modulating cellular function. Specifically, the key role played by RGD, PHSRN, and the spacing and orientation between the peptide sequences in modulating macrophage and FBGC behavior was investigated. Freshly isolated human blood-derived monocytes were preincubated with inhibitors of various signaling molecules at several concentrations to screen candidate signaling cascades in regulating macrophage behavior mediated by fibronectin and fibronectin-derived biomimetic oligopeptides. The signaling and transcriptional events and the corresponding inhibitor chosen for exploration included activated protein tyrosine kinases inhibitor AG82, lavendustin A, which inhibits Src-family kinases, activated protein serine/threonine kinases inhibitor H-7, protein kinase-A inhibitor 14-22 amide, PI-3K inhibitor wortmannin, PCK inhibitor EGF-R fragment, MAPK inhibitor PD98059, and NF $\kappa$ B inhibitor PSI. Activated integrin receptors have been

shown to upregulate these selected signaling molecules under a variety of ligand–receptor associations. For example, Src is involved in integrin signaling upon ligation with extracellular matrix proteins, such as fibronectin, fibrinogen, or vitronectin, leading to macrophage adhesion and focal adhesion kinase formation. Treated cells were incubated with tissue-culture polystyrene or networks terpolymerized with polyethyleneglycols, acrylic acid, and trimethylolpropanetriacrylate. Tissue-culture polystyrene- and polyethyleneglycol-based networks were preadsorbed or immobilized with recombinant human fibronectin or fibronectin-derived biomimetic oligopeptides containing RGD and/or PHSRN domains. Surfaces without preadsorption nor immobilization were employed as negative surface controls. Inhibitor vehicle was also utilized as additional controls, and bovine serum albumin was employed as controls for fibronectin and peptides. From cell adhesion assays, the results showed the following. On networks immobilized with fibronectin-derived oligopeptides, macrophage adhesion was found to be independent of protein tyrosine kinases and protein serine/threonine kinases at 24, 48, and 120 h, except that on surfaces grafted with G<sub>3</sub>PHSRNG and G<sub>3</sub>PHSRNG<sub>6</sub>RGDG where cell adhesion was dependent upon protein serine/threonine kinases at 48 h (Table 4). On networks immobilized with fibronectin or albumin, macrophage adhesion was found to be dependent of protein tyrosine kinases but not Src and dependent of protein serine/threonine kinases but not protein kinase-A at 24 and 48 h. Furthermore, the promotion of protein serine/threonine kinases, and specifically protein kinase-C, compen-

<sup>a</sup> p < 0.1 versus respective values of controls. AG82 inhibits PTK and H7 inhibits PSK. Tissue-culture polystyrene (TCPS).

sated protein tyrosine kinases inhibition in mediating macrophage adhesion at 24 h (Table 5). However, macrophage adhesion on networks immobilized with fibronectin or albumin was found to be independent of both protein tyrosine and serine/threonine kinases at 120 h. On tissue-culture polystyrene immobilized with fibronectin, macrophage adhesion was found to be dependent of protein tyrosine kinases but not Src and dependent of protein serine/threonine kinases but not protein kinase-A at 24 h. The promotion of protein serine/threonine kinases, and specifically protein kinase-C, did not compensate protein tyrosine kinases inhibition in mediating macrophage adhesion at 24 and 48 h. These results indicate that the crosstalk between protein tyrosine and serine/threonine kinases is different between adherent macrophages on fibronectin that was immobilized onto networks or tissue-culture polystyrene. Furthermore, macrophage adhesion on fibronectin-immobilized tissue-culture polystyrene was found to be dependent of protein tyrosine kinases but not Src and dependent of protein serine/threonine kinases, specifically protein kinase-C but not protein kinase-A, by 48 h. Cell adhesion on fibronectin-immobilized tissue-culture poly-

styrene was found to be independent of protein tyrosine and serine/threonine kinases by 120 h. Assays for FBGC demonstrated the following. On networks immobilized with fibronectin, FBGC formation was dependent of protein serine/threonine kinases, specifically protein kinase-A, but was independent of Src (Table 6). It should be noted that macrophage adhesion was independent of protein kinase-A by 48 h and was independent of both protein tyrosine and serine/threonine kinases by 120 h. On tissue-culture polystyrene immobilized with fibronectin, FBGC formation was found to be independent of both protein tyrosine and serine/threonine kinases. Macrophage adhesion on tissue-culture polystyrene immobilized with fibronectin was independent of protein tyrosine and serine/threonine kinases by 120 h. Taken together, these results support the role of activated protein tyrosine kinases and serine/threonine kinases in integrin signalings leading to macrophage adhesion mediated by fibronectin–integrin association. Furthermore, RGD and PHSRN appears to be significant in mediating this receptor–ligand association resulting in the necessary signaling characteristic for macrophage adhesion and the subsequent development. Specifically, pro-

tein kinase-C of tyrosine kinases showed a significant role in modulating FBGC formation mediated by fibronectin, most importantly the RGD and PHSRN domains of fibronectin. Kao et al. showed the important role of RGD and PHSRN domains of fibronectin, and specifically the interpositional spacing between the motifs, in the complexation with integrin receptors to upregulate tyrosine kinases and serine/threonine kinases in mediating macrophage adhesion and FBGC formation. These findings represent a mechanistic correlation between the role of protein functional architectures in ligand–receptor recognition and the postligation signaling events that control cellular behavior. The fundamental understanding of these complex phenomena provides future researchers with necessary tools in the development of unique biomimetic enabling technologies that are vital for the advancement of cellular engineering and tissue engineered devices.

The incorporation of biospecific and biofunctional peptides into polymeric networks has been adopted in other systems in the management of various pathological conditions. Similar to the strategy outlined above by Kao et al., Healy et al. grafted RGD and FHRRKA (putative heparin-binding) peptides onto interpenetrating polymer networks containing poly(acrylamide) and polyethyleneglycol (64–66). The resulting polymer network containing both RGD and FHRRKA peptides mediated extensive adhesion, spreading, and mineralization of the extracellular matrix by human osteoblast–like cells when compared to that of homogenous peptide surfaces and controls. The cellular response was found to rely on the participation of integrin  $\alpha_2$ ,  $\beta_1$ , and  $\alpha_v$  subunits in a temporally dependent manner. Specifically,  $\alpha_2\beta_1$  and  $\alpha_v\beta_3$  integrin receptors mediated the initial cell adhesion; whereas, only  $\alpha_v\beta_3$  integrin receptors governed cell adhesion at a longer culture time. The cited investigations illustrate the diversity and capability of a biomimetic approach in the construction of biofunctional materials to study fundamental cell biology and to potentially manipulate local host environment for biomedical applications.

#### IV. PROTEIN MATRIX AND SUBCELLULAR BIOMIMETICS

In previous sections, examples were given to illustrate the utilization of macromolecules and proteins as templates to develop biomimetic molecules and novel materials. However, biological systems are composed hierarchically; hence, the impact of biological organization at the submicron and subcellular scales needs further elucidation. For example, most cells are intimately associated with basement membrane matrices that have a complex three-dimensional nanoarchitecture of 100–500 nm features. Hence, this submicron architecture may play an important role in mediating cell adhesion and function. A point of note, cellular focal adhesion sites are about 250 nm in size. Various three-dimensional fabrication methods such as inkjet, molding, impregnation, and laser perforation have been developed in an attempt to construct or reconstruct the unique topographical feature of protein layers, extracellular membranes, or extracellular matrices with high resolution and accuracy. Such topographical biomimetics can be utilized in tandem with current clinically utilized materials or novel biofunctional materials as a part of the construction of fully biomimetic material constructs (67–69). Goodman et al. utilized the inherent three-dimensional confinement of nonlinear photo-optical processes to develop three-dimensional freeform fabrication of proteins or synthetic polymers by conventional photochemically induced polymerization methods (70–73). A laser scanning confocal microscope was modified for near-infrared excitation to direct protein crosslinking by 2-photon photoactivation. Albumin, fibrinogen, and alkaline phosphatase were chosen as model proteins for fabrication in solution. Rose bengal was employed as the photoactivator. At the focal point of the lens where the photon density is sufficiently high for 2-photon excitation, crosslinking was induced by a mechanism where the photoactivator directly abstracts hydrogen atoms from protein molecules. Fabrication was then directed point by point and layer by layer

within the solution and proceeded to achieve a desired, predetermined geometry and topography. Features of less than 200 nm, such as three-dimensional lattices, were synthesized by varying the type of lenses. The bioactivity of model proteins was maintained as determined by various biological functional assays. Goodman et al. demonstrated that human platelets extensively adhered to lines fabricated from fibrinogen molecules in vitro, and the lines were ten-fold narrower than the diameter of a platelet cell body. A minimal level of platelet spreading was observed on substrates fabricated from the native albumin molecule in vitro. Furthermore, micron and submicron structures fabricated from alkaline phosphatase molecules demonstrated a high level of enzymatic activity when assayed with enzyme linked fluorescence imaging in vitro. These examples illustrate the feasibility of mimicking the complex hierarchical structure of biological systems that expands from the nano scale to subcellular levels in the study and the partial control of biological functions.

## V. BIOMIMETIC-DERIVED MATERIAL PROCESSING METHODS

Currently, biomaterial development and synthesis have been focused on the utilization of a myriad of synthetic methodologies to obtain a wide range of polymers, ceramics, metal alloys, or biologically derived materials with a diverse physicochemical bulk and surface property. However, synthetic methodologies often result in heterogeneity and anisotropy (i.e., polydispersive molecular weight of polymers, large range of size distributions of polymer and ceramic particulates, phase separation of chemical and/or physical properties). Furthermore, current synthetic fabrication methods cannot incorporate or mimic the complex multilayer microstructure of biological systems to produce materials containing controlled microarchitecture and multifunctional properties present in biological materials, such as cellular membranes, extracellular matrices, or tissues. Several researchers are developing novel material synthesis and processing techniques to enhance the limitation of conventional synthesis and fabrication procedures.

By studying the complex interrelationship of structural organizations in biological systems, biomaterial researchers such as Baer and Hiltner pioneered the development of complex organic and inorganic composites that incorporated some of the ordered microstructure found in nature (32,74–76). For example, load-bearing tissues such as tendon, comprise fibrous organic components embedded in a soft organic matrix that are analogous to fiber- or particle-reinforced polymeric composites. Baer et al. elucidated

that tendon has six discrete levels of structure organized in a hierarchical manner from the molecular to the centimeter scale. Clearly, current composite materials lack the complexity and sophistication necessary to achieve highly ordered and multileveled hierarchical structure. Hence, composite material research has focused on elucidating the microstructure–property correlation that includes the coupling between the properties of an individual organic and inorganic component at various scales and in tandem at different levels of organization. The understanding of the structural organization and relationship between each discrete unit (i.e., molecules, macromolecules, cells, tissues, or extracellular matrix) that makes up a biological system is one important step in understanding basic structure–function relationships and the construction of complex biomimetic materials.

Due to the specificity of biological synthesis pathways such as biomineralization systems and protein and nucleic acid syntheses, microbiological and other biological techniques are currently being adopted and utilized in the construction and processing of novel biomimetic materials (77–83). For example, analysis of a variety of mineralizing biosystems leads to several guiding principles that have significant implications for biology and materials sciences. Biomineralization occurs within specific subunit compartments or microenvironments. The process produces specific minerals with defined crystal size, orientation, and ordered macroscopic growth. Many incremental units are packaged together to form unique composites (76). These complex systems are controlled by the structure and chemistry of the interfaces between the organic substrate, mineral, and medium. The presence of proteins such as osteopontin and catalysts is also critical for the control of biomineralization. Some examples of novel biomaterials synthesized by mimicking biomineralization systems include monolayer films, self-assembled monolayer films, self-assembled amphiphilic structures, and supramolecular templates (76). However, low stability, lack of control over local ordering, and inability to direct crystal growth in three dimensions are some of the existing technological hurdles that have yet to be overcome. One exciting area of research attempts to utilize microorganisms as a mean to synthesize calcium phosphate nanoparticles of a precise size distribution (84). Nanoparticles about 50 nm in diameter with a uniformed crystal size and structure were synthesized on the extracellular membrane of bacteria of the *Citrobacter* genus in the presence of calcium and phosphate ions. The *Citrobacter* genus contains membrane-bound phosphatase enzymes and has been utilized in the water purification process through the accumulation of heavy metal ions as cell-bound insoluble metal phosphates. The nature of the phosphate formed depends on the type of

ions in the culture media. In the presence of calcium and phosphate ions in the culture medium, investigators showed that the crystals formed at the bacteria extracellular membrane were amorphous calcium phosphates produced by membrane-bound phosphatase enzymes via similar mechanisms as those involved in the extraction of heavy metals from water. The 50-nm particles within the bacteria were of the composition of  $\text{CaHPO}_4$  and were produced through migration of calcium through the cell membrane. The exact mechanism of the  $\text{CaHPO}_4$  transport across the extracellular membrane remains unclear. Nanoparticles were analyzed and characterized by Fourier transform infrared spectroscopy, x-ray diffraction, and scanning and transmission electron microscopy.  $\text{CaHPO}_4$  can be further processed to hydroxyapatite and then the bacteria represents a self-constructed soft agglomerate of the particles. Hence, the utilization of *Citrobacter* provides a new approach to produce well-controlled nanoparticulates of optimal characteristics that are hydroxyapatite precursor powders. The use of the natural function of microorganisms in fabricating materials represents a unique ability of novel material synthesis and processing systems based on biomimeticism.

As another example of utilizing the specificity and accuracy of biological systems to synthesize complex materials, genes that contain the instruction for the synthesis of desired macromolecules such as proteins and carbohydrates were incorporated into vectors that were utilized to transfect candidate cells such as bacteria. The new genetic code becomes a part of the genetic and biochemical machinery of the transfected cell. The marriage of microbiology and biomaterial development was pioneered by Tirrell et al. and continued in several other laboratories (29–31). The unique structural and functional properties of biological molecules such as proteins have been an area of intense investigation as potential building blocks for novel biomaterials that contain the multistructure and multifunctional characteristics of native biological molecules. For example, Tirrell et al. developed a series of methods for building proteinlike structural motifs that incorporate sequences of biological origin (28). In one of their studies, Tirrell et al. attached a lipophilic moiety onto the  $\alpha$ -amine of a peptide chain resulting in a peptide–amphiphile. The alignment of amphiphilic compounds at the lipid–solvent interface was employed to facilitate peptide alignment and structure initiation and propagation while the lipophilic region adsorbed to hydrophobic surfaces. Peptide–amphiphiles containing triple-helical or  $\alpha$ -helical structural motifs were synthesized and had been shown to be stable over physiological temperature ranges. These triple-helical peptide–amphiphiles were adopted to study surface modification and cell receptor binding.

## VI. SUMMARY

As illustrated by the investigations discussed, the underlying basis of biomimetics is the need to better understand the structural and functional relationship of biological systems and organizations. Hence, the field of biomimetics represents a diverse and interdisciplinary approach to formulate functional compounds and materials with enhanced physicochemical and biological properties when compared to these synthesized via conventional formulation methodologies. Furthermore, the biomimetic approach offers unique tools that can, in time, be utilized to probe the fundamental questions of the complex biological systems and mechanisms.

## Silicones for Pharmaceutical and Biomedical Applications

**Haissam S. El-Zaim and John P. Heggers**

*University of Texas Medical Branch, Galveston, Texas*

### I. INTRODUCTION

Until the early 1950s, the practice of medicine had not seen major changes for centuries. Before that time surgeons, for example, still used sutures processed from the intestinal walls of sheep or cows to sew wounds together. Around the mid-20th century, Eugene Rochow invented silicone, which proved to be one of the major inventions of the century. Silicone has some unique chemical and physical properties. It is inert, which implies low risk for interaction with the cells and chemicals in the body. It sustains high temperature, which suggests that silicone-based products could be easily sterilized. It was these properties that inspired scientists and physicians to consider the use of silicone for medical applications.

The first successful use of silicone in medical practice came about in 1956. At that time Doctors F. E. Nulsen and E. B. Spitz were cooperating with scientists from Dow Corning to develop a tube to be used in a hydrocephalic shunt procedure (68). In this procedure, an elastic tube is placed in the head of a child suffering from hydrocephalus in order to relieve the intracranial pressure caused by the excess of cerebrospinal fluid (CSF) in the cranial cavity. The shunt allows excess CSF to flow in one direction to the drainage site, which can be either intravenous, intrathoracic, or intra-abdominal. The tube had to be soft, flexible, elastomeric, and biocompatible with the human body. All of these requirements were met by the silicone elastomer that was successfully used in the procedure. Since then

thousands of hydrocephalic shunt procedures have been performed using silicone elastomer. In other words, silicone is responsible for saving the lives of thousands of children borne with this birth defect (1 in 400–600 live birth), as well as improving the quality of life of survivors who otherwise would become mentally retarded. Hydrocephalic shunt is not the only procedure where the use of silicone has made a major contribution. Today, all intracranial indwelling tubing is made of silicone. Silicone is now used in many other surgical and nonsurgical procedures, and its use extends to a variety of medical instruments and indwelling medical devices.

Before we go into the details of the different applications for silicone in medical and pharmaceutical practice, let us briefly review the chemistry and physical properties of silicone.

### II. CHEMICAL AND PHYSICAL PROPERTIES

Knowledge of the fundamental chemistry of the element silicon (Si) and understanding how Si can be integrated in biosystems are essential to understanding the role of Si in health and how it can be responsible for disease. Just like carbon, Si is capable of forming four bonds and is known for its ability to polymerize and form network covalent structures (9,134). However, unlike carbon, stable Si—Si bonds do not usually form. Silicon dioxide (SiO<sub>2</sub>), also

**Figure 3.1** The chemical structure of polydimethylsiloxane, the basic silicone compound used in medicine. (From Ref. 63b.)

called silica, is the most abundant mineral in the earth's crust and is the natural source of Si used in manufacturing silicone.

Silicone is simply a generic term that refers to siloxane polymers (polysiloxanes). In general, they are compounds of the structure  $(\text{R}_1\text{SiR}_2\text{O})_n$ , where atoms of silicon are linked together by oxygen in a fashion analogous to the ether linkage of carbons by oxygen (36,89). The Si—O—Si bond is correctly termed a siloxane bond and thus the silicones are polysiloxanes (38,48,104,133). In polysiloxanes, the relatively stable Si—O bond is further stabilized by substitution of alkyl groups as the two side chain groups pensive from the Si molecule, which were  $\text{CH}_3$  groups. Thus, the most common core structure of medical utility is polydimethylsiloxane (PDMS) (Fig. 1).

These highly hydrophobic compounds are chemically stable under physiologic conditions, can be synthesized with a variety of physical properties, and can be molded easily. Dialkylsiloxanes are prepared by the reaction of the dialkyldichlorosilane (generally dimethyldichlorosilane) with water (Figs. 2 and 3). Originally this structure was

**Figure 3.4** Condensation of two molecules of trimethylchlorosilane into hexamethyldisiloxane. (From Ref. 63b.)

misinterpreted as oxygen linked to Si with a double bond, thus the term silicone. Further reaction with water yields silanol dimethylsiloxanes with terminal hydroxyls. Polymerization usually yields a mixture of silanol oligomers with  $n = 3$  to 9 and cyclic siloxanes.

The polysiloxanes then are "capped" by trimethylsiloxane groups, a process termed *equilibration* (50). This is first accomplished by condensing two molecules of trimethylchlorosilane to hexamethyldisiloxane via the addition of water (Fig. 4) and then reacting hexamethyldisiloxane with silanol oligomers to produce silicones (Fig. 5). This process results in a fluid polysiloxane often termed an "oil." Consequently, these compounds have widespread industrial and consumer uses as dielectric fluids, films, and coatings.

Polydimethylsiloxane, which has a specific gravity lower than that of water, is the most commonly used fluid in medical practice (133). The viscosity of the oil is a primary function of its molecular weight, but also of the ability of the molecules to slip past one another. The pensive methyl groups of silicones have little or no influence on this slippage. The polymerization reactions described can also be conducted using other alkyl or aromatic side chain-

**Figure 3.2** Chemical reaction depicting the formation of dimethylsiloxane from dimethyldichlorosilane in the presence of water. (From Ref. 63b.)

**Figure 3.3** Generation of silanols with terminal hydroxyl groups from dimethylsiloxane with water. (From Ref. 63b.)

Figure 3.5 Production of silicone in a reaction between hexamethyldisiloxane and silanol oligomers. (From Ref. 63b.)

modified chlorosilanes such as ethylmethyldichlorosilane or phenylmethyldichlorosilane as the feedstock and equilibrating with the homologous end groups. These will produce polysiloxanes, with increased viscosity because of the resistance of the more bulky pendent groups to slipping past each other. Silicone gels produced by this procedure consist of covalently crosslinked polysiloxane networks and interpenetrating polymer networks swollen in a silicone fluid. Commercial PDMS are not only produced as fluids or oils and gels, but also as “gums,” or rubber elastomers. The strength and elasticity of polysiloxane elastomers is a function of the length of the polymer chain and the degree of crosslinking. Elasticity occurs because polysiloxanes (like other polymers) exist in highly coiled conformers. As the material is stretched, the polymer unwinds. When tension is released the polymer recoils. Elasticity relies on the ability of adjacent polymer regions to slip past each other and therefore will be influenced by the presence of the bulky pendent groups. The physical rigidity of a siloxane polymer is increased by crosslinking the polymeric chains. Highly crosslinked polymers will lose elasticity because uncoiling will be inhibited as a result of the inability of the adjacent regions to slip past each other, but they will not deform easily and hence are more rigid. A lightly crosslinked polymer will deform easily but will have significant elasticity, with the ability to return to its original shape when stress is released.

The basic ingredient to make silicone elastomers, or silicone rubbers, is a clear and highly viscous PDMS with minor amounts of other substituents, particularly vinyl groups. Other radicals in the silicone rubber determine the physical properties of the resultant elastomer. The most common mechanism by which crosslinking occurs is by a radical attack on the alkyl groups pendent from the Si initiated by heat (heat vulcanization) or benzyl peroxide. The reactive intermediates containing carbon free radicals then combine to form the carbon-carbon covalent crosslinking bonds. In some cases, crosslinking is facilitated by substituting vinyl groups for occasional methyl groups because the double bond of this group is quite susceptible to free radical attack. In order to increase its tear and tensile strength, the prevulcanized silicone is usually mixed with a filler. A common filler used for this purpose is the submicroscopic fumed silica, which has a surface area of approx-

imately 400 m<sup>2</sup>/g. By changing the amount of filler added to a silicone elastomer, one can change its degree of hardness. This same property can be modified by changing the type of polymer used. Polydimethylsiloxane is used to prepare the soft grade silicone elastomers, whereas polysiloxane is used to prepare medium and hard grade silicone elastomers. Another type of silicone rubber is the room temperature-vulcanizing (RTV) silicone rubber. These silicones have much less tensile and tear strength than the high temperature-vulcanized materials. Unlike the other type of silicone elastomers, RTV silicones are provided as intermediate components which require mixing before their intended use (7,11).

### III. BREAST AUGMENTATION IMPLANTS

Thomas Cronin and Frank Gerow, two plastic surgeons at the University of Texas, were looking for an alternative to the spongy breast implants commonly used for reconstruction of breasts among female patients undergoing mastectomy. The problem encountered with the spongy implants was that after a period of time they hardened and started to look and feel less natural. Around the year 1960, the two surgeons developed the first silicone breast implants in collaboration with Dow Corning (28,93). This prototype of silicone rubber sac filled with silicone gel was called a mammary prosthesis and was later marketed by Dow Corning after undergoing the first human trial. Soon after Dow Corning introduced this new product to the market, and to everybody's surprise, the demand for mammary prosthesis was much greater for breast augmentation procedures for cosmetic purposes (80%) rather than reconstruction procedures following mastectomy. It was estimated that by the year 1992, 1-2.5 million North American women and 100,000-150,000 British women received breast implants (62). During the 1960s and 1970s Dow Corning introduced many improvements to enhance the quality of the mammary prosthesis, which became a multimillion dollar product. Other companies joined Dow Corning to cash in on this rapidly growing market.

Silicone breast implants have been associated with complications such as capsular contracture, enlargement of lymph nodes draining the implant site, occasional rup-

ture of the silicone gel sac, and bacterial contamination (26). Capsular contracture, which may be triggered by bleed of the silicone gel through the outer bag, is believed to be due to the natural attempt by the body to engulf the foreign material (18). The drying effect of silicone in the surrounding soft wet tissue enhances the scar formation and is another possible contributing factor to the formation of the capsule. This pseudocapsule is composed of fibrous tissue typically seen in the process of wound healing. Physical changes and alterations of the nature of the silicone implants, as well as use of wetting agents such as provi-done, have reduced the incidence of capsular contracture (45).

It was not these complications but rather the possible link of breast implants to a systemic connective tissue disease that fueled the debate over the safety of this procedure. Several reports appeared in the literature suggesting an association between breast implants and some ill-characterized immunological disorders. Most of the reports described cases of a poorly defined syndrome referred to as "human adjuvant disease." Some reports claimed an association with systemic, probably autoimmune, connective tissue diseases (73,77). The first report of an association between silicone breast implant and connective tissue disease dates back to 1964, and the first documented cases were those of three patients in 1982. It is estimated now that the number of reported cases exceeds 290 patients (62). Reported symptoms and signs include fatigue, joint pain, bone pain, dry eyes, dry mouth, dry skin, cognitive dysfunction, myalgia, weakness, hair loss, nail changes, skin rashes, paresthesia, dysethesia, freckling, pigment change, headache, dizziness, nausea, foul taste, weight gain or weight loss, bruising, increased sensitivity to light, fever, chills, infections, diarrhea, constipation, periodontal disease, skin papules, muscle twitching, urinary symptoms, dysphagia, dysmenorrhea, blurred vision, tinnitus, drug reactions, emotional lability, insomnia, edema, hemangiomas, delayed wound healing, vascular abnormalities, partial hearing loss, reduced smell, tremor, mouth sores, tight skin, shortness of breath, wheezing, palpitations, seizures, parotid gland swelling, heat intolerance, and cancer. The range of symptoms was very large and many of the cases did not fulfill conventional clinical and laboratory criteria for a particular connective tissue disease. Scleroderma was the most common specific diagnosis (10,15, 16,30,76,99, 100).

In 1991, an American jury found that silicone breast implants were responsible for the plaintiffs' symptoms of a mixed connective tissue disease. The jury found that the company was responsible as they misrepresented the safety of their product. After this trial, public awareness of the

issue rose steeply and the Food and Drug Administration, following the recommendations of two independent advisory panels, requested a halt on the use of silicone breast implants other than within clinical trials (27,94). In 1994, while the battle between the litigants and the manufacturers of the implants was raging inside the court and on the media front, a Department of Health advisory group in Great Britain reported that there was no evidence of an increased risk of connective tissue disease in patients with silicone breast implants (43). Analysis of published case series as well as several case-control and cohort studies suggested that the cumulative incidence of connective tissue disorders among recipients of breast implants is no different from that expected in the general population (101). Only one retrospective cohort study, by Hennekens et al., published in the *Journal of the American Medical Association* in 1996, pointed to a weak association (52). The authors of this study themselves concluded that an association between silicone breast implants and increased risk of major connective tissue disease is unlikely. Further, this study was criticized for the lack of certain diagnostic validity with potential bias due to differential over-reporting.

#### IV. OPHTHALMOLOGY PROCEDURES AND OPTIC DEVICES

Retinal detachment is a pathological process in which the neuronal layers of the retina, including the layer of photoreceptors (rods and cones), are separated from the pigment epithelium. Melanin in the pigment epithelium, located in the back of the neuronal retina, captures light that makes it through the photoreceptors layer and therefore prevents reflection of light off the sclera. In addition, the pigment epithelium is essential for the proper metabolism of the neuronal layer of the retina. It supplies the retina with nutrients and is involved in phagocytizing and clearing out the debris generated by the constant turnover of the outer segments of the photoreceptors containing the photopigments. Retinal detachment can be caused by numerous disease conditions. Cytomegalovirus-induced retinitis is a major cause of retinal detachment among patients with acquired immunodeficiency syndrome (AIDS) (56,57). Patients with retinal detachment are at serious risk of total blindness unless the problem is corrected. Traditionally, retinal reapposition was achieved by suturing a sponge or a band to the sclera to produce a "buckle" which closes the hole by external tamponade. With this procedure the retina resumes contact with the pigment epithelium. This procedure works well in uncomplicated cases; however, in

complex retinal detachment, which requires removal of the preretinal membranes by vitrectomy, an external tamponade must be supplemented with an internal tamponade in order to successfully bring the retina and the pigment epithelium together. Investigators felt the need for a substance with stable surface properties at aqueous interfaces, that is biologically inert, and is amenable to surgical procedures to serve this purpose. Gases, such as air, sulfur, hexafluoride, and perfluoropenthrane were tested and proved to be effective in the short term. However, for longer-term maintenance of break closure and relief of retinal traction, a material that is insoluble in tissue fluid seemed to be more appropriate. Because of its long-term biotolerability and optical clarity, silicone seemed to be the perfect substance for this purpose. In 1962, Cibis was the first to report the use of liquid silicone (silicone oil) as a "vitreous prosthesis" in human eyes (23). Since then the use of silicone has been extended to include providing temporary or permanent internal tamponade, delaminating periretinal membranes, manipulating the retinal edge in giant tears, closing macular holes, and maintaining the surgeon's view of the back of the eye during surgery involving vascularized tissue. The use of intraocular silicone is considered a major breakthrough in the treatment of retinal detachment, which when left untreated can lead to blindness. Complex retinal detachments are now routinely repaired, and very few are deemed to be inoperable. Side effects due to intraocular silicone can be avoided or reduced by proper surgical technique. Foaming or emulsification is responsible for the main long-term complications such as glaucoma and impaired vision. This can be avoided with a more complete silicone fill (21,37,41,74,82,90,97).

In addition to the previous example, an experimental procedure to restore accommodation in primate eyes by refilling the lens capsule with injectable silicone compounds is currently being investigated (87,88). Last but not least, polysiloxane lenses coated with povidone are routinely used for patients after cataract surgery (58). Silicone is also used in manufacturing soft contact lenses.

## V. TREATMENT OF URINARY AND FECAL INCONTINENCE AND GENITOURINARY DEVICES

Until the introduction of silicone-based prosthesis, attempts to replace any part of the urinary tract were plagued by the problem of phosphatic encrustation. Whereas silicone catheters may be left indwelling for 8 to 12 weeks with minimal phosphatic deposition, latex or plastic catheters have to be replaced within 3 to 4 weeks (130).

Urinary incontinence is a common problem affecting 10–25% of women between the ages of 15 and 60 years (64). Stress urinary incontinence, which is the involuntary loss of urine during physical activities that increase intra-abdominal pressure, is a common type. This condition could result from loss of pelvic support, and hence hypermobility of the vesicourethral junction (anatomic incontinence) or intrinsic sphincter deficiency (type III stress incontinence). The latter condition may be caused by myelodysplasia, sympathetic nerve injury, and surgical injury or trauma (75). Urinary incontinence may also occur as a result of spinal cord injury or following prostatectomy procedure in males (2,25,131).

As early as the year 1947, attempts to control urinary incontinence by applying a constricting cuff around the urethra via a cutaneous tunnel were reported. In 1973, Joseph Kaufman described a procedure in which a silicone balloon is implanted around the crura of the penis to control incontinence (59). Upon distention the balloon would compress the urethra against the symphysis pubis. Following implantation the balloon can be further enlarged by injecting more fluid into it if necessary. That same year, Brantley Scott and his colleagues developed an artificial sphincter which consisted of a silicone rubber cuff, a small pump, a balloon, and a stainless steel control assembly (98). The cuff is surgically implanted around the neck of the bladder, or sometimes around the bulbous urethra of men. The balloon is positioned in the perivesical space and, for easy access, the pump is placed under the skin either in the scrotum in males or the labia minora in women. The inflated cuff cuts off the flow of urine in a manner similar to that of the natural sphincter muscle. By squeezing the pump several times, forcing the fluid out of the cuff and into the balloon, the patient could deflate the cuff and allow urine to flow. Within minutes the cuff refills automatically restoring continence. An overall success rate of 70% for an average of 3.5 years was reported with this device. Drawbacks of this procedure included cost and complications, such as periurethral fibrosis, tissue erosion, and infection.

Transurethral or periurethral injection of biomaterials into the intrinsic sphincter was developed as a less invasive technique for the treatment of incontinence (8). Various forms of bioinjectable materials have been developed for this purpose. Injection of polytetrafluoroethylene (Teflon) paste has had relatively good results in the short term (24). Long-term follow-up studies on patients treated with Teflon paste injections revealed a low success rate of only 38% and the occurrence of local side effects, such as fibrosis in the urethra and bladder granuloma balls (17). More recently, injection of autologous fat was tested and

the results from this study were not impressive (6,20,95). Collagen has a good (46–77%) long-term (2 years) success rate and is currently the most widely used injectable (4). The major problem encountered with collagen use is the potential development of allergic reactions (3). Collagen, as well as autologous fat, are absorbed rather rapidly, which calls for repeated injections. Recently, reports on use of silicone particles for treatment of urinary incontinence appeared in the literature (61). According to these reports, injection of polydimethylsiloxane is a simple, safe, and effective procedure for the treatment of urinary incontinence. Another possible application for this procedure is in treating vesicoureteral reflux (61).

Soiling (fecal incontinence) is another distressing, demoralizing, and costly condition which may result from various causes. Although the pathophysiologic mechanisms are not fully understood, it is almost always associated with anorectal disorders that can deform the contour of the anus and anal canal. The condition is usually corrected by medical or surgical means; however, in certain situations reconstruction of the contour deformity of the anus is the only successful resort (86). Moderate success with sublevatorial implantation of a silicone ring was reported by Hansen in 1996 (47). Currently, perianal injection of PDMS paste is being investigated for treating soiling.

Silicone is also used in the making of penile implants used to treat male impotence. One model of these implants is a solid polysiloxane component that is inserted subcutaneously in the penis. Another model consists of an inflatable silicone bag connected to a reservoir which is used to pump fluid to the prosthesis when an erection is desired (92).

## VI. ORTHOPEDIC AND RECONSTRUCTIVE SURGERY

Silicone prostheses play a major role in the treatment of degenerative arthritis and rheumatoid arthritis in the hand and wrist. Silicone devices are often used in orthopedic surgery, especially in operations to reconstruct the hand (45). Until the late 1950s, success rates were not impressive in attempts to achieve pain-free, stable implant arthroplasty with metacarpal cups or with soft tissue interpositions (8). The metal hinge implants for the metacarpophalangeal joint introduced in 1959 were not well tolerated due to bone resorption and metal corrosion (12,35). The search for better techniques and new biocompatible materials continued until silicone rubber prostheses were introduced in the late 1960s and early 1970s (13,84,85,

107,109–125). Niebauer and his colleagues introduced a hinged silicone joint with a dacron mesh covering for in-growth fixation. A hinge spacer originally intended to improve the alignment and stability of resection and arthroplasty was introduced by Swanson. Swanson, who pioneered the field of silicone implant arthroplasty, introduced other designs used in the treatment of arthritis in the wrist, ulnar head, scaphoid, lunate, trapezium, and metacarpophalangeal and interphalangeal joints. Designs by Swanson and Niebauer became very popular soon after their introductions, but some of the problems encountered were implant fracture, persistent weakness of grip and pinch, and increasing deformity. This led to careful reconsideration of both prosthesis designs and materials. Today, prostheses based on those original designs continue to be widely used in arthroplasty. Another use for silicone in hand orthopedic surgery is in tendon transplantation (19). In this procedure, Hunter's Silastic rods are used to form a tunnel composed of a thin pseudocapsule in which tendon transplants are inserted later on. The purpose of this tunnel is to prevent the adhesion of the transplanted tendon to the adjacent structures in the hand, which allows for the gliding function of the tendon. Silicone is also used in reconstructing the wrist using silicone joint prostheses or bone prostheses made of silicone. Silicone can also be used to reconstruct larger joints such as the elbow (71,111,117–125). This may involve replacement of the head of the ulna with silicone components. However, reconstruction of large joints and long bones may require additional reinforcement.

The three major complications following silicone implant arthroplasty are fracture, subluxation, and synovitis. Fracture commonly occurs in the wrist and metacarpophalangeal implants, whereas subluxation occurs mainly with the carpal implants (63). Silicone synovitis is an inflammatory response to small particulate debris of 10–100  $\mu\text{m}$  in diameter (5). This phenomenon is more commonly seen in association with high performance (HP) silicone elastomer than with the conventional silicone elastomer (125). Small particles shed from HP elastomer implants are ingested by phagocytes which fail to clear these foreign particles away. Frustrated macrophages release proinflammatory cytokines and attract more immune cells. This results in a chronic inflammatory response characterized by the presence of lymphocytes, eosinophils, and giant multinucleated epithelial cells (42). In very few cases, silicone lymphadenopathy has been reported following silicone implant arthroplasty (22).

In addition to hand orthopedic surgery, silicone is commonly used in maxillofacial reconstructive surgery. Silicone products are used to reconstruct the mandible, to aug-

ment the chin of patients with microgenia and to reconstruct the missing ear of patients with microtia (45,69).

## VII. LARYNGEAL, TRACHEAL, AND ESOPHAGEAL PROSTHESES

A variety of devices used in the upper respiratory and digestive system are made of silicone. The silicone Safe-T-Tube is designed to maintain adequate tracheal airway and to provide support in the stenotic trachea. It can be kept in place for many years, if necessary. It is commonly used in cases with acute tracheal injuries, a need to support a reconstructed trachea or reconstituted trachea, as well as many other procedures (78). In cases such as obstructive sleep apnea, bilateral vocal cord paralysis, laryngeal carcinoma with glottic insufficiency, and neurological disorders with intermittent laryngeal insufficiency, a silicone device called the Tracheal Cannula System is usually used (79). By diverting the saliva into the distal esophagus, a silicone-made salivary bypass tube greatly reduces the healing time in cases with cervical esophageal and hypopharyngeal strictures and fistulas resulting from a variety of causes including malignancy, surgery, irradiation, trauma, and caustic indigestion (80). Esophageal tube is used to bridge the gap between the pharyngostome and esophagostome following laryngoesophagectomy and reconstructive surgery of the cervical esophagus (78,80,126,127). Silicone laryngeal stent can be used alone or in combination with the Safe-T-Tube to prevent and treat laryngeal stenosis, when the glottic stenosis involves the midglottis, posterior glottis, supraglottis, and subglottis (80). Laryngeal keel, an umbrella-shaped silicone prosthesis, is used to prevent and treat anterior laryngeal stenosis limited to the anterior commissure of the vocal cords (80). Silicone esophageal stents are used as a palliative therapy for tracheoesophageal fistula, a life-threatening late complication of carcinoma of the esophagus and lung (83,108). This procedure prevents food and gastric refluxate from entering the respiratory tract and restores the ability to swallow so proper nutrition intake can be maintained (54). Without treatment, most of these patients succumb to respiratory problems and die in a matter of few months (31,60).

Since the first laryngectomy was performed in 1866, several methods to restore speech have been attempted (1,44). This required an alternative vibratory source to replace the larynx in the reconstructed pharyngoesophageal region. This goal can be achieved by means of an artificial larynx that has an electric pharyngeal speech vibrator which can be externally applied to the neck. However, of

all the speech restoration methods, the method of shunt esophageal speech by means of silicone tracheoesophageal valve prosthesis have the most consistently high success rate (102,132).

The major risks associated with the silicone devices are bacterial and fungal infections (55,72). The risk of infection can be greatly reduced by proper surgical techniques and by patient education on how to properly use, maintain, and clean their prostheses. Also, early intervention to disinfect or replace a contaminated device has been very efficient in preventing major complications.

## VIII. CARDIOVASCULAR PROCEDURES AND DEVICES

With the advent of extracorporeal circulation in 1954 and the introduction of heart-lung machine by Gibbon (40), direct open treatment of valvular diseases became possible. Deformed, calcified valves could not be completely fixed by conservative procedures such as valvuloplasties and calcium debridement. Such procedures represented a major challenge to the cardiac surgeon (34). Early attempts to use artificial valves were not very successful in the long run due to the loss of flexibility of the material and to ingrowth of tissue (14). Charles Hufnagel was the first to implant a valvular prosthesis (46,53). His design consisted of a caged Lucite ball valve which he used to treat aortic insufficiency. Hufnagel's attempt set the stage for other investigators to develop more biocompatible and safer prostheses (33,49,106). Today, there are numerous heart valves available from different manufacturers and many of them consist of or contain silicone (34). Valvular endocarditis is the most dreaded complication of valve replacement (32). The source of bacteria in early nosocomial infection is believed to be patients themselves or their environment. Staphylococci and gram-negative bacilli are the leading cause of prosthetic valve infections (103). When the patient presents with symptoms of acute septicemia secondary to valvular endocarditis, death may ensue within few days. The best approach to treat early valvular endocarditis is the institution of appropriate antibiotics followed by surgery (70). The prognosis for late valvular endocarditis is less severe and may be responsive to antibiotics alone.

The idea of externally stimulating the heart with an electric current was first conceived in 1952 by Paul Zoll (135). The first method of pacing was described in 1958 by Furman and Robinson (39). According to their method a catheter electrode with a metal guide wire was inserted into the right ventricle through a peripheral vein. The pace-

maker itself was kept external to the body. Today, the transvenous approach is the most commonly applied procedure (91). In this method, a permanent pacemaker is implanted near the site where the electrode enters the cephalic vein just beneath the clavicle. In a pacemaker the only metal exposed to the body fluids is the tip of the electrode in contact with the heart muscle and the ground plate; all other parts are insulated with silicone rubber. Complications related to pacing leads include lead fracture, thrombosis and embolism, infection, lead failure, migration of epicardial leads, malposition, dislodgment, myocardial penetration and perforation, electrode corrosion, insulation failure, exit block, and silicone-induced endocarditis (128).

Other important silicone cardiovascular devices include silicone-coated tubing for extracorporeal circulation. Such tubing is important in open-heart surgery. The lower reactivity of silicone with blood reduces the thrombogenic effect of the polyethylene tubing during cardiopulmonary bypass, therefore making the use of silicones most advantageous in these circumstances. Catheters for intra-arterial and intravenous lines are encased in or coated with silicone to minimize thrombogenic activity. The silicone membrane in the artificial lining device allows the transport of oxygen and carbon dioxide (45). Silicone antifoams are essential in cardiopulmonary bypass procedures. They are used in bubble oxygenators to prevent gas bubble emboli (38).

## IX. SILICONE FLUID LUBRICANTS

Silicone fluid lubricants facilitated the development of disposable hypodermic syringes and needles. In 1950, Darling and Spencer reported that silicone lubricant is chemically stable and withstands autoclave sterilization, and they recommended its use for lubrication of hypodermic syringes (29). Today, silicone remains an effective lubricant with both sterilization and time. Being chemically nonreactive and compatible with injectables, it is widely used in manufacturing disposable hypodermic needles and syringes.

## X. MISCELLANEOUS DEVICES

Silicone is used in manufacturing dental impression materials, anti-gastric reflux devices, implantable drug-binding matrices for drug-release capsules such as implantable contraceptives, and peritoneal venous shunts. Silicone tubing is used routinely in kidney dialysis. Silicone net dressing is used on skin-grafted sites, and silicone cream occlu-

sive dressing is used in the treatment of hypertrophic scars and keloid. Silicone is also used in manufacturing a variety of many other useful devices (65).

## 4

# Biodegradable Polymers as Drug Carrier Systems

Abraham J. Domb, Neeraj Kumar, Tzviel Sheskin, Alfonso Bentolila,  
Joram Slager, and Doron Teomim

*The Hebrew University of Jerusalem, Jerusalem, Israel*

## I. INTRODUCTION

Over the past decade the use of polymeric materials for the administration of pharmaceuticals and as biomedical devices has increased dramatically. The most important biomedical applications of biodegradable polymers are in the areas of controlled drug delivery systems (1–4) and in the form of implants and devices for fracture repairs (5,6), ligament reconstruction (7), surgical dressings (8), dental repairs, artificial heart valves, contact lenses, cardiac pacemakers, vascular grafts (9), tracheal replacements (10), and organ regeneration (11). The purpose of this chapter is to review the chemistry, properties, and formulation procedures of the different biodegradable polymers actually available and to describe some of their release kinetics, safety, and biocompatibility considerations.

## II. BIODEGRADABLE POLYMERS

### A. Polyesters

#### 1. Lactide and Glycolide Copolymers

Linear polyesters of lactide and glycolide have been used for more than three decades for a variety of medical applications (5–8,12–14). Extensive research has been devoted to the use of these polymers as carriers for controlled drug delivery of a wide range of bioactive agents for human and animal use (15). They have been used for the delivery of steroids (16,17), anticancer agents (18), peptides and

proteins (19), antibiotics (20), anesthetics (21,22), and vaccines (23). Injectable formulations containing microspheres of lactide/glycolide polymers have received the most attention in recent years.

#### a. Synthesis

Linear lactide- and glycolide-based polymers are most commonly synthesized by ring-opening melt polymerization of lactide and glycolide at 140–180°C for 2–10 h using a catalyst (24,25). When polymerization temperature is less than the melting point of polymer (~175°C), crystallization of the polymerizing polymer occurs, resulting in solid-state polymerization as with poly(glycolide) (PG). Solid-state polymerization has been found useful for very high molecular weight polymers, around 1000 kD (26). The polymerization reaction was studied and several mechanisms were proposed including cationic (27–30), anionic (31–34), and coordination–insertion (35,36). The common polymerization catalysts are tin derivatives such as tin octoate or tin hexanoate. A hypothetical mechanism of the ring-opening polymerization of lactide using a tin catalyst was suggested by Kissel et al. (Scheme 1) (37).

In this mechanism, Lewis acid character of the tin catalyst activates the ester carbonyl group in the dilactone (a, in Scheme 1). The activated species reacts with the alcohol initiator to form an unstable intermediate, which opens to the ester alcohol (b, in Scheme 1). The propagation reaction proceeds by tin catalyst activation of another dilactone carbonyl group and reaction with the hydroxyl end group.

**Scheme 1** Hypothetical mechanism of ring-opening polymerization using tin octoate as catalyst. (From Ref. 37).

Ring-opening rate for cyclic lactone can be increased by activation of a Zn- or Sn-based catalyst with carbonyl ester. Stannous octoate  $\text{Sn}''[\text{CO}_2\text{CH}(\text{Bu})(\text{Et})_2]_2$  is commonly used because it has FDA approval as a food stabilizer (38). Alternatively, resorbable Fe(II) salts have been utilized as initiators for lactide polymerization above  $150^\circ\text{C}$  (39). Zinc powder and  $\text{CaH}_2$  have also been evaluated as potential nontoxic catalysts for copolymerization of poly(lactic acid) (PLA) with poly(ethylene oxide) (PEG) (40). Lauryl alcohol is generally added to control the molecular weight of the polymer (24,25). Polymers with a molecular weight as high as 500,000 can be obtained by the melt process when high purity monomers ( $>99.9\%$ ) are used (37). Since  $\text{Sn}(\text{OCT})_2^-$  promoted polymerizations are hardly controlled, a variety of organometallic derivatives, particularly metal alkoxides, are continuously tested as initiators in the polymerization of lactides (41,42). The aluminum alkoxide initiators are the most versatile and readily available. Both monoalkoxides ( $\text{R}_2\text{-AlOR}'$ ) and trialkoxides ( $\text{Al}(\text{OR})_3$ ) were applied by several groups (43,44). By using only one form of the trialkoxide isopropoxyide ( $\text{Al}(\text{O-iPr})_3$ ), namely, its trimer, a perfect control of polymerization can be achieved.

Polymerization of L,L- and (L,L + D,D)-LA initiated with  $\text{Al}(\text{O-iPr})_3$  is claimed to be the first example of fully controlled synthesis of high molecular weight PLA (45). The aluminum trialkoxide-growing species belong to the most selective ones, in comparison with other metal (e.g., K, Sm, La, Fe, Sn, Ti) alkoxides.

Low molecular weight poly(lactic acid) ( $<3000$  kD) can be synthesized by direct polycondensation of lactic or glycolic acid using phosphoric acid, *p*-toluene sulfonic acid, and antimony trifluoride as acid catalysts (46).

An interesting method of polymerization of  $\alpha$ -hydroxy acids was offered by Tighe and coworkers (47–49), which did not receive much attention. In this method, the anhydrosulfite (I) and the anhydrocarboxylate (II) cyclic derivatives of  $\alpha$ -hydroxy acids are polymerized in refluxing dioxane or nitrobenzene for 18–52 h with alcohol catalysis (Scheme 2).

The polymerization was preceded by thermal decomposition of (I) to give the sulfur dioxide and  $\alpha$ -lactone (III). The  $\alpha$ -lactone polymerizes by ring-opening polymerization using an alcohol catalysis to give exclusively poly( $\alpha$ -hydroxyalkanoic acid). The formation of (III) was rate controlling, and the subsequent polymerization was so rapid that sulfur dioxide and polymer were formed simultaneously. Pure polymers in  $>80\%$  yield and molecular weights of  $\text{MN} = 20,000$  were reported (49).

**Scheme 2** Polymerization of  $\alpha$ -hydroxy acids using anhydrosulfite cyclic derivatives of  $\alpha$ -hydroxy acids.

Branched lactide polymers prepared from the polymerization of lactide and pentaerythritol as branching agent were reported. These branched polymers are degraded in a monophasic character, and their degradation is in general faster than for the linear polymers (50). Various polyol molecules were used to prepare a range of branched structures with different properties (37,51).

Copolymers of LA/GA 55:45 branched with 0.2–1 wt% of small polyols like manitol, cyclodextrine, pentaerythritol, and xylitol had a weight average molecular weight of 15,000 to 46,000. The copolymers branched with 1 wt% of poly(vinyl alcohol) of 3,000 to 72,000 molecular weight range resulted in a tenfold increase in molecular weight of 182,000 to 676,000, respectively. Star poly(ethylene oxide)-polylactide copolymers in a spherical form were obtained from the block copolymerization of lactic acid on the end groups of three or four arm poly(ethylene oxide) molecules (51).

Blends of low and high molecular weight poly(DL-lactide) were studied as carriers for drugs. As expected, the addition of low molecular weight polymer accelerated the release of drug from the blend formulation (52).

Different interactions are known to be involved in complex formation between two polymer molecules. It was found that PLA complex was formed in a solution of both enantiomers in chloroform. The reaction proceeds very slowly at room temperature (53). First, gel formation was noticed which turned into a precipitate only after about 30 days. For high molecular weight PLA the reaction takes even longer, up to 1 year. A quicker procedure was found by precipitating D-PLA and L-PLA together. This can be achieved by pouring a solution of D- and L-PLA in dichloromethane into a nonsolvent like methanol or ether. When a film is casted from a solution of low molecular weight isotactic PLA enantiomers in dichloromethane or chloroform, preferably stereocomplex crystals are formed. With PLA of higher molecular weight, less stereocomplex formation was noticed. An easy procedure to obtain the stereocomplex both for low and for high molecular weight PLA consists of heating a mixture of both enantiomers at 60°C in acetonitrile. Poly(lactic acid) was soluble in acetonitrile only at elevated temperatures (from 52°C upwards). Within several hours the solution became turbid and a precipitate was obtained after 3 days. It is suggested that complex formation takes place during precipitation from a solvent. Neither L-PLA or D-PLA gives a reaction on its own in various solvents under similar conditions (54,55). Differential scanning calorimetry (DSC) shows a shift of the melting temperature of about 50°C (from  $T_m = 180^\circ\text{C}$  for D- or L-PLA, MW = 100,000, to  $T_m = 230^\circ\text{C}$  for PLA stereocomplex of similar molecular weight) (54–56).

Scanning electron microscope (SEM) images revealed the formation of particles whose shape was influenced by

the initial concentration of polymer. In concentrations up to 10 mg/mL discs were formed either with or without cavity in the middle (shape of a red blood cell). Polymers of higher molecular weight formed spheres consisting of a fiberlike structure. If polymer was used of 150,000 or higher molecular weight, a three-dimensional network could be noticed in which the previously mentioned spheres were absorbed (55).

The PLA stereocomplex appears to be soluble in dichloromethane or hexafluoroisopropanol (HFIP). By casting a low-concentrated solution on mica crystals PLA stereocomplexes were obtained. As opposed to isotactic PLA several reports indicate the formation of triangle-shaped crystals. There is a difference in opinion as to whether the PLA stereocomplexes consist of  $3_1$ -helices ( $\beta$ -form) or  $10_3$ -helices ( $\alpha$ -form). Brizollara et al. predicted  $3_1$ -helix on the basis of computer calculations. The D- and L-helices are intertwined forming “double strand” helices, which are packed in a hexagonal cell forming triangle-shaped crystals (57). On the other hand x-ray data suggested no change in the  $10_3$ -helical conformation. “Frustration” of the packing of the L- and D-helices was suggested to cause the triangular shape (58). According to the latter view, the helices are not intertwined, as was also suggested in earlier reports for stereocomplexes of other polymers (59,60). Recently it has been reported that both conformations exist in the PLA stereocomplex:  $10_3$ -helix with a minimum of 11 units and  $3_1$ -helices with a minimum of 7 monomers since only two helical turns are needed for complexation reaction (61). Also, stereocomplexes of PLA containing PEG have been synthesized and characterized by means of DSC and various microscopic techniques (62).

#### b. Polymer Properties

Polyesters based on poly(lactic acid), poly(glycolic acid), and poly(lactic-co-glycolic acid) are found as the best biomaterial with regard to design and performance. Among them, lactic acid contains an asymmetric  $\alpha$ -carbon atom with three different isomers as D-, L-, and DL-lactic acid. The physicochemical properties of optically active homopolymers poly(D-lactic acid) (PDLA) and poly(L-lactic acid) (PLLA) are the same, whereas the racemic PLA has very different characteristics (63). Racemic PLA and PLLA have  $T_g$  of 57 and 56°C, respectively, but PLLA is highly crystalline with a  $T_m$  of 170°C, and racemic PLA is purely amorphous. The polymer characteristics are affected by the comonomer composition, the polymer architecture, and molecular weight. The crystallinity of the polymer is an important factor in polymer biodegradation and varies with the stereoregularity of the polymer. Sterilization using  $\gamma$ -irradiation decreases the polymer molecular weight by 30 to 40% (64). The irradiated polymers con-

tinue to decrease in molecular weight during storage at room temperature. This decline in molecular weight affects the mechanical properties and the release rate from the polymers. Poly(lactic acid) and its copolymers with less than 50% glycolic acid content are soluble in common solvents such as chlorinated hydrocarbons, tetrahydrofuran, and ethyl acetate. Poly(glycolic acid) is insoluble in common solvents, but soluble in hexafluoroisopropanol and hexafluoroacetone sesquihydrate (HFASH). In its highly crystalline form, PGA has a very high tensile strength (10,000–20,000 psi) and modulus of elasticity ( $\sim 1,000,000$  psi) (65).

The solubility parameters of several polymers were determined by Siemann (66). The solubility parameters were in the range of 16.2 and 16.8, which is comparable to those of polystyrene and polyisoprene (67).

A comparison study on the physicomechanical properties of several biodegradable polyesters was reported (68). The thermal properties, tensile properties, and the flexural storage modulus as a function of temperature were determined. The following polymers were compared: poly(L-lactic acid), poly(DL-lactic acid), poly(glycolic acid), poly( $\epsilon$ -caprolactone), poly(hydroxybutyrate) and copolymers with hydroxyvaleric acid, and poly(trimethylene carbonate). The thermal and mechanical properties of several of the polymers tested are summarized in Table 1 (68). A comprehensive review on the mechanical properties of several biodegradable materials used in orthopedic devices

has been published (69). The tensile and flexural strength and modulus, as well as the biodegradation of various lactide/glycolide polymers, polyorthoester, and polycaprolactone have been summarized in a tabular or diagram format.

### c. Biodegradation

Lewis (70), Gopferich (71), Holland et al. (72), and Tracy (73) reviewed the biodegradation behavior of lactide/glycolide polymers. The molecular weight and polydispersity as well as the crystallinity and morphology of the polymers are important factors in polymer biodegradation.

The factors that may affect the polylactide degradation include chemical and configurational structure, molecular weight and distribution, fabrication conditions, site of implantation, physical factors, and degradation conditions (74,75). The degradation of semicrystalline polymers proceeds in two phases: in the first phase the amorphous regions are hydrolyzed, and then the crystalline regions in the second. The polymers degraded by bulk hydrolysis of the ester bonds, which resulted in a decrease in molecular weight with no weight loss.

A comprehensive investigation on the hydrolysis of lactide polymers was described recently by Vert et al. (76). In these studies, a standardized set of experiments was designed. All specimens ( $2 \times 10 \times 15$  mm) were prepared in a similar way and allowed to hydrolyze at 37°C in dis-

**Table 4.1** Thermal and Mechanical Properties of Biodegradable Polyesters<sup>a</sup>

Polymer	MW	T <sub>g</sub> (°C)	T <sub>m</sub> (°C)	Tensile strength (MPa)	Tensile modulus (MPa)	Elongation

tilled water or isotonic phosphate buffer. The changes in the polymer during hydrolysis were monitored by weighing for water uptake and weight loss, gel permeation chromatography (GPC) for molecular weight change, and DSC and x-ray scattering for thermal properties and crystallinity change, potentiometry and enzymatic assays for pH change and lactic acid release, and dynamic mechanical tests for changes in mechanical properties (76). The polymer, semicrystalline PLA lost about 50% of its mechanical strength after 18 weeks in buffer, with no weight loss until about 30 weeks of hydrolysis. The degradation of branched PLA was characterized as bulk erosion, like the linear polymers (37).

Vert et al. (77) demonstrated the complexity of PLA, PGA, and PLGA degradation, and suggested that size dependency exists for hydrolytic degradation of PLA systems. Other research efforts suggest that PLA-derived microparticles will degrade faster than nanoparticles derived from PLA (78,79) and that this phenomenon is based on a diffusion mechanism.

The biodegradation of branched PLA with glucose or macromolecular polyol in rats is determined by weight loss (37). In vitro degradation was essentially the same, indicating minimal involvement of enzymatic degradation. The branched materials degraded much faster than the reference linear PLA. On the contrary, the linear PLA had a higher water uptake than the branched polymers. For example, after 36 weeks the linear PLA contained about 21 wt% water, while the corresponding branched PLA contained only 2%. No adequate explanation was given for this phenomenon.

The degradation of several aliphatic polyesters in the form of microspheres in phosphate buffer solution at 37 and 85°C was reported (80). Lower molecular weight polymers degraded faster than higher molecular weight polymers. Degradation at 85°C resulted in a similar degradation profile, but faster. The biodegradation of low molecular weight PLA used in tablets for oral delivery of drugs was also studied (81).

#### d. Other Copolymers of Lactic Acid

Low molecular weight homopolymers of D,L-mandelic acid (MA) and its copolymers with lactic acid were reported (82,83).

copoly(lactide-mandelate)

The polymers were prepared by direct condensation of mandelic acid and lactic acid at 200°C under vacuum. The copolymers containing 15 to 100% MA were amorphous, and the degradation rate decreased with the increase in MA content with no degradation observed for the MA homopolymer after 15 weeks in buffer at 37°C.

Low molecular weight  $\alpha$ -hydroxy acid copolymers composed of 70 mole% L-lactic acid and 30 mole% DL-hydroxy acids of the structure

Monomer	R
DL-LA	-CH <sub>3</sub>
DL-HBA	-CH <sub>2</sub> CH <sub>3</sub>
DL-HIVA	-CH(CH <sub>3</sub> ) <sub>2</sub>
DL-HICA	-CH <sub>2</sub> CH(CH <sub>3</sub> ) <sub>2</sub>

were synthesized by direct polycondensation in the absence of catalysts (82,84). The polymers had a molecular weight of 5000 and  $T_g$  in the range of 20 to 37°C. These polymers were evaluated in vivo for their capabilities as biodegradable carriers for drug delivery systems. Small cylinders (2 × 10 mm) implanted subcutaneously in rats were 60 to 90% degraded in 15 weeks postimplantation. The copolymer L-LA/DL-HBA degraded the least with a lag time of no weight loss for 5 weeks. Polymer cylinders containing luteinizing hormone releasing hormone (LHRH) agonist were implanted in rats and released the drug for 15 weeks, with poly(L-LA/DL-HICA) being the most pharmacologically effective.

## 2. Polycaprolactones

The successful use of lactide and glycolide polymers in absorbable drug delivery systems and medical devices and absorbable sutures encouraged the evaluation of other polyesters for this purpose. The most studied polymers in this category are the polycaprolactones, polyhydroxybutyrate, and polymers of other  $\alpha$ -hydroxy acids. These polymers were developed originally as synthetic plastics to be degraded by microorganisms in the environment (85,86).

### a. Synthesis

Poly( $\epsilon$ -caprolactone) (PCL) has been synthesized from the anionic, cationic, and coordination polymerization of  $\epsilon$ -

caprolactone. The synthesis of polycaprolactones has been recently reviewed (87,88). A schematic description of caprolactone polymerization using these three types of initiators is shown in Scheme 3 (87).

Various initiators and polymerization conditions were reported for each type of catalyst. Effective anionic reaction systems are tertiary amines, alkali metal alkoxides, and carboxylates in tetrahydrofuran, toluene, and benzene (89). The anionic method of polymerization is most useful for the synthesis of low molecular weight hydroxy-terminated oligomers and polymers (90).

Known cationic catalysts in organic synthesis affect cationic polymerization and include protic acids, Lewis acids, acylating agents, and alkylating agents. The following agents,  $\text{FeCl}_3$ ,  $\text{BF}_3$ ,  $\text{Et}_2\text{O}$ , alkyl sulfonate, and trimethylsilyl triflate, have been used in 1,2-dichloroethane at  $50^\circ\text{C}$  to yield polymers with a molecular weight range of 15,000 to 50,000. High molecular weight homopolymers and random copolymers with lactides and other lactones were obtained using coordination catalysts such as di-*n*-butyl zinc, stannous octoate, and alkoxides and halids of Al, Sn, Mg, and Ti. Polymerization occurs at  $120^\circ\text{C}$  under argon to yield polymers with a narrow molecular weight distribution ( $\text{MW}/\text{MN} = 1.1$ ) and molecular weights above 50,000 (91,92). Polycaprolactone was also obtained from the radical polymerization of 2-methylene-1,3-dioxepane (93).

In contrast to random copolymers, block and graft multicomponent systems are most often multiphase materials with properties that are different from the homopolymers or random copolymers (94). They are useful in improving the phase morphology, the interfacial adhesion and, accordingly, the ultimate mechanical properties of immiscible polymer blends. As an example, block copoly-

merization of  $\epsilon$ -caprolactone (CL) and lactides (LA) allows the permeability of the PCL to be combined with the rapid biodegradation of PLA (95).

Block copolymers of CL and LA were synthesized by ring-opening polymerization of lactides (D,L and L,L) and  $\epsilon$ -caprolactone using aluminum isopropoxide as initiator (96). Block copolymerization of CL and LA was also reported by Feng and Song using bimetallic (Al, Zn  $\mu$ -oxo alkoxides) initiators (97,98). Because of the difference in reactivity, the sequential polymerization of these two monomers can only be achieved when CL is first polymerized followed by the lactide (99). Formation of large amounts of homo-PLA is observed and has been attributed to the increase in the mean degree in association of aluminum alkoxide in toluene from one to three in the presence of CL and LA, respectively. The homopolymer formation can be prevented by the addition of a small amount of an alcohol, like 2-propanol, or the use of Al derivative that bears only one alkoxide group (99).

Degradable block copolymers with polyethylene glycol, diglycolide, substituted caprolactones, and  $\lambda$ -valerolactone were also reviewed (87).

### b. Polymer Properties

Polycaprolactone is soluble in chlorinated and aromatic hydrocarbons, cyclohexanone, and 2-nitropropane, and it is insoluble in aliphatic hydrocarbons, diethyl ether, and alcohols. The homopolymer melts at  $59$ – $64^\circ\text{C}$  with a  $T_g$  of  $-60^\circ\text{C}$ . Copolymerization with lactide increases the  $T_g$  with the increase in the lactide content in the polymer (100). The crystallinity of the polymer decreases with the increase in polymer molecular weight; polymer of 5000 is 80% crystalline, whereas the 60,000 polymer is 45% crystalline (101).

### c. Biodegradation

The biodegradation of PCL has been extensively studied in the past 30 years and several reviews are available (87,102). Like the lactide polymers, PCL and its copolymers degrade both *in vitro* and *in vivo* by bulk hydrolysis (101), with the degradation rate affected by the size and shape of the device and additives.

The kinetic equivalency of the degradation of PCL in buffer and in rabbit was demonstrated by measuring the polymer intrinsic viscosity for 60 weeks (87). The polymers degrade in two phases. In the first phase a random hydrolytic chain scission occurs, which results in a reduction of the polymer molecular weight. In the second phase the low molecular fragments and the small polymer particles are carried away from the site of implantation by solu-

**Scheme 3** Polymerization of  $\epsilon$ -caprolactone using (A) anionic, (B) cationic, and (C) coordination catalysts.

bilization in the body fluids or by phagocytosis, which results in a weight loss. Complete degradation and elimination of PCL homopolymers may last for 2 to 4 years. The degradation rate is significantly increased by copolymerization or blending with lactide and glycolide. The rate of degradation can be increased also by the addition of oleic acid or tertiary amines to the polymer, which catalyzes the chain hydrolysis (103,104).

### 3. Poly( $\beta$ -hydroxybutyrate)

#### a. Synthesis

Poly( $\beta$ -hydroxybutyrate) (PHB) is made by a controlled bacterial fermentation. The producing organism occurs naturally. An optically active copolymer of 3-hydroxybutyrate (3HB) and 3-hydroxyvalerate (3HV) has been produced from propionic acid or pentanoic acid by *Alcaligenes eutrophus* (105):

The copolymer compositions (0 to 95 mole% 3HV content) can be controlled by the composition of the carbon sources. Random copolymers of 3HB and 4HV were produced from 4-hydroxybutyric acid and butyric acids by *Alcaligenes eutrophus* (106,107):

#### b. Properties and Biodegradation.

The polymers are characterized as having a high molecular weight ( $>100,000$ ,  $[n] > 3$  dL/g) with a narrow polydispersity and a crystallinity of around 50%. The melting point depends on the polymer composition; P(3HB) homopolymer melts at  $177^\circ\text{C}$  with a  $T_g$  at  $9^\circ\text{C}$ , the 91:9 copolymer with 4HB melts at  $159^\circ\text{C}$ , and the 1:1 copolymer with 3HV melts at  $91^\circ\text{C}$ . The PHB properties in the living cells of *Alcaligenes eutrophus* were determined using x-ray and variable-temperature  $^{13}\text{C}$  NMR relaxation studies (108). Polyhydroxybutyrate is an amorphous elastomer with a  $T_g$  around  $-40^\circ\text{C}$  in its "native" state within the granules. The biodegradation of these polymers in soil and activated sludge show the rate of degradation to be in the following order: P(3HB-co-9% 4HB)  $>$  P(3HB) = P(3HB-co-50% 3HV).

The hydrolytic degradation of HB polymers was studied (109). Microspheres degraded slowly in phosphate buffer at  $85^\circ\text{C}$ , and after 5 months 20 to 40% of the polymer eroded under these conditions. Copolymers having a higher fraction of 3HV and low molecular weight polymers were more susceptible to hydrolysis.

### 4. Polycarbonates

Poly(ethylene carbonate) and poly(propylene carbonate) have been tested as biodegradable carriers for the delivery of 5-fluorouracil (5-FU) (110). They are linear thermoplastic polyesters of carbonic acid with aliphatic dihydroxy compounds.

#### a. Synthesis

The polymers are synthesized from the reaction of dihydroxy compounds with phosgene or with bischloroformates of aliphatic dihydroxy compounds by transesterification and by polymerization of cyclic carbonates:

These polymers have been synthesized from carbon dioxide and the corresponding epoxides in the presence of organometallic compounds as initiators (111).

#### b. Biodegradation

Since the carbonate linkage may be labile to hydrolysis, the biodegradability of polycarbonates has been studied (110,111). Pellets of poly(ethylene carbonate) and poly(propylene carbonate) were implanted into the peritoneal cavity of rats, and the toxicity and weight loss of polymer pellets were determined. Poly(ethylene carbonate) was completely eliminated 15 days postimplantation, while poly(propylene carbonate) remained intact after 60 days. When pellets of the polymers were incubated in phosphate buffer pH 7.4 and  $37^\circ\text{C}$ , both polymers did not degrade even after 40 days. These data indicate that poly(ethylene carbonate) was degraded by enzymes. No visible inflammatory reaction was noted at the implantation sites. In vitro release of 5-FU from poly(ethylene carbonate) pellets containing 20% 5-FU was poor, 20% of the drug was released in 2 h, and only an additional 15% of 5-FU were released during the following 60 days. Better release profiles were obtained when poly(propylene carbonate) was used.

Copolymers of aliphatic carbonates and lactide showed excellent biocompatibility and mechanical properties. Block copolymers of trimethylene carbonate (TMC) and

lactide were synthesized from the reaction of the monomers with stannous octoate as catalyst at 160°C for 16 h:

The polymers were soluble in common organic solvents and had a weight average molecular weight of 90,000. They completely degraded in vivo in 1 year (112).

## 5. Other Polyesters

Poly(dihydropyrans) were developed for contraceptive delivery. The in vivo and in vitro release of contraceptive steroids and antimalarial agents from polymer matrices has been studied (113).

poly(dihydropyrans)

Poly(*p*-dioxanone) is clinically used as an alternative to poly(lactide) in absorbable sutures with similar properties to poly(lactide) with the advantage of better irradiation stability during sterilization (114):

poly(*p*-dioxanone)

This polymer has not yet been developed as a carrier for controlled drug delivery.

Biodegradable polymers derived from naturally occurring, multifunctional hydroxy acids and amino acid have been investigated by Lenz and Guerin (115). The monomers, malic acid, and aspartic acid were polymerized into a polyester or polyamide using a ring-opening polymerization process as follows:

The molecular weights of the polymers were highly dependent on the purity of the cyclic monomers. Polymers of 50,000 were obtained in 93% polymerization yield when very pure monomers were used. Both polymers are water soluble; however, crystallinity and controlled number of

acid groups in the polymer chains can be used to alter water swellability and solubility of the polymers. Biocompatibility evaluation in mice indicated that poly( $\beta$ -malic acid) is nontoxic (115).

A series of polyesters, poly(propylene fumarate) (PPF), based on the reaction product of fumaric acid (116,117), and tartaric acid (118,119) with different aliphatic diols have also been evaluated as drug carriers. Poly(propylene fumarate) with acrylate and epoxide terminal groups was produced by Domb et al. (120). The polymers were cross-linked in a ratio of 30 wt% PPF to 70 wt% calcium carbonate–tricalcium phosphate mixture and were synthesized by a direct melt condensation of the acids with the diols with acid catalysis.

## B. Poly(amides)

### 1. Synthesis and Biodegradation

The utilization of amide-based polymers, especially natural proteins, in the preparation of biodegradable matrices has been extensively investigated in recent years (121). Microcapsules and microspheres of crosslinked collagen, gelatin, and albumin have been used for drug delivery (122). The synthetic ability to manipulate amino acid sequences has seen its maturity over the last two decades, with new techniques and strategies continually being introduced. Poly(amides) such as poly(glutamic acid) and poly(lysine) and their copolymers with various amino acids have also been studied as drug carriers (123,124). Recently, Nathan and Kohn (125) have excellently reviewed the history of amino acid-derived polymers.

Pseudopoly(amino acids), a new approach for biomaterials based on amino acids, were first suggested by Kohn and Langer (126,127), who prepared a polyester from *N*-protected trans-4-hydroxy-L-proline, and poly(iminocarbonate) from tyrosine dipeptide as monomeric starting material. The structures of poly(*N*-acylhydroxyproline esters) and a homologous series of tyrosine-derived polymers is described in Scheme 4 (121).

The properties, biodegradability, drug release, and biocompatibility of this class of polymers have been reviewed (121,122). Biodegradable polyamides for use in controlled delivery of drugs were obtained from the reaction of 2,2'-bis[5(4HO-oxazolones)] and alkane diamines (128). Drug release time from these polymers was short, less than 24 h.

Copolymers of glutamic acid and ethylglutamate were used for the delivery of naltrexone (129). The polymers were synthesized in three steps: (1) synthesis of *N*-carboxyanhydrides of  $\gamma$ -benzyl-L-glutamate and  $\gamma$ -ethyl-L-glutamate; (2) polyamidation of the benzyl blocked monomers; and, (3) debenzilation of the intermediate. Poly(amino acids) are generally hydrophilic, and their deg-

**Scheme 4** Molecular structure of pseudopoly(amino acids). (A) Poly(N-acylhydroxyproline esters); (B) Tyrosine-derived polyiminocarbonate, poly(CTTE),  $x = 1$ ; poly(CTH),  $x = 4$ ; poly(CTTP),  $x = 15$ .

radiation rates are dependent upon hydrophilicity of the amino acids.

The degradation rate increases as the glutamic acid content increases. For example, copolymer containing 13 mole% glutamic acid remained intact for more than 79 days, while the 40% copolymer disintegrated in 7 days. Tubular capsules of 18:82 glutamic acid/ethylglutamate copolymer were used as a reservoir implant. The copolymer was biocompatible and completely degraded in 90 days. The degradation process involves hydrolysis of the ethyl esters followed by hydrolysis of the peptide bonds to produce glutamic acid, which enters the metabolic cycle. Amino acids are attractive due to their functionality by which they provide a polymer. Recently, poly(lactic acid-co-lysine) (PLAL) was synthesized using a stannous octoate catalyst from lactide and a lysine-containing monomer analogous to lactide (130). Inclusion of the amino acid lysine provides an amino group that allows for further modification of the PLAL system. In a recent report, Cook and coworkers (131) have successfully attached a peptide sequence which promotes cell adhesion to PLAL. The use of N-carboxyanhydride-activated amino acids was the first efficient method for production of amino acid homopolymers. In a further study, they have exploited the PLAL system by the reaction with lysine N-carboxyanhydride derivatives to increase the system's functionality with a poly(lysine) graft. Poly(lactic acid-co-lysine) has been formulated into microspheres that exhibit deep lung delivery from porous particles (132).

Copolymers of n-hydroxyalkyl-L-glutamine and  $\gamma$ -methyl-L-glutamate were synthesized from the reaction of poly( $\gamma$ -methyl-L-glutamate) and 2-amino-1-ethanol or 5-amino-1-pentanol as follows (133):

The *in vitro* enzymatic degradation using pronase E as protease showed that these polymers degrade from the surface, and the polymers were completely dissolved in from several hours to several days as a function of polymer structure and enzyme concentration. Negligible weight loss was detected without the enzyme.

Random copolymers of the  $\alpha$ -amino acids N-(3-hydroxypropyl)-L-glutamine and L-leucine were synthesized and used as carriers for naltrexone (134). Naltrexone was covalently bound through the 3-phenolic or the 14-tertiary hydroxyls to the polymer hydroxyl side chains via a carbonate bond. Naltrexone was released from the polymer in a relatively constant way for 30 days, in both *in vitro* and *in vivo* experiments in rats (134). Tyrosine-derived poly(carbonates) are readily processible polymers that support the growth and attachment of the cells and have also shown a high degree of tissue biocompatibility (135,136). *In vitro* degradation of these compounds occurs due to hydrolysis of the pendant ester bonds and the imino-carbonate bonds of the backbone (136). Degradation goes over a period of months and rates are comparable to the degradation time of poly(L-lactic acid).

### C. Poly(phosphate Esters)

Poly(phosphoester) has been studied as a potential biodegradable matrix for drug delivery (137,138). The polymers were synthesized from the reaction of ethyl or phenyl phosphorodichloridates and various dialcohols including bisphenol A and poly(ethylene glycol) of various molecular weights:

Interfacial condensation using a phase transfer catalyst and bisphenol A as comonomer yielded polymers with a weight average molecular weight around 36,000. Leong et al. have incorporated phosphoester groups into poly(urethanes) (139). Poly(urethanes) have been used as blood contacting biomaterials due to having a broad range of physical properties that can be obtained, from hard and brittle to soft and tacky. Leong et al. designed inert biomaterial for controlled release applications by introducing

**Scheme 5** Synthesis of poly(phosphoester-urethanes).

phosphoester linkage in poly(urethane). Introduction of phosphoester linkage does not change the mechanical properties inherent in the poly(urethanes) and provides an excellent biodegradable material.

Poly(phosphoester-urethanes) are obtained by the reaction of polydiols and di-isocyanates with phosphates as chain extenders as shown in Scheme 5.

Phosphoester bonds are readily cleaved under physiological conditions, and hydrolysis of poly(phosphoester-urethanes) leads to phosphates, alcohols, amines, and carbon dioxide, which makes it an excellent biomaterial for drug delivery applications. Leong et al. observed that the release kinetics of poly(phosphoester-urethanes) were influenced by the side chains attached via the phosphoester of the polymer backbone and thus pentavalency of the phosphorus contributes a site for future functionalization (140). The release mechanism was dependent combinedly on diffusion, swelling, and degradation of polymer.

The polymers based on bisphenol A release drug for a long period of time; 8 to 20% cortisone was released after 75 days in buffer solution. The degradation rate depends on the nature of the polymer side chain; polymers with phenyl side chains degrade much slower than those containing ethyl or ethoxyethyl side chains (138). The *in vivo* degradation of these polymers in rabbits was faster than *in vitro*.

#### D. Polyphosphazenes

The uniqueness of the polyphosphazenes stems from the inorganic backbone (N = P), which with certain organic side groups can be hydrolyzed to phosphate and ammonia. Several polymer structures have been used as matrix carriers for drugs (141,142) or as a hydrolyzable polymeric drug, where the drug is covalently bound to the polymer backbone and released from the polymer by hydrolysis (143). A comprehensive review on the synthesis, charac-

terization, and medical applications of polyphosphazenes was published by Allcock (144).

#### 1. Synthesis and Biodegradation

The polymers are most commonly synthesized by a substitution reaction of the reactive poly(dichlorophosphazene) with a wide range of reactive nucleophiles such as amines, alkoxides, and organometallic molecules (Scheme 6). The reaction is carried out in general at room temperature in tetrahydrofuran or aromatic hydrocarbon solutions. Polymers containing mixed substituent can be obtained from the sequential or simultaneous reaction with several nucleophiles (Scheme 6) (145).

The properties of the polymers depend on the nature of the side groups. Hydrolytically degradable polyphosphazene was obtained when amino acid and imidazole derivatives were used as substituents (142,146). The first bioerodible polymer was the ethylglycinato derivative ( $R = \text{NHCH}_2\text{COOEt}$ ), which hydrolytically degrades to ethanol, glycine, phosphate, and ammonia (146). *In vitro* degradation studies on poly(phosphazenes) with different amino acid derivatives show that it takes several months to degrade the material depending on the amino acid present (147). Allcock et al. (148,149) synthesized three different poly[(amino acid ester)phosphazenes]: poly[di(ethylglycinato)phosphazene], poly[di(ethylalano)phosphazene], and poly[di(benzylalano)phosphazene]. According to the order of polymers, they show a tendency to decrease the molecular weight and mass loss with release of small molecules. The release of small molecules occurred through diffusion and decomposition of polymer.

Biodegradable poly(phosphazenes) that are insoluble in water prior to hydrolysis have been employed in the temporal controlled release of many drug classes including nonsteroidal anti-inflammatory agents and peptides (150–153). Amino acid ester-substituted polyphosphazenes have been used for controlled release of the covalently

**Scheme 6** Synthesis and hydrolysis of polyphosphazenes.

bonded anti-inflammatory agent naproxen. Steroids having a hydroxyl group were bound to the polymer chain through the hydroxyl group (154).

Poly(organophosphazenes) have been synthesized that possess amino acid side groups. The mechanical properties and rates of degradation have been controlled by appropriate selection of amino acid side chain groups (155). The versatility of these polymers has been demonstrated by the formation of 200-nm diameter poly(organophosphazene) nanoparticles that present covalently coupled poly(ethylene glycol) at their surface (156).

Imidazolyl-substituted polyphosphazenes are hydrolytically unstable and hydrolyze in room moisture (142). The rate of hydrolysis can be slowed by the incorporation of hydrophobic side groups such as phenoxy or methylphenoxy groups (141). The *in vivo* and *in vitro* release of progesterone and bovine serum albumin (BSA) from imidazole, 4-methylphenoxy-substituted polyphosphazene matrices were reported (141). Almost 90% of the loaded progesterone was released in 30 days with about 60% released in 8 days when placed in phosphate buffer pH 7.4 at 37°C. An *in vivo* release study in rats using radiolabelled progesterone demonstrated a zero-order release for 30 days. Various hydrophilic and hydrophobic polymers, hydrogels, water-soluble polymers, bioactive polymers, and various drug-polyphosphazene conjugates have been reviewed (144).

A number of approaches have been proposed to generate crosslinked polyphosphazene for temporal controlled release. Andianov and coworkers have synthesized poly[bis(carboxylatophenoxy)-phosphazene] crosslinked with Ca<sup>2+</sup> ions for an ionically stabilized system (157). This polymer allowed drug molecules to be encapsulated into poly(phosphazene) microspheres under mild environmental conditions. Recently, pH-sensitive hydrogels have been synthesized by the formation of poly(phosphazenes) with oxybenzoate and methoxyethoxy side group. Swelling at different pH values was controlled by varying the ratios of the two side groups (158).

### E. Poly(orthoesters)

Poly(orthoesters) were invented during the pursuit of developing a bioerodible polymer, subdermally implantable, that would release contraceptive steroids by close to zero-order kinetics for at least 6 months (159). An additional objective was that the polymer erosion and drug release should be concomitant so that no polymer remnants are present in the tissue after all the drug has been released. These objectives could only be met if the polymer were truly surface eroding. For a surface-eroding polymer, the erosion process at the surface of the polymer should be

much faster than in the interior of the device. To exhibit such a phenomenon, the polymer has to be extremely hydrophobic with very labile linkages. Hence, it was envisioned that polymeric devices with an orthoester linkage in the backbone, which is an acid-sensitive linkage, could provide a surface-eroding polymer if the interior of the matrix is buffered with basic salts.

#### 1. Synthesis

The first poly(orthoesters) were reported in a series of patents by Choi and Heller (160–163), assigned to Alza Corporation. These proprietary polymers were first designated as Chronomer and later as Alzamer. They were prepared by a transesterification reaction, as follows (164):

The general synthesis involved the heating of the reaction mixture to 110 to 115°C for about 1.5 to 2 h and then further heated at 180°C and 0.01 torr for 24 h. The synthesis of such polymers, with a minimal amount of cross-linkage, requires an orthoester starting material in which one alkoxy group has a greatly reduced reactivity. This can be achieved by using a cyclic structure as shown in the reaction.

Hydrolysis of these polymers regenerates the diol and  $\gamma$ -butyrolactone (165). The  $\gamma$ -butyrolactone rapidly hydrolyzes to -hydroxybutyric acid. The production of -hydroxybutyric acid would further catalyze the breakdown of orthoester linkages leading to bulk erosion of the matrix. Thus it was decided to incorporate basic salts into the polymer matrix to neutralize the generated acid and keep the hydrolysis process under control. These Alzamer materials were investigated as bioerodible implants for the release of naltrexone and contraceptive steroids. Human clinical trials of the steroidal implant revealed local tissue irritation, and thus further work was discontinued (166). Recently the use of these polymers for the release of indomethacin in the prevention of reossification of experimental bone defects was reported (167).

Subsequently, another family of poly(orthoesters) was developed not related to Alzamer (168). These polymers are prepared by the addition of polyols to diketene acetals. The general reaction can be schematically represented as follows:

Initial work was conducted with the monomer, diketene acetal, derived from pentaerythritol, and 1,6-hexanediol. The reaction is exothermic and proceeds to completion virtually instantaneously. The reaction is as follows:

where R = H, for 3,9-bis(methylene 2,4,8,10-tetra oxaspiro [5,5] undecane). The diols investigated were 1,6-hexanediol trans-1,4-cyclohexane dimethanol, 1,6-cyclohexanediol, ethylene glycol, and biophenol A.

## 2. Polymer Properties

The molecular weight of poly(orthoesters) were significantly dependent on the type of diol and catalyst used for synthesis. A linear, flexible diol like 1,6-hexanediol gave molecular weights greater than 200 K, whereas bisphenol A in the presence of catalyst gave molecular weight only around 10,000 (169).

Mechanical properties of the linear poly(orthoesters) can be varied over a large range by selecting various compositions of diols. It was shown that the glass transition temperature of the polymer prepared from DETOSU can be varied from 25 to 110°C by simply changing the amount of 1,6-hexanediol in trans-1,4-cyclohexane dimethanol from 100 to 0% (170). There seems to be a linearly decreasing relationship between the  $T_g$  and percentage of 1,6-hexanediol. One could take advantage of this relationship in selecting the polymer for in vivo applications because in vivo the  $T_g$  of the polymer would drop due to inhibition of water. This can result in the loss of stiffness and rigidity of the polymer.

## 3. Crosslinked Poly(orthoesters)

To prepare a crosslinked polymer, there should be at least one monomer which has a functionality greater than 2. In case of poly(orthoesters), it is possible for a ketene acetal or an alcohol to have a functionality greater than 2. Due to the difficulty in preparing trifunctional ketene acetals, triols were used to prepare the crosslinked polymer.

**Scheme 7** Synthesis of crosslinked polyorthoesters.

The general method used for the synthesis of crosslinked polymers was by reacting prepolymer with the triols or a mixture of diols and triols (Scheme 7) (171).

The prepolymer is an acetal with a diol and is a viscous liquid at room temperature. Thus, the compound of interest could be incorporated into the prepolymer along with the triol, and the mixture can be crosslinked at temperatures as low as 40°C. This can be a good method for incorporating thermolabile drugs. However, one should be cautious with using compounds with hydroxyl functionality.

In a series of experiments, Heller et al. (172) have reported the family of poly(orthoesters) which can be prepared by reacting a triol with two vicinal hydroxyl groups and one removed by at least three methylene groups with an alkyl orthoacetate as shown:

The use of flexible triols such as 1,2,6-hexanetriol produces highly flexible polymers that have ointmentlike properties even at relatively high molecular weights. However, properties such as viscosity, and hydrophobicity can be readily varied by controlling molecular weight and the size of the alkyl group R'. This polymer has an ointmentlike consistency at room temperature and is applicable where sensitive therapeutic agents such as proteins are incorporated into the polymer without use of solvent.

In another experiment, Heller et al. replaced the flexible triol to a rigid one such as 1,1,4-cyclohexanetriol to obtain a solid poly(orthoester), as shown:

#### 4. Polymer Hydrolysis

The primary mechanism for the degradation of poly(orthoesters) is via hydrolysis. Depending on the reactants used during the synthesis of the polymer, the hydrolysis products are diol, or a mixture of diols, and pentaerythritol dipropionate or diacetate if 3,9-bis(methylene-2,4,8,10-tetraoxaspiro [5,5]undecane) was used (144). The pentaerythritol esters hydrolyze at a slower rate to pentaerythritol and the corresponding acetic or propionic acid. The sequence of reaction is as follows:

The difference in the sensitivity of the hydrolysis of orthoester linkages in an acid versus alkaline medium has been used to advantage in designing the orthoester-based delivery systems. Incorporating acid anhydrides into the matrix to accelerate the rate of hydrolysis uses this preferential sensitivity. While, on the other hand, a base is used to stabilize the interior of the matrix.

Acid-catalyzed hydrolysis of these polymers can be controlled by introducing acidic and basic excipients into the matrices. Rate of hydrolysis can be increased by the addition of acidic excipients, e.g., suberic acid, as demonstrated by the zero-order release of 5-fluorouracil over a 15-day period (173). Alternatively, basic excipients stabilize the bulk of the matrix but diffuse out of the surface region. This approach has been used in the temporal controlled release of tetracycline over a period of weeks in the treatment of periodontal disease (174). Ng et al. described the synthesis of self-catalyzed poly(orthoesters) that contain glycolide sequences and can be degraded hydrolytically without excipient catalysis (175).

Wuthrich et al. (176) proposed the hydrolysis of poly(orthoesters) derived from 1,2,6-hexanetriol as follows:

This initial hydrolysis is proceeded at a slow rate to produce a carboxylic acid and a triol, thus no autocatalysis is observed.

#### 5. Polymer Processing

The orthoester linkage is inherently unstable in the presence of water. However, because of the polymer's highly hydrophobic nature, they can be stored without careful exclusion of moisture.

Even though the polymer is relatively stable in trace amounts of moisture, it is unstable to heat and undergoes disproportionation to an alcohol and ketene acetal. The combination of moisture and heat can be fatal for the processing of poly(orthoesters), which are designed to erode within days (177). Thus, if injection molding is necessary to fabricate the device, then moisture must be rigorously excluded during fabrication. One should also consider the interaction between the incorporated anhydride as catalysts, the polymer, and the drug during the thermal processing.

In one of the studies it was shown that phthalic anhydride reacted with the free hydroxyl end groups of the polymers. Using high-performance liquid chromatography and infrared spectroscopy the formation of half phthalate esters of 1,6-hexanediol and trans-cyclohexane dimethanol was confirmed (178). The reaction led to the decrease in concentration of phthalic anhydride, leading to increased time for erosion of the matrix. The preferred method for fabricating the devices would be under low thermal and shear stresses (179). This would include solution mixing or powder blending followed by compression molding of the devices.

#### F. Poly(anhydrides)

A large number of biodegradable polymers have been investigated as carriers in the design of controlled drug delivery systems. It has been generally recognized that the matrix should undergo heterogeneous degradation to max-

imize the control over release process. In the early 1980s, Rosen et al. (180) envisioned the use of hydrophobic polyanhydrides in designing the surface-eroding matrix for applications in controlled drug delivery. However, the invention and development of polyanhydrides dates as far back as the early 1900s.

In 1909, Bucher and Slade (181) reported the development of aromatic polyanhydrides composed of isophthalic acid and terephthalic acid. Subsequently, Hill and Carothers (182,183) reported a series of aliphatic polyanhydrides. Systematic development of polyanhydrides as substitutes for polyesters in textile applications was undertaken initially by Conix (184,185) and then followed by Yoda and Miyake (186,187). They prepared and studied a number of aromatic and heterocyclic polyanhydrides. These polymers were not suitable for textile applications because of the extreme reactivity of anhydride linkage toward water. The fact that they are extremely hydrophobic and hydrolytically unstable renders them useful in drug delivery applications (187–189).

#### a. Synthesis

*Melt polycondensation.* The majority of the polyanhydrides are prepared by melt polycondensation. The sequence of reaction involves first the conversion of a dicarboxylic acid monomer into a prepolymer consisting of a mixed anhydride of the diacid with acetic anhydride. This is achieved by simply refluxing the diacid monomer with acetic anhydride for a specified length of time. The polymer is obtained subsequently by heating the prepolymer under vacuo to eliminate the acetic anhydride (190):

This procedure was used by most of the early investigators. The polyanhydride thus obtained was of low molecular weight. For most practical applications high molecular weight polyanhydrides are desirable. Hence, a systematic study was undertaken to determine the factors that affected the polymer molecular weight (191). It was found that the critical factors were monomer purity, reaction time and

temperature, and an efficient system to remove the byproduct, acetic anhydride. The highest molecular weight polymers were obtained using pure isolated prepolymers and heating them at 180°C for 90 min with a vacuum of  $10^{-4}$  mmHg, using a dry ice/acetone trap. Molecular weights in excess of 125,000 were obtained.

Significantly higher molecular weights were obtained in shorter times by using coordination catalysts such as cadmium acetate, earth metal oxides, and  $\text{ZnEt}_2 \cdot \text{H}_2\text{O}$  (159). The weight average molecular weight varied from 90,000 to 240,000 when the concentration of cadmium acetate was changed from 0.5 to 3 mole%, with the reaction time of less than 1 h. Other catalysts, such as titanium and iron, inhibited the polymerization reaction and the polymers were dark brown in color. Acidic catalysts, such as p-toluene sulfonic acid, did not show any effect on polymer molecular weight, while the basic catalyst 4-dimethyl amino pyridine caused a decrease in molecular weight.

*Solution polymerization.* Syntheses of polyanhydrides using melt polycondensation is useful to obtain high molecular weight polymers but is not useful if the monomers are thermolabile. Hence, methods were developed to synthesize polyanhydrides under ambient conditions for heat-sensitive monomers such as dipeptides and therapeutically active diacids.

The solution polymerization is carried out by the Schotten–Baumann technique. In this method the solution of diacid chloride is added dropwise into an ice-cooled solution of a dicarboxylic acid. The reaction is facilitated by using an acid acceptor such as triethylamine. Polymerization takes place instantly on contact of the monomers and is essentially complete within 1 h. The solvents employed can be a single solvent or a mixture of solvents like dichloromethane, chloroform, benzene, and ethyl ether. It was found that the order of addition is very important in obtaining relatively high molecular weight polyanhydrides. Addition of a diacid solution dropwise to the diacid chloride solution consistently produced high molecular weight polymers (192):

The drawback of this homogeneous Schotten–Baumann condensation reaction in solution is that the diacid chloride monomer should be of very high purity. An alternative approach was the conversion of dicarboxylic acid monomer into the polyanhydride using a dehydrative coupling agent under ambient conditions. The dehydrative coupling agent, N,N-bis[2-oxo-3-oxazolidinyl]phosphonic chloride was the most effective in forming polyanhydrides with the degree of polymerization around 20 (193). It is

essential that the catalyst be ground into fine particles before use and should be freshly prepared. A disadvantage of this method is that the final product contains polymerization byproducts which have to be removed by washing with protic solvents such as methanol or cold dilute hydrochloric acid. The washing by protic solvents may evoke some hydrolysis of the polymer.

Coupling agents such as phosgene and diphosgene could also be used for the polyanhydride formation. Polymerization of sebacic acid using either phosgene or diphosgene as coupling agents with the amine based heterogeneous acid acceptor poly(4-vinyl pyridine) produced higher molecular weights in comparison to nonamine heterogeneous base  $K_2CO_3$  (194).

*Ring-opening polymerization.* Ring-opening polymerization (ROP) takes place in two steps; the first step is preparation of the cyclic monomer and the second is polymerization of the cyclic monomers. Albertsson and coworkers prepared adipic acid polyanhydride from cyclic adipic anhydride (Oxepane-2,7-dione) using cationic [e.g.,  $AlCl_3$  and  $BF_3 \cdot (C_2H_5)_2O$ ] anionic (e.g.,  $CH_3COO^-K^+$  and NaH) and coordination-type inhibitors such as stannous-2-ethylhexanoate and dibutyltin oxide (195–197).

### b. Polymer Properties

Almost all polyanhydrides show some degree of crystallinity as manifested by their crystalline melting points. An in depth x-ray diffraction analysis was conducted with the homopolymers of sebacic acid (SA); bis(carboxyphenoxy) propane (CPP); bis(carboxyphenoxy)hexane (CPH) and fumaric acid; and the copolymers of SA with CPP, CPH, and fumaric acid. The results indicated that the homopolymers were highly crystalline and the crystallinity of the copolymers was determined, in most cases, by the monomer of highest concentration. Copolymers with a composition close to 1:1 were essentially amorphous (198).

The melting point, as determined by differential scanning calorimetry, of aromatic polyanhydrides are much higher than the aliphatic polyanhydrides. The melting point of the aliphatic aromatic copolyanhydrides is proportional to the aromatic content. For this type of copolymer there is characteristically a minimum  $T_m$  between 5 to 20 mole% of the lower melting component (191).

The majority of polyanhydrides dissolves in solvents such as dichloromethane and chloroform. However, the aromatic polyanhydrides display much lower solubility than the aliphatic polyanhydrides. In an attempt to improve the solubility and decrease the  $T_m$ , copolymers of two different aromatic monomers were prepared. These copolymers displayed a substantial decrease in  $T_m$  and an increase in solu-

bility compared to the corresponding homopolymers of aromatic diacids (199).

The data on mechanical properties of polyanhydrides are very limited. The fibers of poly[1,2-bis(p-carboxyphenoxy) ethane anhydride] showed a tensile strength of 40 kg/mm<sup>2</sup> with an elongation of 17.2% and a Young's modulus of 505 kg/mm<sup>2</sup>. A systematic study on the tensile strength of the copolymers of CPP and SA showed that increasing the CPP content in the copolymer or the molecular weight of the copolymer increased the tensile strength (177). Unsaturated polyanhydrides of the structure  $[-(OOC-CH=CH-CO)_x-(OOC-R-CO)_y]_n$  were developed to improve the mechanical properties of the polymers. The advantage of the unsaturated polyanhydrides is that they can undergo secondary polymerization of the double bonds to create a crosslinked matrix (200)

### c. Polymer Hydrolysis

Anhydride linkage is extremely susceptible to hydrolysis in presence of moisture to generate the dicarboxylic acids (201). Hydrolysis of monomeric anhydrides is catalyzed by both acid and base, the hydrolytic degradation rate of polyanhydrides increases with increase in pH. It is believed that the poor solubility of the oligomeric products, under low pH conditions, formed at the surface of the matrix impedes the degradation of the core. In general, the hydrophobic polymers such as P(CPP) and P(CPH) display constant erosion kinetics. The degradation rates of the polyanhydrides can be altered in a number of ways. The degradation rates can be enhanced by incorporating the aliphatic monomer, such as sebacic acid, into the polymer. The degradation can be slowed by increasing the methylene groups into the backbone of the polymer. For example, in the case of the poly[bis(p-carboxyphenoxy)alkane] series, increasing the methylene groups from one to six increased the hydrophobicity of the polymer, and the erosion rates underwent a decrease of three orders of magnitude.

To achieve a variety of degradation rates, aliphatic aromatic homopolyanhydrides of the structure  $-(OOC-C_6H_4-O(CH_2)_x-CO-)_n$  were prepared with x varying from 1 to 10. Increasing the value of x decreases the erosion rates (202). Increased erosion rates were also observed when poly(sebacic acid) was branched with either 1,3,5-tricarboxylic acid or low molecular weight poly(acrylic acid) (203).

Apart from the reactivity of anhydride linkage toward water, aliphatic polyanhydrides and their copolymers are found to undergo self-depolymerization under anhydrous conditions in the solid state and in solution (204). The de-

polymerization reaction mainly affects the high molecular weight fraction of the polymer. Aromatic homopolymers show no sign of depolymerization when stored under anhydrous conditions. The depolymerization rate is found to follow a first-order kinetics, accelerate with temperature, and increase with polarity of the solvent (204). The depolymerized polymer can be repolymerized to yield the original polymer, suggesting that inter- or intramolecular anhydride interchange takes place during depolymerization.

#### d. Polymer Processing

Drug-incorporated matrices can be formulated either by compression or injection molding. The polymer and drug can be ground in a Micro Mill grinder, sieved into a particle size range of 90–120  $\mu\text{m}$  and can be pressed into circular discs using a Carver press. Alternatively, the drug can be mixed into the molten polymer to form small chips of drug–polymer conjugate. These chips are fed into the injection molder to mold the drug–polymer matrix into the desired shaped device. One must consider the thermal stability of the polymer and potential chemical interaction between drug and polymer at the high temperatures of injection molding.

The preferred method of drug delivery, in many instances, is by injection. This requires the development of microcapsules or microspheres of the drug. Several different techniques have been developed for the preparation of microspheres from polyanhydrides, including hot-melt microencapsulation (205) and solvent removal technique (206).

#### e. Other Polyanhydrides

In addition to the previously discussed aliphatic aromatic and the copolyanhydrides of the respective diacids, several other modifications of the backbone of the polyanhydrides have been reported. These new polyanhydrides were developed to improve their physicochemical, mechanical, thermal, and hydrolytic properties.

One of these new polyanhydrides is polyanhydride-imides, also referred to as copolyimides (207). They showed good thermal resistance but were essentially insoluble in most organic solvents (208). In an attempt to improve the solubility in more polar solvents, polyanhydrides were synthesized using imide-diacids containing aliphatic aromatic characteristics. A systemic study was reported in which the starting monomers, imide-diacids, were prepared from aromatic acid anhydrides and  $\alpha$ -amino acids. Varying the number of methylenic units in the  $\alpha$ -amino acids provided the variability in the aliphatic character of the aromatic aliphatic monomer.

A typical example of such an aromatic aliphatic monomer is the one obtained by the reaction of trimellitic anhydride with glycine:

For the synthesis of polyanhydride, the aliphatic aromatic diacid is first converted to the diacetyl derivative by refluxing the diacid in the presence of excess acetic anhydride. The diacetyl derivative is polymerized either by melt polycondensation or in solution. The polyanhydride-imides thus obtained are very soluble in polar organic solvents. However, they showed melt transitions at temperatures of 245°C and above (209). Along with that, insufficient data are available on the hydrolytic stability of these materials rendering them questionable materials as a carrier in drug delivery systems.

On similar lines, another research group has developed polyanhydrides containing amido groups. The polyanhydrides thus synthesized were of relatively low molecular weight, low melting points, and a glass transition higher than the room temperature (210). The same group also developed polyanhydrides containing ester groups (211). These polymers are in the early stages of development and have not been characterized with respect to their suitability in drug delivery systems.

Another class of polyanhydrides are based on natural fatty acids. The dimers of oleic acid and erucic acid are liquid oils containing two carboxylic acids available for anhydride polymerization. The homopolymers are viscous liquids. Copolymerization with increasing amounts of sebacic acid forms solid polymers with increasing melting points as a function of SA content. The polymers are soluble in chlorinated hydrocarbons, tetrahydrofuran, 2-butanone, and acetone (212).

Polyanhydrides synthesized from nonlinear hydrophobic fatty acid esters based on ricinoleic, maleic, and sebacic acid possessed desired physicochemical properties such as low melting point, hydrophobicity, and flexibility to the polymer formed in addition to biocompatibility and biode-

gradability. The polymers were synthesized by melt condensation to yield film-forming polymers with molecular weights exceeding 100,000 (213).

The properties of polyanhydrides were modified by the incorporation on long chain fatty acid terminals such as stearic acid in the polymer composition, which alters its hydrophobicity and decreases its degradation rate (214). Since natural fatty acids are monofunctional, they would act as polymerization chain terminators and control the molecular weight. A detailed analysis of the polymerization reaction shows that up to about 10 mole% content of stearic acid, the final product is essentially a stearic acid-terminated polymer. Whereas higher amounts of acetyl stearate in the reaction mixture resulted in the formation of increasing amounts of stearic anhydride byproduct with minimal effect on the polymer molecular weight, which remains in the range of 5000. Physical mixtures of polyanhydrides with triglycerides and fatty acids or alcohols did not form uniform blends.

### III. BIOCOMPATIBILITY AND TOXICITY

In all the potential uses of polymeric material, a direct contact between the polymer and biological tissues is evident. Therefore, for the eventual human application of these biomedical implants and devices, an adequate testing for safety and biocompatibility of the specific polymer matrix used in each case is essential.

Whenever a synthetic polymer material is to be utilized in vivo, the possible tissue-implant interactions must be taken into consideration. In the case of biodegradable matrices, not only the possible toxicity of the polymer have to be evaluated, but also the potential toxicity of its degradation products.

The last section of this chapter reviews existing data about the biocompatibility and toxicity of the different polymers actually available for biomedical applications.

## A. Polyesters

### 1. Lactide/Glycolide Copolymers

Biocompatibility of monomer is considered as the foundation for biocompatibility of degradable polymer systems, not the polymer itself. Thus, PLLA is found as an excellent biomaterial and safe for in vivo use because its degradation product L-lactic acid is a natural metabolite of the body. Even though PLGA is extensively used and represents the gold standard of degradable polymers, increased local acidity due to its degradation can lead to irritation at the site of polymer implant. Agrawal and Athanasiou have introduced a technique in which basic salts are used to control the pH in local environment of PLGA implant (215). The feasibility of lactide/glycolide polymers as excipients for the controlled release of bioactive agents is well proven, and they are the most widely investigated biodegradable polymers for drug delivery.

Most of the research work on the use of lactide/glycolide polymers as matrices for delivery systems has focused on the development of injectable microsphere formulations, although implantable rod and pellet devices are also being investigated.

The lactide/glycolide copolymers have been subjected to extensive animal and human trials without any significant harmful side effects (211). No evidence of inflammatory response, irritation, or other adverse effects have been reported upon implantation of lactide/glycolide polymer devices. However some limited incompatibility of certain macromolecules with lactide/glycolide was observed.

Lam and coworkers (216,217) studied the particles of PLA with particles of polytetrafluoroethylene (PTFE) as control. They injected intraperitoneally in mice as well as in rats. After up to 7 days, cells were harvested from the abdominal cavity. Microscopic examinations of cell morphology revealed the evidence of cell damage and death caused by phagocytosed PTFE particles. It was observed that there was more pronounced inflammatory response with PLA films than with PTFE films in subcutaneous tissues of rats.

Many conventional pharmaceutical agents formulated in lactide/glycolide polymer matrices were widely studied almost two decades ago, especially as injectable microsphere dosage forms (16–23). One of the most successful lactide/glycolide drug delivery formulations, in terms of clinical results obtained, is the steroid-loaded injectable microspheres for the controlled release of contraceptives

(218–221). Many animal and clinical trials with these systems were performed showing very good biocompatibility. For example a 90-day female contraceptive based on norethisterone as the active hormone and 85:15 DL-lactide/glycolide as the excipient has undergone successful Phase I and Phase II clinical trials in various geographic areas, demonstrating safety and efficacy of the formulation in about 300 subjects (222).

The success of the steroid microsphere system based on lactide/glycolide matrices is probably due to the combination of several factors: the reproducibility of the microencapsulation process, the *in vivo* drug-release performance, reliability in the treatment procedure, and the safety of the polymer (223).

Lactide/glycolide implants containing naltrexone and other narcotic antagonist agents have also been extensively studied (224–227). In one of these studies describing the clinical evaluation of a bead preparation containing 70% naltrexone and 30% of a 90:10 lactide/glycolide copolymer, a local inflammatory reaction at the site of implantation was reported in two of three subjects after subcutaneous implantation of the beads containing the drug (226). This finding prevented further clinical testing of that particular formulation. No similar problems were reported with other lactide/glycolide polymer preparations, and that incident was related to some unique aspect of that product (226).

Bergshma et al. (228) reported the use of a copolymer made of 96% L- and 4% D-lactic acid in subcutaneous tissues of rats for up to 52 weeks. Prior to implantation, discs made from the copolymer and homopolymer PLA were predegraded *in vitro* (229). The degradation of copolymer was faster than the homopolymer while inflammation was observed with both (230).

Good biocompatibility data were also reported with lactide/glycolide copolymer matrices containing antineoplastic drugs, antibiotics, and anti-inflammatory compounds (211).

The delivery of therapeutic molecules to the brain has been limited in part due to the presence of the blood–brain barrier. The biocompatibility of lactide/glycolide copolymer in the brain was examined regarding the gliotic response following implants of lactide/glycolide copolymer into the brains of rats. It was found that lactide/glycolide copolymer is well tolerated following implantation into the CNS and that the astrocytic response to lactide/glycolide copolymer is largely a consequence of the mechanical trauma that occurs during surgery (231).

Regarding the encapsulation of bioactive macromolecules as proteins, peptides, and antigens, the studies carried out so far show mixed biocompatibility results. Serious

problems in achieving long-term release have been reported in several cases where the macromolecules lost bioactivity *in vivo* after a few days, as in the case of lactide/glycolide copolymer containing growth hormone. A complex interaction apparently occurs *in vivo* between the acidic polymer and the hormone. *In vitro* release studies have shown that growth hormone can become insoluble when incorporated in poly(lactide) films. Similar problems in maintaining biological activity for longer than 5–10 days were also observed with interferon–lactide/glycolide polymer formulation (211). On the other hand, promising results were obtained with luteinizing hormone–releasing hormone (LHRH) incorporated in lactide/glycolide polymer showing long-term delivery of the macromolecule (232,233). In general, hydrophilic polypeptides of low molecular weight (<5000) are considered quite stable in the presence of lactide/glycolide excipients and their acidic bioerosion byproducts.

Lactide/glycolide polymer implants, in the form of microbeads and pellets, containing insulin were reported to be effective in lowering blood glucose levels in diabetic rats for about 2 weeks, and no adverse effects, including inflammation at the implant site or deactivation of the macromolecule, were observed (234).

Toljan and Orthner (235) published details of the clinical use of an interference screw made from PGL copolymer. After 6 months, MRI data show the presence of local reactions at the implant site and a ‘‘liquidization’’ of the screw in 41% of the patients. Clinically, no febrile episodes or sterile effusions were observed.

Bezwada et al. (13) studied *in vitro* and *in vivo* biocompatibility and efficacy of block copolymer of poly(glycolide) and PCL in the form of MONOCRYL<sup>R</sup> sutures. Using the size 2/0 monofilament sutures implanted subdermally in rats, MONOCRYL sutures retain 50% of their original strength after about 1 week, whereas homopolymeric PCL monofilament size 2/0 sutures retain 50% of their strength after about 52 weeks.

## 2. Poly(caprolactone)

The biocompatibility and toxicity of poly(caprolactone) have mostly been tested in conjunction with evaluations of Capronor<sup>TM</sup>, which is an implantable 1-year contraceptive delivery system composed of a levonorgestrel-ethyl oleate slurry within a poly(caprolactone) capsule. In a preliminary 90-day toxicology study of Capronor in female rats and guinea pigs, except for a bland response at the implant site and a minimal tissue-encapsulating reaction, no toxic effects were observed (236).

The lack of an inflammatory response was confirmed

by implanting polyvinyl alcohol sponges impregnated with the powdered polymer in rats. In the Ames mutagenicity assay polycaprolactone was negatively tested (87).

The Capronor–polycaprolactone contraceptive delivery system was also tested implanted in rats and monkeys in a 2-year period (87). The results of this second, more extensive study, based on animal clinical and physical data such as blood and urine analysis, ophthalmoscopic tests, and histopathology after necropsy, showed no significant differences between the test and control groups.

Phase I and II clinical trials with Capronor were recently carried out in different medical centers (87).

## B. Poly(amides)

### 1. Natural Polymers

The use of natural biodegradable polymers to deliver drugs continues to be an area of active research despite the advent of synthetic biodegradable polymers (237–239). Natural polymers remain attractive primarily because they are natural products of living organisms, readily available, relatively inexpensive, and capable of a multitude of chemical modifications (240).

Most of the investigations of natural polymers as matrices in drug delivery systems have focused on the use of proteins (polypeptides or polyamides) as gelatin, collagen, and albumin. Collagen is a major structural protein found in animal tissues where it is normally present in the form of aligned fibers. Because of its unique structural properties, collagen has been used in many biomedical applications such as absorbable sutures, sponge wound dressings, composite tissue–tendon allografts, injectables for facial reconstructive surgery, and as drug delivery systems especially in the form of microspheres (241).

Besides the collagen's biocompatibility and nontoxicity for most tissues (242), several factors such as the possible occurrence of antigenic responses, tissue irritation due to residual aldehyde crosslinking agents, and poor patient tolerance of ocular inserts have adversely influenced its use as a drug delivery vehicle (241). For example, 5-fluorouracil and bleomycin crosslinked sponges made from purified bovine skin collagen were implanted in rabbit eyes to test their possible use in preventing fibroblast proliferation following ophthalmic surgery, resulting in a chronic inflammatory reaction elicited by the sponges even in the absence of drug (243).

Noncollagenous proteins, particularly albumin and to a lesser extent gelatin, continue to be developed as drug delivery vehicles. The exploitable features of albumin include its reported biodegradation into natural products, its lack of toxicity, and its nonimmunogenicity (244,245).

Although many examples on the use of albumin microspheres were reported in the literature, there are only a few studies describing gelatin systems. Despite this, compared with albumin, gelatin offers the advantages of a good history in parenteral formulations and lower antigenicity. A biocompatibility study with gelatin microspheres reported no untoward effects when injected intravenously into mice over a 12-week period (246).

In a second study, when albumin microspheres were injected repeatedly into the knee joints of rabbits, pronounced rapid joint swelling occurred after the second and subsequent injections, compared to no swelling when gelatin microspheres were injected in the same way (247).

### 2. Pseudopoly(amino Acids)

The pseudopoly(amino acids), belonging to the poly(amides) group, represent one of the latest and therefore less advanced biodegradable polymers for medical use. Only a few of them have been synthesized and characterized, and no clinical tests have thus far been conducted. However, preliminary promising results were obtained showing no gross toxicity or tissue incompatibility upon subcutaneous implantation for the presently available pseudopoly(amino acids), and they are now being actively investigated in several laboratories for medical applications ranging from biodegradable bone nails to implantable adjuvants (121).

In an initial evaluation of hydroxyproline-derived polyesters, poly(N-palmitoyl hydroxyproline ester) was tested in a series of biocompatibility tests (248).

In the rabbit cornea bioassay, implantation of four small pieces of the polymer into four rabbit corneas elicited a pathological response in three of them and a very mild inflammatory response in one cornea. Histological examination of the corneas 4 weeks after implantation showed no invading blood vessels or migrating inflammatory cells in the area around the implants (249).

In a second biocompatibility study, 10-mg implants of poly(N-palmitoyl hydroxyproline ester) were inserted subcutaneously in mice in the dorsal area of the animals between the dermis and the adipose tissue layer. The mice responses were examined up to 1 year postimplantation (248).

No inflammatory reaction at the implantation site was observed in any of the mice during the first 7 weeks. A thin but distinct layer of fibrous connective tissue appeared around the implant by week 14 and, occasionally, a few multinucleated giant cells were associated with the fibrous connective tissue. Animal necropsies performed at 16 and 56 weeks postimplantation showed no histopathological abnormalities (248).

These preliminary biocompatibility results from two animal models, rabbit and mouse, indicate that the poly(*N*-palmitoyl hydroxyproline ester) elicits a very mild, local tissue reaction typical of a foreign body response, resulting in encapsulation of the foreign biomaterial without evidence for any significant pathological abnormalities. However, additional safety and toxicity tests need to be performed to evaluate possible systemic toxic effects, allergic reactions, or any mutagenic, teratogenic, and carcinogenic activities.

Pseudopoly(amino acids) containing aromatic side chains of tyrosine in their backbone structure were also developed recently to investigate whether biodegradable polymers that incorporate aromatic components would combine a high degree of biocompatibility with a high degree of mechanical strength (121).

In order to test the tissue compatibility of tyrosine-derived poly(iminocarbonates), solvent cast films of poly(CTTH) were subcutaneously implanted into the back of mice. In this study, conventional poly(*L*-tyrosine) served as a control (250). The data obtained from this biocompatibility assay were very similar to those observed with poly(*N*-palmitoyl hydroxyproline ester), showing no gross pathological changes from visual inspection of the implantation sites over a 1 year period.

Silver et al. (135) reported a comparative study on biocompatibility of solvent cast films of poly(desaminotyrosyl-tyrosine hexylester-iminocarbonate), or poly(DTH-iminocarbonate), in a subcutaneous rat model. In this study, high-density polyethylene (HDPE) and medical grade poly(D,L-lactic acid) served as controls. Considering the significantly faster degradation rate of poly(DTH-iminocarbonate), one would expect a different response from this material. After 7 days of postimplantation, a greater cell density and inflammatory response was noted for poly(DTH-iminocarbonate). However, at a later time point, the biological response observed for poly(DTH-iminocarbonate) was almost similar with the response observed for poly(DTH-iminocarbonate). The tissue response was characterized by a thin tissue capsule, absence of giant cells, and a low inflammatory cell count and was not statistically different from the response observed for polyethylene and poly(lactic acid).

In vitro attachment and proliferation of fibroblasts on tyrosine-derived polycarbonates was a function of the pendant chain length. Ertal and Kohn fabricated poly(DTH-carbonate) pins and compared them to commercially available orthosorb<sup>R</sup> pins made of polydioxanone (136). The pins were implanted transcortically in the distal femur and proximal tibia of New Zealand white rabbit for up to 26 weeks. In addition to routine histological evaluation of the implant sites, bone activity at the implant-tissue interface

was visualized by UV illumination of sections labeled with fluorescent marker, and the degree of calcification around the implants was ascertained by backscattered electron microscopy. The bone tissue response was characterized by active bone remodeling at the surface of the degrading implant, the lack of fibrous capsule formation, and an unusually low number of inflammatory cells at the bone-implant interface. Poly(DTH-carbonate) exhibited very close bone apposition throughout the 26-week period of the initial study. A roughened interface was observed which was penetrated by new bone as early as 2 weeks postimplantation. Bone growth into the periphery of the implant material was visible at the 26-week time point.

### C. Polyphosphazenes

Two different types of polyphosphazenes are of interest as bioinert materials: those with strongly hydrophobic surface characteristics and those with hydrophilic surfaces. Polyphosphazenes bearing fluoroalkoxy side groups are some of the most hydrophobic synthetic polymers known (251, 252). Such polymers are as hydrophobic as poly(tetrafluoroethylene) (Teflon), but unlike Teflon polyphosphazenes of this type are flexible or elastomeric, easy to prepare, and can be used as coatings for other materials.

Graft polymerization with dimethylaminoethylmethacrylate (DMAEM) onto the poly(phosphazene) surfaces highly enhances their biocompatibility. Surface modification of poly(trifluoroethoxy-phosphazenes) (PTFP) with polyethylene glycols was heading to materials with enhanced biocompatibility in comparison to nonmodified polymers (253). In the next study, the PTFP was grafted with hydrophilic monomers like dimethylacrylamide (DMAA) and acrylamide (AAm) (254). Large differences in the biocompatibility of these materials were found. Biocompatibility of AAm-grafted samples was greatly enhanced while an opposite behavior for DMAA-grafted samples was observed. All studies with these samples were done by intraperitoneal implantation of thin films in adult male wistar rats. Tissue around the implantation site was evaluated by histological examination after 25 days.

Biocompatibility and safety testings of these polymers by subcutaneous implantation in animals have shown minimal tissue response, similar in fact to the response reported with Teflon (255). The connection between hydrophobicity and tissue compatibility has been noted for classical organic polymers (256). Thus, these hydrophobic polyphosphazenes have been mentioned as good candidates for use in heart valves, heart pumps, blood vessel prostheses, and as coating materials for pacemakers or other implantable devices. However, more in vivo testing and clinical trials are needed (144).

In their bioerosion reactions polyphosphazenes display a uniqueness that stems from the presence of the inorganic backbone, which in the presence of appropriate side groups is capable of undergoing facile hydrolysis to phosphate and ammonia. The phosphate can be metabolized and the ammonia excreted. Theoretically, if side groups attached to the polymer are released by the same process being excretable or metabolizable, then the polymer can be eroded under hydrolytic conditions without the danger of a toxic response. Polyphosphazenes of this type are potential candidates as erodible biostructural materials for sutures or as matrices for controlled delivery of drugs (144).

Polyphosphazenes containing amino acid ester side groups were the first bioerodible polyphosphazenes synthesized (146). They are solid materials which erode hydrolytically to ethanol, glycine, phosphate, and ammonia. These polymers were tested in subcutaneous tissue response experiments showing no evidence of irritation, cell toxicity, giant cell formation, or tissue inflammation (143,255).

Imidazolyl groups linked to polyphosphazene chains are also hydrolyzed very easily, showing good biocompatibility tests (141,154). Langone et al. (257) studied poly[(ethyl-alanate)-co-(imidazole) phosphazene] derivatives for in vivo evaluation. Polymer films were subcutaneously implanted in rats. The animals were killed after 30 or 60 days. Biopsy samples of the implant zone were histologically examined. In both cases, animals were healthy and biological material surrounding to the polymers was found to correspond to fibroblast collagen with only a few monocytes in the internal site.

#### D. Polyorthoesters

As mentioned previously, the Chronomer polyorthoester material from Alza Corporation, or Alzamer, has been investigated as bioerodible inserts for the delivery of the narcotic antagonist naltrexone, and for the delivery of the contraceptive steroid norethisterone (258,259). The steroidal implant was tested in two separate human clinical trials causing local tissue irritation, and therefore further work with this formulation was discontinued (166,167). The reasons for the local irritation were never properly elucidated. New types of poly(orthoesters) were developed, but no data on the biocompatibility and safety of these materials were reported.

In vitro studies have shown that good control over release of tetracycline could be achieved and very good in vitro adhesion to bovine teeth was demonstrated (173). However, studies in beagle dogs with naturally occurring periodontitis were not successful because ointmentlike polymers with a relatively low viscosity are squeezed out

of the pocket within about 1 day, despite good adhesiveness.

#### E. Polyanhydrides

Polyanhydrides are a novel class of biodegradable polymers under development as vehicles for the release of bioactive molecules including drug peptides and proteins (1). The polyanhydrides constitute so far the only class of surface-eroding polymers approved for clinical trials by the Food and Drug Administration.

A series of biocompatibility studies reported on several polyanhydrides have shown them to be nonmutagenic and nontoxic (189). In vitro tests measuring teratogenic potential were also negative. Growth of two types of mammalian cells in tissue culture was also not affected by the polyanhydride polymers (189); both the cellular doubling time and cellular morphology were unchanged when either bovine aorta endothelial cells or smooth muscle cells were grown directly on the polymeric substrate.

Subcutaneous implantation in rats of high doses of the 20:80 copolymer of bis-(p-carboxyphenoxy) propane and sebacic acid for up to 8 weeks indicated relatively minimal tissue irritation with no evidence of local or systemic toxicity (260). Since this polymer was designed to be used clinically to deliver an anticancer agent directly into the brain for the treatment of brain neoplasms, its biocompatibility in rat brain was also studied (261). The tissue reaction of the polymer was compared to the reaction observed with two control materials used in surgery, oxidized cellulose absorbable hemostat (Surgicel<sup>®</sup>, Johnson and Johnson) and absorbable gelatin sponge (Gelfoam<sup>®</sup>, Upjohn). The inflammatory reaction of the polymer was intermediate between the controls (261). A closely related polyanhydride copolymer poly(CPP)-SA 50:50 was also implanted in rabbit brains and was found to be essentially equivalent to Gelfoam in terms of biocompatibility evaluations (262). In a similar study conducted in monkey brains, no abnormalities were noted in the CT scans and magnetic resonance image, nor in the blood chemistry or hematology evaluations (263). No systemic effects of the implants were observed on histological examinations of any of the tissues tested (264).

New classes of polyanhydrides have been recently synthesized and are undergoing extensive preclinical testing, including a wide range of biocompatibility studies. Examples of these new materials are polymers of sebacic acid, poly(SA), and copolymers 1:1 of SA with fatty acid dimer (FAD) [poly(FAD:SA)], fumaric acid (FA) [poly(FA:SA)], and isophthalic acid [poly(ISO:SA)]. These materials were implanted in rabbits intramuscularly, subcutaneously, and in the cornea. Ocular and muscle irritation stud-

ies were performed compared to the material controls Gelfoam, Surgicel, and Vycryl®, a synthetic absorbable suture (Ethicon) (265). Detailed observations of toxicity, bleeding, swelling, or infection of the implantation site were conducted daily. At the end of the study the animals were sacrificed and a gross necropsy examination of the tissues surrounding the implant site was performed. No significant clinical signs or abnormalities of the incision sites were observed during the study period (4 weeks). No meaningful differences could be seen in reaction between the various polymer implants tested and the control materials (265).

In the rabbit cornea bioassay, no evidence of inflammatory response was observed with any of the implants at any time. On an average, the bulk of the polymers disappeared completely between 7 and 14 days after the implantation (265). The cornea is a very sensitive indicator of inflammatory reactions (266,267). The rabbit cornea possesses clear advantages over other implant sites for studying implant–host interactions due to the easy accessibility for frequent observations without having to gain surgical access to the implantation site. The transparency and avascularity of the cornea also enable the observer to distinguish among the different inflammatory characteristics such as edema, cellular infiltration, and ingrowth of blood vessels from the periphery of the cornea or neovascularization, which are strong indications that the biomaterial under testing is unsuitable for implantation (268).

In similar animal experiments in which polyanhydride matrices containing tumor angiogenic factor (TAF) were implanted in rabbit cornea, a significant vascularization response was observed without edema or white cells. Moreover, and most importantly from the biocompatibility standpoint, polymer matrices without incorporated TAF showed no adverse vascular response (268,269).

The biocompatibility of a new class of polyanhydrides based on ricinoleic acid as compared to Vycryl surgical suture and sham surgery was tested in rats (213). No evidence for tissue necrosis was detected in any of the treated animals upon evaluation of the tissues 21 days postimplantation. No indication for postimplantation test site contamination was noted.

Generally, in all tested groups there was a clear indication of a time-related healing process (i.e., there was a time-related reduction in the incidence and severity of necrosis and acute to subacute inflammatory reaction associated with increased fibroplasia).

The tissue reaction in the different treatment groups showed a clear trend of healing with time. In particular, comparison of the tissue reactivity along the three different time periods (3, 7, and 21 days) indicated that the only noted remnants of tissue reaction at the 21-day time period

were minimal subacute inflammation and mild fibrosis. In comparison, under the same conditions, Vycryl implant induced minimal fibrosis associated with the presence of minimal quantity of giant cells and encapsulated foreign material.

Based on the biocompatibility and safety preclinical studies carried out in rats (260,261), rabbits (262,266), and monkeys (263,264) reviewed here showing acceptability of the polyanhydrides for human use, a Phase I and II clinical protocol was instituted (270). In these clinical trials, a polyanhydride dosage form (Gliadel™), consisting of wafer polymer implants of poly(CPP-SA) 20:80 and containing the chemotherapeutic agent Carmustine (BCNU), was used for the treatment of glioblastoma multiforme, a universally fatal form of brain cancer. In these studies, up to eight of these wafer implants were placed to line the surgical cavity created during the surgical debulking of the brain tumor in patients undergoing a second operation for surgical debulking of either a grade III or IV anaplastic astrocytoma. In keeping with the results of the earlier preclinical studies suggesting a lack of toxicity, no central or systemic toxicity of the treatment was observed during the course of treating 21 patients under this protocol. Phase III human clinical trials have demonstrated that site-specific delivery of BCNU from a poly(CPP-SA) 20:80 wafer (Gliadel) in patients with recurring brain cancer (glioblastoma multiforme) significantly prolongs patient survival (271). Gliadel has finally won approval from the FDA as therapy for the treatment of brain tumors.

# Biodegradable Biomaterials Having Nitric Oxide Biological Activity

C. C. Chu

*Cornell University, Ithaca, New York*

### I. INTRODUCTION

The chemical incorporation of biologically active compounds into synthetic biodegradable biomaterials was successfully synthesized by using nitric oxide derivatives (e.g., 4-amino-2,2,6,6-tetramethylpiperidine-1-oxyl) as the biochemical agents and synthetic aliphatic polyesters like polyglycolide as the biodegradable biomaterials. The resulting new biomaterial was characterized and its *in vitro* hydrolytic degradation property was studied to examine the release profiles of the chemically incorporated nitric oxide derivative from polyglycolide. The biological activity of this new class of biodegradable biomaterial was tested by examining its ability to retard the proliferation of human smooth muscle cell *in vitro*. It was found that this new class of biologically active biodegradable biomaterial has indeed one of the well-known biological functions of nitric oxide: retardation of the proliferation of smooth muscle cells. The potential biomedical applications of this new biomaterial include the treatment of hyperplasia in cardiovascular disorders, promoting wound healing in healing-impaired patients, and nitric oxide-related diseases.

The interests in biodegradable polymeric biomaterials for biomedical engineering use have increased dramatically during the past decade. This is because this class of

biomaterials has two major advantages that nonbiodegradable biomaterials do not have. First, they do not elicit permanent chronic foreign body reaction due to the fact that they would be gradually absorbed by human body and do not permanently retain trace of residual in the implantation sites. Second, some of them have recently been found to be able to regenerate tissues, via so-called tissue engineering, through the interaction of their biodegradation with immunologic cells like macrophages. Hence, surgical implants made from biodegradable biomaterials could be used as temporary scaffold for tissue regeneration. This approach toward the reconstruction of injured, diseased, or aged tissues is one of the most promising fields in the future medicine.

Although the earliest and most commercially significant biodegradable polymeric biomaterials are originated from linear aliphatic polyesters like polyglycolide and polylactide from poly(-hydroxyacetic acids), recent introduction of several new synthetic and natural biodegradable polymeric biomaterials extends the domain beyond this family of simple polyesters. These new commercially significant biodegradable polymeric biomaterials include poly(orthoesters), polyanhydrides, polysaccharides, poly(esteramides), tyrosine-based polyarylates or polyiminocarbonates or polycarbonates, poly(D,L-lactide-urethane), poly(-hydroxybutyrate), poly(-caprolactone), poly[bis(car-

boxylatophenoxy) phosphazene], poly(amino acids), pseudopoly(amino acids), and copolymers derived from amino acids and non-amino acids.

The earliest and most successful and frequent biomedical application of biodegradable polymeric biomaterials has been in wound closure (1). All biodegradable wound closure biomaterials are based upon glycolide and lactide family. For example, polyglycolide (Dexon from American Cyanamid), poly(glycolide-L-lactide) random copolymer with 90-to-10 molar ratio (Vicryl from Ethicon), poly(ester-ether) (PDS from Ethicon), poly(glycolide-trimethylene carbonate) random block copolymer (Maxon from American Cyanamid), and poly(glycolide-caprolactone) copolymer (Monocryl from Ethicon). Some of these materials like Vicryl have been commercially used as surgical meshes for hernia and body wall repair. Besides wound closure application, biodegradable polymeric biomaterials that are commercially satisfactory include those for drug control/release devices. Some well-known examples in this application are polyanhydrides and poly(orthoester). Biodegradable polymeric biomaterials, particularly totally resorbable composites, have also been experimentally used in the field of orthopedics, mainly as components for internal bone fracture fixation like PDS pins. However, their wide acceptance in other parts of orthopedic implants may be limited due to their inherent mechanical properties and their biodegradation rate. Biodegradable polymeric biomaterials have been experimented as vascular grafts, vascular stents, vascular coupler for vessel anastomosis, nerve growth conduits, augmentation of defected bone, ligament/tendon prostheses, intramedullary plug during total hip replacement, anastomosis ring for intestinal surgery, and stents in ureteroureterostomies for accurate suture placement. The details of the biomedical applications of biodegradable polymeric biomaterials and their chemical, physical, mechanical biological, and biodegradation properties can be found in other recent reviews (1–7).

There is one common characteristic among all these biodegradable biomaterials: they do not “actively” participate in the process of wound healing, tissue regeneration and engineering. In other words, these biomaterials are not “alive” and cannot remodel and/or release cytokines upon stimulation like normal tissues. These biomaterials, however, elicit inflammatory and foreign body reactions and play a “passive” role in wound healing. It would be ideal if these synthetic biomaterials could be engineered so that they could become alive after implantation and hence actively participate in the biological functions with the surrounding tissues, such as the ability to modulate inflammatory reactions, to facilitate wound healing, or to mediate host defense system to combat diseases. In this chapter, we

would describe the new biodegradable biomaterials having nitric oxide function.

## II. BIODEGRADABLE BIOMATERIALS HAVING NITRIC OXIDE FUNCTION

Nitric oxide ( $\text{NO}\cdot$ ) is a very small but highly reactive and unstable free radical biomolecule with expanding known biological functions. This small biomolecule and its biological functions have recently become one of the most studied and intriguing subjects as recently reviewed by several investigators (8–18). Nitric oxide is extremely labile and short lived (about 6 to 10 s).

Nitric oxide and its radical derivatives have been known to play a very important role in a host of expanding biological functions, such as inflammation, neurotransmission, blood clotting, blood pressure, cardiovascular disorders, rheumatic and autoimmune diseases, antitumor activity with a high therapeutic index, antimicrobial property, sensitization or protection of cells and tissues against irradiation, oxidative stress, respiratory distress syndrome, and cytoprotective property in reperfusion injury, to name a few (8–30). Nitric oxide acts both as an essential regulatory agent to normal physiological activities and as cytotoxic species in diseases and their treatments. Nathan et al. reported that nitric oxide is a potent antiviral compound against two disfiguring poxvirus and herpes simplex virus type 1, which causes cold sores in humans (12). Levi et al. also found that nitric oxide could protect human heart against low oxygen supply, a condition known as myocardial ischemia, by widening blood vessels so that more oxygen-rich blood reaches the heart (14). Elliott et al. reported that a new  $\text{NO}\cdot$ -releasing nonsteroidal anti-inflammatory drug has the benefits of accelerating gastric ulcer healing (31,32). It is important to know, however, that excessive introduction of  $\text{NO}\cdot$  into body may have adverse effects like microvascular leakage, tissue damage in cystic fibrosis, septic shock, B cell destruction, and possible mutagenic risk, to name a few (18,19,27,33–35).

Nitric oxide and  $\text{NO}\cdot$ -derived radicals are not normal biological messengers whose trafficking depend on specific transporters or channels. Instead, nitric oxide radicals released by cells like macrophage and endothelial cells would diffuse randomly in all directions from the site of release. Because of this unusual property, the only way to control the biological functions of nitric oxide is to control its site of synthesis. This suggests that the only way to deliver the desirable biological functions of nitric oxide is through nature. Existing science and technology are not able to modulate the release of nitric oxide according to our wish for a variety of therapeutic purposes.

### A. Synthesis and Characterization

We recently used a patented chemical method to incorporate nitric oxide derivatives into a series of synthetic biodegradable biomaterials (36,37). Upon the hydrolytic degradation of the host biomaterials, nitric oxide derivatives could be released to the surrounding and the rate of release could be controlled by the nature of the biodegradable biomaterials. The amounts of the nitric oxide derivatives that can be incorporated into biodegradable biomaterials would depend on the molecular weight of the biomaterials. Figure 1 illustrates the chemical scheme of this patented method of incorporating 4-amino-2,2,6,6-tetramethylpiperidine-1-oxyl (TAM) as the source of nitroxyl radicals nitric oxide into synthetic biodegradable polyesters like polyglycolide or polylactide.

Due to the free radical characteristic of Tempamine nitroxyl radicals, the radical incorporated polyglycolide (PGA) must exhibit an electron paramagnetic resonance (EPR) spectrum that has the characteristic of nitroxide. Figure 2 is such an EPR spectrum of TAM-PGA. This EPR spectrum shows a considerable broadening of linewidth when compared with an EPR spectrum of free TAM nitric oxide. An EPR characterization of nitroxyl radicals is based on the measurement of the signal intensity of an EPR spectrum. This measurement can provide fundamental information of free radicals, such as linewidth, which bears a relationship to the tumbling motion of free radicals;  $g$  value, which largely depends on the immediate environments of the free radicals; and hyperfine splitting constants, which describe the classical multiplicity of EPR spectrum due to the interaction of the unpaired electron spins with nuclear spins.

**Figure 5.1** Chemical scheme for incorporating 4-amino-2,2,6,6-tetramethylpiperidine-1-oxyl into the carboxyl chain ends of linear aliphatic polyesters like polyglycolide.

**Figure 5.2** Electron paramagnetic resonance spectra of TAM radical (A) in conjugation with polyglycolide and (B) in free form.

The considerable broadening of the EPR spectrum of the TAM-PGA biomaterial (Fig. 2A) when compared with free TAM nitroxyl radical (Fig. 2B) is attributed to the viscous macromolecular environment surrounding TAM nitroxyl radicals that were chemically bound to PGA chain ends. These nitroxyl radicals cannot move as freely as free nitric oxide due to the restricted PGA chain segmental motion. This relationship between free radical motion and the characteristic of its immediate environment would provide a useful means to study the release pattern of nitroxyl radicals that were chemically bound to biodegradable substrates.

Because TAM nitroxyl radicals were incorporated only into the carboxylic chain ends of PGA macromolecules, their physical, thermal, and mechanical properties are insignificantly different from the parent PGA macromole-

**Figure 5.3** The kinetics of in vitro release of TAM nitroxyl radicals from TAM-PGA biomaterials in buffer media of original pH 7.44 at 37°C.

cules, such as similar melting temperature and heat of fusion. This lack of change in fundamental properties between TAM-PGA and parent PGA biomaterials should be beneficial because the similar processing conditions that have been used to fabricate PGA for a variety of clinical applications could also be used to fabricate the new TAM-PGA. In addition, the knowledge of the well-known biodegradation properties of PGA could be applied to estimate the release pattern of TAM nitroxyl radicals from PGA upon its biodegradation. The main difference between the parent and TAM-PGA, however, is their degradation products and their subsequent biological properties.

### B. In Vitro Hydrolytic Degradation

Since the expected biological functions of the TAM-PGA must come from the nitroxyl radicals that would be re-

**Figure 5.4** The reversible one-electron reduction and oxidation reactions of nitroxyl free radicals.

**Figure 5.5** The effect of pH of the media on the EPR spectra intensity of TAM nitroxyl radical at 10 g/mL. The media was glycolic acid: (a) pH 7.44, (b) pH 4.0, (c) pH 3.5, (d) pH 3.0.

leased into the surrounding environment upon hydrolytic degradation of PGA, the amount and the rate of release of TAM nitroxyl radicals should have a direct impact on the applicability of the newly synthesized TAM-PGA biomaterials to medicine. Figure 3 illustrates such an in vitro release pattern of TAM radicals from PGA. The release of Tempamine nitroxyl radicals upon PGA hydrolysis fol-

**Figure 5.6** The change in pH of the buffer medium used for the in vitro release study of TAM-PGA at 37°C.

**Figure 5.7** The hydrolytic release mechanism of TAM radicals from TAM-PGA biomaterials via alkaline and acid hydrolytic degradation. (A) Initial alkaline hydrolytic degradation of the ester linkages in polyglycolide backbone during the early stage of immersion. (B) Acidic hydrolytic degradation of the ester linkages in polyglycolide backbone during the middle stage of immersion. (C) Acidic hydrolytic degradation of the amide linkage to free TAM radical from the polyglycolide substrate during the late stage of immersion.

lowed a double exponential behavior in which significant amounts of nitroxyl radicals were released before 20 days followed by a gradual release thereafter.

It was well known that the nitroxyl free radicals could participate in one-electron reduction reaction in an acidic medium to yield relatively stable diamagnetic products, hydroxypiperidines structure (NOH), and *oxo*-piperidinium cations (NO<sup>+</sup>). Figure 4 shows such one-electron reduction and oxidation reaction of free nitric oxide derivatives.

Because the conversion of TAM nitroxyl radical (i.e., chemical reduction of nitroxyl radical) to hydroxypiperine

structure in an acidic environment would remove the free radical characteristic of TAM, EPR could not detect the presence of hydroxypiperine, and the spin numbers of TAM would continue decrease with time. The extent of this conversion and hence the number of spins of TAM would depend on the strength of acidity of the medium. Figure 5 illustrates such an effect of pH on the peak intensity of EPR spectra of TAM nitroxyl radicals in glycolic acid media. As the pH of the media decreased from 7.44 to 4.0 (EPR spectrum b in Fig. 5) and 3.0 (EPR spectrum d in Fig. 5), the EPR spectra peak intensities were reduced accordingly. This would suggest that more TAM nitroxyl radicals would be reduced to hydroxypiperine at a lower pH, and fewer TAM nitroxyl radicals would be remained in an acidic medium and exhibit weaker EPR signal.

In addition, the nitroxyl group could also be easily polarizable by acids toward its ionic resonance form resulting in an increased electron–nuclear coupling constant (hyperfine splitting constant) since the spin density of the nitroxyl bond has been influenced by the proton activity in the acidic media.

The acidifying of the degradation media can be demonstrated by the decrease in pH as shown in Fig. 6. The result indicated a similar double exponential reduction [ $y(x) = 3.83 e^{-0.39x} + 3.57 e^{-0.0018x}$ ] in pH as for the number of spins versus time in Fig. 3. The pH of the medium was reduced from the initial 7.4 at day 0 to 3.5 during the first 14 days of hydrolysis, and there was a very little reduction in pH thereafter. A comparison between Figs. 3 and 6 showed a remarkable similarity between the release pattern of TAM nitroxyl radicals and the profile of the reduction in pH of the degradation media.

The observed in vitro release pattern of TAM nitroxyl radicals from the TAM-PGA biomaterial and the close similarity between the TAM release pattern and the media pH reduction profiles suggested that pH must play a major role. Based on the well-known hydrolytic degradation mechanism of PGA biomaterial, we postulated the hydrolytic degradation mechanism of TAM-PGA biomaterial as illustrated in Fig. 7. TAM-PGA biomaterials experienced both alkaline and acid catalyzed hydrolytic degradation as evident in the change of pH of the media (Fig. 3).

Alkaline hydrolysis would occur during the very early stage (within a few days) because of the initial pH of the buffer (7.4). The possible products of this early stage alkaline hydrolysis of TAM-PGA were expected to be carboxylic fragments of PGA segments (II in Fig. 7A) and the TAM-PGA fragments (Ia in Fig. 7A). As hydrolysis time proceeded further, the PGA fragments would eventually be degraded into glycolic acid or/and its cyclic dimers (glycolide) as the pH of the media became more acidic. The length of the PGA segment of the TAM-PGA frag-

**Figure 5.8** Electron paramagnetic resonance spectra of the degradation products from the in vitro hydrolytic degradation of TAM-PGA in buffer media over a period of 55 days at 37°C. (A) 3 days, (B) 23 days, (C) 55 days. Note the presence of split peaks in A and B that are not there in C.

ments (Ia) would also be reduced via ester hydrolysis in both alkaline and acidic media till all the ester linkages were scissioned (III or/and IIIa in Fig. 7B). Because the amide linkages where the TAM nitroxyl radicals were attached to PGA were far more hydrolytic resistant than ester linkages, we did not expect the formation of free TAM nitroxyl radicals via the scission of the amide linkage (VII in Fig. 7C) until at the late stage of hydrolysis.

Based on the proposed hydrolytic degradation mechanism of TAM-PGA biomaterials shown in Fig. 7, one should expect only one type of TAM nitroxyl radical (I or Ia in Fig. 7A) in the very early stage of hydrolysis, as hydrolysis proceeded further, a mixture of TAM nitroxyl radicals with different PGA chain length (i.e., different  $m$  in I or Ia, would be the predominant products in the degradation media). At the late stage of hydrolysis, all PGA segments of the TAM-PGA fragments were hydrolyzed and eventually the amide linkages where the TAM radicals were attached would be hydrolyzed to free TAM radicals (VII in Fig. 7C).

These different types of TAM radicals due to different PGA chain lengths attached might be evident in the EPR spectra shown in Fig. 8, which was a series of EPR spectra from three different stages of hydrolysis time.

At 3 days of hydrolysis, its EPR spectrum had a unique character on its first peak (i.e., a spectral feature with splitted peaks) that was characteristically different from the typical 3 EPR peaks of homogeneous nitroxyl radicals in solution. This spectral feature could imply that there was a mixture of TAM-PGA nitroxyl radicals with various PGA chain lengths (heterogeneity). In other words, there

might be at least two different segmental lengths with different tumbling rate of TAM nitroxyl radicals (i.e., two different A tensor and  $g$  factors). The largest EPR spectral feature of the first peak was observed at 23 days hydrolysis. This EPR spectral feature persisted for a long period up to 40 days of hydrolysis. At the late stage of hydrolysis (55 days), however, this spectral feature of TAM radicals disappeared and the typical 3 EPR spectrum of nitroxyl radicals reappeared. This suggested that a more homogeneous type of nitroxyl radical, like VII or IIIa shown in Fig. 7, were present in the media. Due to the lack of restriction imposed by the PGA long chain segments, the tumbling motion of free TAM nitroxyl radicals in aqueous solution was easier than their polymeric counterparts and was reflected in the typical nitroxyl radical hyperfine spectrum.

### C. In Vitro Biological Activity on Human Smooth Muscle Cells

The biological activity of TAM-PGA can best be illustrated by the level of retardation of smooth muscle cell (SMC) in cell culture. This is because NO has been theorized to be able to retard SMC proliferation in humans. As shown in Fig. 9, TAM-PGA showed profound retardation of the proliferation of SMC in vitro. There was virtually no change in the number of live SMCs in the culture medium having TAM-PGA over the entire period of cell culture, while the number of live SMCs in the culture medium control had been more than double (134% increase) during the same culture period. This level of SMC retardation of TAM-PGA biomaterial was found to be similar with free

**Figure 5.9** The effect of TAM-PGA on the proliferation of human smooth muscle. The cell density at day 0 was  $5.0 \times 10^4/2$  mL.

TAM nitroxyl radicals at 1  $\mu\text{g/mL}$ . Figure 9 also shows that any higher concentrations of TAM nitroxyl radicals in the culture media ( $>1 \mu\text{g/mL}$ ) would appear toxic to SMC as evident in the reduction in SMC population from the initial number (0 day), particularly at 100  $\text{g/mL}$ .

The preliminary in vitro SMC culture data suggest that the newly synthesized TAM-PGA biomaterials have the same biological function as free nitric oxide in terms of the retardation of SMC proliferation. Although the intermediate and final degradation products from the hydrolysis of TAM-PGA biomaterials (I/Ia, III/IIIa, and VII) are chemically different from pure nitric oxide they exhibited the same retardation of SMC proliferation as free TAM nitroxyl radicals. Thus, it appears that both the free TAM and the TAM-PGA nitroxyl radicals would have the same biological function as pure nitric oxide. The long PGA chain segments where the TAM nitroxyl radicals were attached appeared not to interfere with the biological functions of the nitric oxide portion of the TAM-PGA molecules. Since the level of retardation of SMC proliferation by TAM-PGA biomaterials at a concentration of 1  $\text{mg/mL}$  was found to be similar to the pure TAM nitroxyl radicals at 1  $\mu\text{g/mL}$  over the entire culture period, it appears that the amounts of TAM that were incorporated into PGA chain ends based on the stipulated chemical reaction conditions were adequate for this particular purpose.

### III. POTENTIAL BIOMEDICAL APPLICATIONS

Some examples of the potential use of this new generation of biologically active biodegradable polymers are the treatment of intimal hyperplasia after balloon angioplastic procedures, anticancer drugs, wound closure materials with improved healing and antimicrobial capability, and synthetic vascular grafts that would not clot. In the anticancer drug area, the nitroxyl radical-incorporated biodegradable biomaterials could be used as the vehicles to precisely deliver the antitumor property of nitroxyl radicals to tumor sites via the biodegradation release of the incorporated nitroxyl radicals. The nitroxyl radical-incorporated biomaterials could also be used to improve the efficacy of radiation therapy in cancer because nitroxyl radicals are known to be able to considerably sensitize tumor cells toward radiation. The benefit will be lessened side effects of radiation therapy because a lower dosage of radiation could be used without compromising the therapeutic effect. In addition to the therapeutic effect and reconstruction of injured or diseased tissues, the nitroxyl radical-incorporated biomaterials may also be used as a useful tool for a fundamental study of a host of biochemical reactions involving free rad-

icals and superoxide anions because these nitroxyl radical-labelled biomaterials could react with any reactive free radicals and neutralize them. These modified biomaterials could also be used to mimic the functions of superoxide dismutase, a naturally occurring enzyme to neutralize superoxide anions and other reactive radicals. Thus, the modified biomaterials may be used to control local inflammatory reaction induced by wounds or/and surgical implants.

### ACKNOWLEDGMENTS

The author wishes to thank his former graduate student, Dr. Keun-Ho Lee, for his thesis upon which the bulk of this chapter is based. The in vitro smooth cell proliferation was conducted by Professor Fred Quimby and his research staff, Suzanne Klaessig, Department of Pathology, College of Veterinary Medicine, Cornell University.

### I. INTRODUCTION

Hydrogels are a three-dimensional network of hydrophilic polymers held together by association bonds such as covalent bonds and weaker cohesive forces such as hydrogen and ionic bonds and intermolecular hydrophobic association. These networks are able to retain a large quantity of water within their structure without dissolving. Due to their superior chemical and physical properties, hydrogels have received much attention for preparing biomedical materials. The elastic nature of the hydrated hydrogels when used as implants has been found to minimize irritation to surrounding tissue. The low interfacial tension between the hydrogel surface and the aqueous solution has been found to minimize protein adsorption and cell adhesion. The research for an ideal biocompatible material was pioneered by Wichterle and Lim (1). They developed the first synthetic hydrogel and the subsequent development of therapeutic soft contact lenses. Since then the research for hydrogels increased year by year. There are some reviews and textbooks for historical and detailed information of hydrogels (2–4). In this chapter, we deal with a brief overview of hydrogels and focus on the ongoing researches.

### II. FUNDAMENTALS

#### A. Classification

Hydrogels are classified in several ways (Table 1). The most simple classification is hydrogels obtained from natural products and hydrogels made of synthetic materials. Peppas classified hydrogels in three ways: method of preparation, ionic charge, and physical structure features (5). Based on the method of preparation, hydrogels are classified further into four groups: homopolymer hydrogels, copolymer hydrogels, multipolymer hydrogels, and interpenetrating polymeric hydrogels. Based on ionic charges, hydrogels are classified as neutral, cationic, anionic, or amphoteric hydrogels. Based on physical structural features, they are classified as amorphous hydrogels, semicrystalline hydrogels, or hydrogen-bonded structures.

Another classification is based on the crosslinking method. It basically involves two types of gel preparation. One is the chemical crosslinking, and the other is the physical crosslinking. In the former case, functional groups on polymer chains are bound with crosslinking agent or radiation to form insoluble gels. On the other hand, the physical method introduces physical crosslinks between polymer chains through intermolecular force such as van der Waals

**Table 6.1** Classification of Hydrogels

Classification	Contents
Source	Natural Synthetic
Component	Homopolymer Copolymer Multipolymer
Preparation method	Simultaneous polymerization Crosslink of polymer
Electric charge	Nonion Anion Cation Zwitter ion
Physical structure	Amorphous Semicrystalline Hydrogen bonded
Crosslink	Covalent bond Intermolecular force
Functions	Biodegradable Stimuli responsive Superabsorbent Etc.

force and hydrophobic association, for example. Classification by function of hydrogel is also useful. A wide variety of functional hydrogels have been proposed such as biodegradable, stimuli-responsive, and superporous hydrogels.

## B. Preparation

Hydrogels are prepared by various methods. In many situations, water may be present during the initial formation of the crosslinked structure. Typical methods of preparing hydrogels are irradiation, chemical reactions, and physical association. The radiation method utilizes electron beams, gamma rays, x-rays, or ultraviolet light to excite polymer chains to produce a crosslinking point (6). Chemical crosslinking requires a di- or trifunctional crosslinking agent and polymers with reactive functional groups in the side chain or the chain ends. Another chemical crosslinking method is a simultaneous copolymerization–crosslinking reaction between one or more monomers using polymerizable crosslinking agent. Physical crosslink association introduces physical crosslinks between polymer chains through intermolecular force.

A wide variety of synthetic hydrogels can be manufactured by selecting an appropriate polymer or monomer source. There are three basic types of monomers and polymers used to create hydrogels: neutral, acidic or anionic, and basic or cationic. Among the neutral monomers and

polymers, hydrophilic or hydrophobic groups may be available. Most of the monomers and the polymer are hydrophilic because the water-soluble groups contribute to swelling. In order to improve the mechanical strength of hydrogels, hydrophobic portion is incorporated. For instance, when 2-hydroxyethyl methacrylate (HEMA) is copolymerized with hydrophobic monomers, hydrogels with superior tensile strength and machinability are obtained (7). To incorporate water into hydrogels, various hydrophilic groups can be applied, such as hydroxyl, amide, and ether group. Monomers with acidic groups are thought to minimize calcification when the hydrogels is implanted (8,9). Cationic hydrogels acquire positive charge, which has a favorable effect on the permeability of anions such as phosphate, a property important in hemodialysis (10).

## C. Properties

### 1. Water Content and Swelling Ratio

The polymer chains of hydrogels interact with the solvent molecule and tend to expand to the fully solvated state. On the other hand, the crosslink structure works as the retractive force to pull back the polymer chain inside. This retractive force is described by the Flory rubber elasticity theory (11). The counterbalance of the expanding and retracting force attains to equilibrium in a particular solvent at particular temperature.

To describe the swelling behavior of hydrogels, their swelling ratio or water content is currently used in most cases. The water content of a hydrogel is expressed in terms of percentage of water by weight:

$$\text{water content} = \frac{\text{weight of water}}{\text{weight of water} + \text{weight of dry gel}} \times 100$$

For instance, most of hydrogel contact lenses have water content between 38 and 75%. When the water content of the hydrogel is over 90%, the hydrogel is called superabsorbent hydrogel. Another index which characterizes hydrogels is the swelling ratio, expressed by the ratio of the weight of swollen sample over that of the dry sample:

$$\text{swelling ratio} = \frac{\text{weight of swollen gel}}{\text{weight of dry gel}}$$

Peppas suggested that the swelling characteristic of hydrogels is a key for the use of hydrogels in biomedical and pharmaceutical applications, since the equilibrium swelling ratio influences the solute diffusion coefficient, surface wettability and mobility, and optical and mechanical properties of hydrogels.

## 2. Permeability

The permeability of target molecules is of utmost importance for medical application of hydrogels. For instance, oxygen permeation for contact lens, nutrient and immunological biosubstance transport for immunoisolation, and releasing drugs and proteins for drug delivery systems are core characteristics for each application.

### III. MEDICAL APPLICATIONS OF HYDROGELS

Because of their extraordinary biocompatibility, hydrogels have been successfully used in a wide range of biomedical applications that include lubrication for surgical gloves, urinary catheters and surgical drainage systems, contact lenses, wound dressings, and drug delivery systems.

#### A. Lubricant

Hydrogels have been used extensively for lubricating the surfaces of biomaterials. As the dry surface of latex gloves and catheters exhibits a high friction coefficient, hydrogels were applied to provide a low friction surface (12). Similarly, drainage tubes used to evacuate collections of fluid within body cavities require surface lubricity to facilitate insertion and removal.

The mechanical friction between a catheter and the mucosa tissue may injure the urethra and may cause microhematuria (13). Because of this side effect, hydrogel coatings have been applied to catheters to protect the urethra and form a hydrophilic lubricious surface. Hydrogels swell on contact with water and retain a significant proportion of water, so that the hydrogel surface becomes slippery, providing a less frictional interface between the mucosa. Then the hydrogel-coated catheter provides protection to the contacting urethral epithelium during the catheter use.

Jackson and Fleming proposed five prerequisites for the optimal performance of a surgical drain: a slippery surface, antithrombogenicity, softness, radiopacity, and sterilizability (14). One example of this hydrogel formation is to react poly(vinylpyrrolidone) with an isocyanate prepolymer on a silicone drain (15).

#### B. Contact Lens

Contact lenses are used to correct the optical function of the eye with intimate contact to the eye (16,17). Contact lenses are classified into two groups: soft (flexible) and hard contact lenses. Hydrogel contact lenses are a member of soft contact lens group. The hydrogel lenses are made of slightly crosslinked hydrophilic polymers and copolymers.

The original material for hydrogel contact lens was poly(2-hydroxyethyl methacrylate) (polyHEMA) (1); at the equilibrium swelling in physiological saline solution, it contains about 40% water of hydration.

Hydrogel contact lenses are more comfortable than other types and are easier to fit. On the other hand, they are more easily damaged and require more hygienic care than rubber or plastic lenses. The hydrogel contact lens is only comfortable when it has a large diameter, thin edges, and when they move on a limited region. Another factor to be considered in the comfort of a hydrogel contact lens is the surface quality. There has been little study about this problem; however, less interaction of eyelid with hydrogel contact lens is one of the possible reasons for the comfortability of this type of contact lens.

Wide varieties of hydrogel contact lenses have been developed, while the "traditional" material, HEMA, is still the most frequently used material for contact lenses. As the oxygen permeability of the original, rather thick polyHEMA hydrogel contact lenses was found to be insufficient for the corneal metabolism, improved hydrogel contact lenses were developed to enhance oxygen transport. One method was to increase the water content by copolymerizing with a more hydrophilic monomer, and the other method was to fabricate ultrathin lenses. The oxygen permeability coefficient of hydrogel materials increases exponentially with the water content. Ultrathin fabrication is applicable to any lens type. Generally, the oxygen flux through the lens will double when the thickness is halved.

Other hydrogel contact lens materials are methacrylic acid, 1-vinyl-2-pyrrolidone (NVP), dimethylacrylamide, glyceryl methacrylate, and so on. A variety of other monomers as well as a variety of crosslinking agents are used as minor ingredients in hydrogel contact lenses (Table 2) (18). Hydrogel lenses have been classified by the U.S. Food and Drug Administration (FDA) into four general groups (Table 2): low water (<50% H<sub>2</sub>O) nonionic; high water (>50% H<sub>2</sub>O) nonionic; low water ionic; and high water ionic. The ionic character is mainly due to the presence of methacrylic acid. This ionic character contributes to high water content, while it is responsible for higher surface protein binding to the contact lenses. High hydration is a desirable property for good oxygen permeability, but there are some disadvantages, such as low tear tolerance and protein penetration into the hydrogel. For daily-wear lenses, ultrathin low-water-content contact lenses are currently recommended.

Of all the studies for permeability, oxygen permeation through hydrogel has been investigated in detail for a long time. Most of the available contact lenses were developed with the important property of oxygen permeability in mind. The oxygen permeability coefficient,  $Dk$ , is a prop-

**Table 6.2** Classification of Contact Lens by U.S. FDA

Note: HEMA: 2-hydroxyethyl methacrylate; MAA: methacrylic acid; VP: 1-vinyl-2-pyrrolidone; NDOAAm: N-(1,1-dimethyl-3-oxobutyl) acrylamide; DHPMMA: 2,3-dihydroxypropyl methacrylate.

erty characteristic of a material, where  $D$  is the diffusion coefficient and  $k$  is Henry's law solubility coefficient. The dimension of  $Dk$  is generally written in  $\times 10^{-11}$  (cm<sup>2</sup>/s)(mL O<sub>2</sub>/mL mmHg). For a given contact lens, oxygen transmissibility ( $Dk/L$ ) is defined as the oxygen permeability coefficient of the material divided by the average thickness of the lens ( $L$ , in cm) (19).

### C. Dressing

Historically, gauze or nonwovens of cotton or wool have been used in medicine for a long time. Nowadays, there exist a plenty of polymeric wound covering materials. They are subdivided into polymer films, polymer foams, hydrogels, hydrocolloids, and alginates. The prerequisites for a successful wound covering material are flexibility, strength, nonantigenicity, and permeability of water and metabolites (20). As a barrier effect, a secure wound covering is also necessary to prevent infection (21). Hydrogels possess all of these characteristics except high mechanical strength. The swelling capacity of hydrogels in water, which gives them advantageous permeability and flexibility, reduces the tensile strength (21). In order to solve this contradiction, composite blends of hydrogels and other polymers have been created.

There are many successful examples of hydrogel composite wound dressings (22). The Hydron (23,24) (National Patent Hydro Med Science Division) was the first hydrogel developed for use as a wound covering material. Vigilon (25) (Bard Home Health), Gelperm (26) (Geistlich), Intrasite (Smith & Nephew), and Biolux (Catalina

Biomedical) are currently available. All these hydrogel wound dressings are composed of hydrophilic monomers, such as HEMA, and other ingredients, such as poly(ethylene glycol), acrylamide, or agar. Some of these dressings have a multiple layer structure. The success of various hydrogel composites for wound covering depends on their ability to protect against infection and to promote wound healing by keeping a moist atmosphere.

## IV. PHARMACEUTICAL APPLICATIONS OF HYDROGELS

### A. Drug Delivery System

Hydrogels are currently being studied as controlled release carriers of drugs and proteins because of their good tissue compatibility, easy manipulation under swelling condition, and solute permeability (27,28). There are two general methods for loading drugs into hydrogels as drug carriers. In one method, a hydrogel monomer is mixed with drug, initiator, and crosslinker and is polymerized to entrap the drug within the matrix. In another method, a preformed hydrogel (in most cases lyophilized) is allowed to swell to equilibrium in a suitable drug solution. The release of these drugs from the hydrogel delivery system involves absorption of water into the polymer matrix and subsequent diffusion of the drugs as determined by Fick's Law. Kim et al. (27) reviewed the detailed consideration of swelling, drug loading, and drug release. They reported that factors that affect the drug release from hydrogels include the drug loading method, the local partition of drugs, the overall hydrophilic/hydrophobic balance, the osmotic effect of dissolved drugs, and the polymer chain elasticity. The preparation of hydrogel matrix for a specific drug carrier should be tailored considering the aforementioned effects as well as the physical properties of drugs, loading level, and release kinetics.

Due to an enormous number of drugs and proteins, the number of tailored hydrogels for specific drugs is also countless. Some typical examples are reviewed herein.

Pluronic polyols or polyoxamers are block copolymers of poly(ethylene oxide) and poly(propylene oxide). Some grades of pluronics have a unique character of reversible thermal gelation and good nondenaturing effects on proteins. Pluronic gels have been used as delivery systems for several proteins including IL-2 (29,30), urease (30), rat intestinal natriuretic factor (31). Poly(vinyl alcohol) (PVA) is used for releasing bovine serum albumin in vitro (32). The initial release of the drug was attributed to diffusion of drug through water-filled pores near the surface of the polymer matrix. Physically crosslinked PVA gels have been prepared by a freeze-thawing process, which causes

structural densification of the hydrogel, and have been studied as protein-releasing matrices (33,34). One of the pioneer studies on the use of a chemically crosslinked hydrogel as a protein-delivery system were done with incorporation of chymotrypsin in poly(NVP) (PVP) hydrogels (35). Because of their high porosity, the protein underwent a rapid diffusional release within a time of 2–3 days, and the kinetics were reported to be difficult to control. Beck et al. used 3% methylcellulose gels to deliver transforming growth factor  $\beta$ 1 (TGF- $\beta$ 1) both to topical skin wounds (36,37) and to bone defects (38). In both cases, the protein in the gel showed a significant enhancement in the healing of skin wounds or bone defects when compared to protein that was applied to the site in a saline buffer solution. It means that the incorporated TGF- $\beta$ 1 was not denatured and worked appropriately.

Hydrogels from natural products are also used as drug carriers, similar to synthetic polymer hydrogels. Alginate is one of most popular natural hydrogel matrices for drug release. Ionically crosslinked alginate hydrogels have been used to incorporate several different proteins for controlled release applications including TGF- $\beta$ 1 (39), basic fibroblast growth factor (bFGF) (39), tumor necrosis factor receptor (40), epidermal growth factor (EGF), and urogastrone (41). Most of these proteins are incorporated into alginate hydrogels via ionic bonding to the polymer, but sometimes the bioactivity of incorporated proteins was reduced by such ionic interaction. The addition of poly (acrylic acid) to the alginate hydrogel was shown to prevent the inactivation of proteins by alginate. Another method is preincorporation with other polymers. Basic FGF adsorbed to heparin-sepharose beads can keep its activity after incorporation into the alginate matrix (41).

Hyaluronic acid derivatives are a good example of naturally occurring polymers that have been modified to control the degradation and release rates. Hyaluronic acid has a high molecular weight ( $MW = 5$  to  $6 \times 10^6$ ) and exhibits excellent biocompatibility. In most cases, hyaluronic acid was applied after modification by chemical crosslinking and derivatization for enhancement of the rheological properties or for control of the degradation time (42–44). The controlled releases of insulin (45) and nerve growth factor (NGF) (46) from hyaluronic acid esters were reported.

Several groups have demonstrated the release of proteins from collagen matrices. Fujiwara et al. reported incorporation of IL-2 into a collagen pellet (47,48). A similar collagen system was used to release NGF (49). Collagen gels have been also reported to effectively deliver EGF (50) and TGF- $\beta$ 1 (51) to experimentally induced wounds in a mouse model. In both cases, the growth factors were shown to accelerate wound healing. The protein release

from collagen gel is thought to be a diffusion-controlled system because the *in vitro* release rates were linear with the square root of time in many cases. Gelatin is a denatured substance of collagen and is soluble in water under the physiological condition. An appropriate crosslinking is necessary to obtain gelatin–hydrogel. Tabata et al. reported a gelatin microsphere delivery system containing IFN- $\alpha$ . The gelatin was often crosslinked with glutaraldehyde (52). Gelatin-based matrices are studied in many aspects, such as the release of insulin (53), and granulocyte macrophage colony stimulating factor (GM-CSF) (54,55), bFGF (56), and TGF- $\beta$ 1 (57). The gelatin system was shown to be a useful delivering matrix, but glutaraldehyde crosslinking still remains as a potential problem in clinical application if gelatin is crosslinked in the presence of protein pharmaceuticals.

## V. FUTURE PERSPECTIVES

### A. Immunoisolation

The basic concept of immunoisolation is very simple: to capsule living cells with a semipermeable barrier which permits bidirectional passage of small molecules (nutrients, oxygen, and bioactive cell secretions) while restricting transport of larger molecules and host immune cells. Several different approaches to immunoisolation have been proposed and evaluated (58). The current types of the system are cylindrical or planar diffusion chambers (macrocapsules) and dispersions of spherical beads (microcapsules). The objective cells may be allowed to float freely within a capsule but are mostly supported on a three-dimensional hydrogel matrix. In many studies, the immunoisolative barrier was made of hydrogels prepared from naturally occurring polysaccharides (alginate, agar, or chitosan). Modified hydrogel membrane barriers are fabricated either from weak polyelectrolytes, typically poly (lysine)-alginate, or from engineering thermoplastics, such as polysulfone, poly(acrylonitrile-vinyl chloride), or polyolefins (59–64).

Among the many requirements to these matrices, their permeability may be the most important issue. Oxygen and nutrients should be supplied at a sufficiently high rate through the membrane, though passage of components of the host immune system should be prevented by the semipermeability of the membrane. The properties required for the semipermeable membrane used in cell transplantation highly depend on the source of cells, whether allo- or xenogeneic.

An allograft is a graft between different individuals from the same species. It is believed that the predominant cause of allograft rejection is activation of cellular immu-

nity by interactions of host T cells with a graft, while humoral immunity including antibodies and complement proteins is thought to play a major role in the rejection of xenografts. For the allograft applied to a recipient without preformed antibodies, a membrane which can physically inhibit the contact of host immune cells with the graft is expected to effectively protect the graft from rejection. For xenografts, the semipermeable membrane must be designed to be highly permeable to low molecular weight molecules, but be able to prevent permeation of high molecular weight biomolecules, such as antibodies and complement proteins for a long time. The development of immunoisolative membranes applicable to xenografts is challenging because of shortage of allogeneic donors. Although various membranes which allow xenotransplantation have been reported, there is still ambiguity in their long-term effectiveness.

A hydrogel membrane does not have a distinct molecular weight cutoff and its selectivity is characterized by the diffusion coefficient of solutes. Iwata et al. (65) employed a 5% agarose hydrogel to immunoisolate islets of Langerhans. Most xenogeneic recipients with microencapsulated hamster islets in 5% agarose hydrogel could not demonstrate normoglycemia for more than 10 days. The agarose gel cannot effectively protect xenogeneic cells from the humoral immunity. To solve this problem, they tried to control the complement cytolytic activities by using poly(styrene sulfonic acid) (65).

## B. Tissue Engineering

Tissue engineering has been extensively studied by many researchers in a wide area. Tissue engineering, as well as cell transplantation, has been the most widely investigated strategy in the recent biomaterials field. Tissue engineering aims at restoring a tissue defect by inducing endogenous tissue regeneration and manipulating the cascades of cellular events during the healing process. Tissue engineering uses polymer devices with controlled macro- and microstructures and chemical properties to achieve organ regeneration. Combination of cells and an immunoisolative membrane forms biohybrid organs, which become a permanent part of the host organ by acting as the functional analog of the original organ by continuously supporting the organ.

Polymers play an important role in tissue engineering, providing a scaffold for cell adhesion and a space for cell proliferation. The interest in hydrogel as a biomaterial for soft tissue replacement existed in their ability to retain water within the polymer network and also in the possibility to retain the bioactive proteins such as growth factors without inactivating. The swelling characteristics of hydrogels provide the maintenance of a chemical balance with the

surrounding tissue and allow the exchange between water in the hydrogel and ions and metabolites of tissue fluids. In addition, the viscoelastic behavior, low interfacial tension with biological fluids, and structural stability make hydrogels suitable for scaffold for tissue engineering (66–68).

In particular, the use of porous hydrogels to assist tissue repair and axonal regeneration in the brain (69–71) and the spinal cord (72–75) has been investigated. Hydrogels with a three-dimensional network of hydrophilic copolymers are well tolerated by living tissues and may serve as a substrate for tissue formation.

It has been widely recognized that growth factors greatly contribute to tissue regeneration at different stages of cell proliferation and differentiation. However, successful tissue regeneration by the use of growth factors has not always been achieved. One of the reasons for this is the very short half-life periods of growth factors in the body to sustain biological activities. Thus, it is highly necessary to contrive the dosage of growth factors for enhancing the *in vivo* efficacy.

Tabata et al. reported a series of growth factor release by using gelatin as a basic material (56,57,76–81). The skull bone regeneration induced by TGF- $\beta$ 1-containing gelatin hydrogels (TGF- $\beta$ 1-hydrogels) is significant (57). Gelatin hydrogels with a water content of 95 wt% that incorporated at least 0.1  $\mu$ g of TGF- $\beta$ 1 induced significant bone regeneration at the rabbit skull defect site 6 weeks after treatment, whereas TGF- $\beta$ 1 in solution form was ineffective, regardless of the dose. The *in vivo* degradability of the hydrogels, which varied according to the water content, played an important role in skull bone regeneration induced by TGF- $\beta$ 1-hydrogels. In their hydrogel system, TGF- $\beta$ 1 is released from the hydrogels as a result of hydrogel degradation. When the hydrogel degrades too quickly, it does not retain TGF- $\beta$ 1 or prevent ingrowth of soft tissues at the skull defect site and does not induce bone regeneration at the skull defect. It is likely that hydrogel that degrades too slowly physically impedes formation of new bone at the skull defect. Following the treatment with 0.1  $\mu$ g TGF- $\beta$ 1-hydrogel (95 wt%), newly formed bone remained at the defect site without being resorbed 6 and 12 months later. The histological structure of the newly formed bone was similar to that of the normal skull bone. Overgrowth of regenerated bone and tissue reaction were not observed after treatment with TGF- $\beta$ 1-hydrogels.

Tabata et al. also reported the sustained release of TGF- $\beta$ 1 by using a biodegradable hydrogel based on polyion complexation for the enhancement of bone regeneration activity (77). The TGF- $\beta$ 1 was adsorbed onto the biodegradable hydrogel of acidic gelatin with an isoelectric point of 5.0 by electrostatic interaction. The TGF- $\beta$ 1 could not be adsorbed onto the basic gelatin. When acidic gelatin

hydrogels incorporating  $^{125}\text{I}$ -labelled TGF- $\beta$ 1 were implanted into the back of mice, the radioactivity decreased with time and the *in vivo* retention of TGF- $\beta$ 1 was prolonged with a decrease in the water content of hydrogels. The higher the water content of hydrogels, the faster their biodegradation. The *in vivo* retention of TGF- $\beta$ 1 was correlated well with that of gelatin hydrogels, indicating that TGF- $\beta$ 1 was released from the gelatin hydrogel as a result of hydrogel biodegradation. The ability of TGF- $\beta$ 1 incorporated into acidic gelatin hydrogels to induce bone regeneration was evaluated in a rabbit calvarial defect model. Eight weeks after treatment, the gelatin hydrogels with water contents of 90 and 95 wt% induced significantly high bone regeneration compared with those with lower and higher water contents and free TGF- $\beta$ 1. This indicates that the sustained release of TGF- $\beta$ 1 from the hydrogel with suitable *in vivo* degradability is necessary to effectively enhance its osteoinductive function. Rapid hydrogel degradation will result in too short retention of TGF- $\beta$ 1 to induce bone regeneration. It is possible that the slow degradation of the hydrogel physically blocked TGF- $\beta$ 1-induced bone regeneration at the skull defect.

The polyion complexation is applicable for release of other growth factors. Acidic gelatin hydrogel was used as a biodegradable vehicle for bFGF release (78). This growth factor was incorporated by polyion complexation into a biodegradable hydrogel prepared by crosslinking acidic gelatin with the isoelectric point of 4.9. The dried hydrogel was hydrated with bFGF aqueous solution including different doses of bFGF (20, 50, 125, 250, and 500 ng) and implanted into a rabbit corneal pocket. Corneal angiogenesis was evaluated by biomicroscopy, corneal fluorescein angiography, and histology for 21 days. The hydrogel degraded with time after its implantation into the corneal pocket. Experimental eyes receiving the hydrogel containing more than 50 ng of bFGF demonstrated significant corneal angiogenesis. Control eyes and eyes receiving the hydrogel containing 20 ng of bFGF showed no corneal angiogenesis. Corneal angiogenesis, which occurred on the third or fourth day after implantation, reached maximal growth on about day 7 and regressed from day 10 after implantation. The area of angiogenesis showed a dose dependency on bFGF. The gelatin hydrogel itself induced neither angiogenesis nor inflammation. These results suggest that acidic gelatin hydrogel releases bioactive bFGF with its biodegradation, resulting in corneal neovascularization.

*In vivo* release of bFGF from a biodegradable gelatin hydrogel carrier was compared with the *in vivo* degradation of hydrogel (79). When gelatin hydrogels incorporating  $^{125}\text{I}$ -labelled bFGF were implanted into the back of mice, the bFGF radioactivity remaining decreased with time, and the retention period was prolonged with a decrease in the water content of the hydrogels. The lower the

water content of  $^{125}\text{I}$ -labelled gelatin hydrogels, the faster both the weight of the hydrogels and the gelatin radioactivity remaining decreased with time. The decrement profile of bFGF remaining in hydrogels was correlated with that of the hydrogel weight and gelatin radioactivity, irrespective of the water content. Subcutaneous implantation of bFGF-incorporating gelatin hydrogels into the mice induced significant neovascularization. The retention period of neovascularization became longer as the water content of the hydrogels decreased. To study the decrease of activity of bFGF when implanted, bFGF-incorporating hydrogels were placed in a diffusion chamber and implanted in the mouse subcutis for certain periods of time. When hydrogels explanted from the mice were again implanted significant neovascularization was still observed, indicating that most of the biological activity of bFGF was retained in the hydrogels. It was concluded that biologically active bFGF was released as a result of *in vivo* degradation of the hydrogel. The release profile was controllable by changing the water content of hydrogels.

Other approaches for releasing growth factors from hydrogels were also reported. Among cytokines, bFGF is a well-known heparin-binding growth factor which has mitogenic activity for many cell types (82). It has been reported that heparin protects bFGF from proteolytic degradation and thermal inactivation (83), strongly potentiates its activity (84), and stabilizes its molecular conformation. Heparan sulfate and other sulfated glycosaminoglycans, which are functional analogs of heparin, are also present in the extracellular matrix and work as stabilizers for bFGF. In order to prepare the bFGF-reserving and -activating matrix on the inner surface of porous materials, the use of sulfated polysaccharide seems to be promising. Glucosyloxyethyl methacrylate (GEMA) is a novel methacryloyl monomer, and radical polymerization of GEMA gives highly water-soluble polymers [poly(GEMA)] and hydrogels with a crosslinking agent (85–87). The sulfation of poly(GEMA) provided poly(GEMA) with a heparinlike activity (88). Hence, poly(GEMA) was considered as one of polysaccharide model compounds. The reserving and activating ability of poly(GEMA)-sulfate, and its hydrogel for bFGF was investigated. It was revealed that poly(GEMA)-sulfate hydrogel has activity for activating bFGF and enhances the cell proliferative activity of bFGF.

### C. Hydrogels of Stimuli-Responsive Polymers

#### 1. Overview

Some polymers undergo strong conformational changes when only small changes occur in the environment, such as temperature, pH, and ionic strength. These polymers are called stimulus-responsive polymers. Nonlinear responses by the polymer systems have mainly been observed in wa-

ter. An appropriate balance of hydrophobicity and hydrophilicity in the molecular structure of the polymer is required for the phase transition to occur. There have been a lot of reviews of this field (89–93).

## 2. Immobilized Biocatalysts

When an enzyme is incorporated in a hydrogel, phase transition of stimuli-responsive polymer can significantly affect the enzyme activity and substrate access to the enzyme molecule. A wide range of stimuli-responsive polymers have been used for the development of reversibly soluble biocatalysts whose solubility is controlled by pH (94) or temperature (95–99). A biocatalyst preparation sensitive to magnetic fields has been produced by immobilizing invertase and  $\gamma\text{-Fe}_2\text{O}_3$  in a poly(N-isopropylacrylamide (NIPAAm)-co-acrylamide) hydrogel. The heat generated by the exposure of  $\gamma\text{-Fe}_2\text{O}_3$  to a magnetic field causes the hydrogel to collapse, followed by a sharp decrease in the rate of sucrose hydrolysis.

## 3. Drug Delivery

The swelling or shrinking of stimuli-responsive hydrogel in response to small changes in pH or temperature can be used to control drug release (92). The development of a glucose-sensitive insulin releasing system for diabetes therapy was developed by using pH-responsive polymer, poly[(N,N-dimethylamino) ethyl methacrylate-co-ethylacrylamide]. The polymer was mixed and compressed with glucose oxidase, bovine serum albumin, and insulin. When the matrix was exposed to glucose, it was oxidized to form gluconic acid. As the hydration state was changed by a decrease in the pH, then insulin was released. A variety of designs for an insulin-delivery system that responds to glucose were also developed using glucose oxidase.

## 4. Biomimetic Actuators

Biomimetic actuators, which mimic the conversion of chemical energy into mechanical energy in living organisms, have become of major interest lately (100). Ionic hydrogels are known to show a discontinuous volumetric change above a certain threshold of an external stimulus such as pH, temperature, ionic strength, or concentration of organic solvent. The volume change of several hundred times over and under the threshold is utilized to exert a significant force. As a stimulus that induces a volumetric change in a hydrogel, an electric field is utilized. For example, a crosslinked hydrogel of poly(vinyl alcohol) chains entangled with poly(acrylic acid) chains has good mechanical properties and shows rapid electric field-associated bending deformation. Hydrogels capable of mechanical response to electric field have also been developed using the

cooperative binding of positively charged surfactant molecules to the polyanionic polymer poly(2-acrylamido-2-methyl-1-propanesulfonic acid).

Copolymer gels consisting of NIPAAm and acrylic acid were studied for constructing biomimetic actuators. A pH-induced change in the -COOH ionization of acrylic acid alters the repulsive force. NIPAAm produced the attractive force by hydrophobic interactions over lower critical solution temperature (32°C). Glucose dehydrogenase was used here again for converting neutral glucose into gluconic acid. When this reaction occurs inside the gel, the repulsive force is eliminated owing to protonation of COO- groups. As a result, the attractive force dominates, followed by collapse of the gel. The problem of this system is extremely slow response to the stimuli.

## D. Novel Hydrogels

Hubbell et al. have been studying applications of a novel hydrogel prepared by poly(ethylene glycol) (PEG) diacrylate derivatives (101–105). The hydrogel obtained by photopolymerization of poly(ethylene glycol) diacrylate was derivatized with Arg-Gly-Asp (RGD)-containing peptide sequences (101). Incorporation was achieved by functionalizing the amine terminus of the peptide with an acrylate moiety, thereby enabling the adhesion peptide to copolymerize rapidly with the PEG diacrylate upon photoinitiation. Hydrogels incorporated the peptide with a PEG spacer arm and incorporation of RGD-promoted fibroblast spreading. Water-soluble macromers based on block copolymers of PEG and poly(lactic acid) or poly(glycolic acid) with terminal acrylate groups were used for a nonadhesive barrier at the free surface on the treated wound site. These materials, photopolymerized in vivo in direct contact with tissues, appear to form an adherent hydrogel barrier that is highly effective in reducing postoperative adhesions in the models used.

Yui and coworkers have proposed new drug release systems: dual stimuli-responsive release (106,107) and pulsatile release systems (108). For the dual stimuli-responsive system, interpenetrating polymer network (IPN)-structured hydrogels of gelatin and dextran were prepared with lipid microspheres as a drug microreservoir. The IPN-structured hydrogel prepared below the transition temperature of gelatin exhibited a specific degradation-controlled lipid microsphere release behavior: lipid microsphere release from the hydrogel in the presence of either  $\alpha$ -chymotrypsin or dextranase alone was completely hindered, whereas lipid microsphere release was observed in the presence of both enzymes. For the pulsatile release system, multilayered hydrogels consisting of PEG-grafted dextran (PEG-g-Dex) and ungrafted dextran were prepared. In these formulations, it is expected that the grafted PEG do-

mains act as a drug reservoir dispersed in the dextran matrix based on aqueous polymer two-phase systems. The formulations exhibited surface-controlled degradation by dextranase, and insulin release was observed in a pulsatile manner because of the multilayered structure in which PEG-g-Dex hydrogel layers contained insulin, and dextran hydrogel layers did not.

### E. Other Hydrogels

Some hydrogels are currently used for biomedical applications, but the use of hydrogels under physiological conditions is sometimes limited by calcification. The calcification of biomaterials is an important pathologic process, and has been observed not only in hydrogels but also in many kinds of biomaterials, for example, in devices (109), artificial blood pumps (artificial hearts) (110), heart valves (111,112), and soft contact lenses (113), as well as in polyurethane (109) and silicone rubber (114). As calcification lowered the performance of the materials by changing the bulk properties or causing thrombosis, a great deal of research has been done to make clear the calcification mechanism (115–118). On the other hand, calcification is useful as a biomedical material which requires bone bonding. Hydroxyapatite [HAp:  $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ ], which is one of the main components of calcified materials, is a biofunctional inorganic material. In some orthopedic and tissue adhesive applications, many researchers have attempted to create polymer–HAp composites by mixing (119), plasma spray (120,121), and coating (122,123); they reported that formation of composite was good. However, there have been few studies about hydrogel–HAp composites. If hydrogel–HAp composites can be formed, the use of hydrogels as implantable materials will increase. However, the calcification mechanism (HAp formation) has not yet been clarified.

Many possible factors, such as animal species, age, hormone level, type of materials, shear stress, surface defect, protein adsorption, hydrophilicity, and thrombus, may contribute to calcification of biomedical materials in vivo (124,125). In regard to studying calcification, the main obstacle was the lack of an adequate in vitro experimental system. Most studies of calcification have been done in vivo (118) because it is assumed that devitalized cells and cellular debris are keys to calcification. Recent research has revealed that the physicochemical aspect of materials is another essential factor for calcium phosphate deposition in the initial stage of calcification. Animal models can provide useful data, but it takes a long period of time to study calcification. In 1990, Kokubo et al. developed a biomimetic process and noted that a HAp layer with the desired thickness was formed on ceramic, metal, and polymer films at a normal temperature and pressure in vitro (126). Using this experimental procedure, some research (127) in

regard to creating polymer–HAp composites has been done (122,128). Assuming the biomimetic process as an in vitro calcification model, HAp formation (which is a type of calcification) on/in hydrogels was analyzed. There are many kinds of hydrogels and many factors to study, including chemical formula, functional group, swelling ratio, and so on. Imai et al., who used PHEMA copolymer hydrogels, found that the amount of calcified deposits depends on the HEMA content in the hydrogels and that their chemical structure was a more important factor in calcification than hydrophilicity. Using various hydrogels that carried hydroxyl groups, the relationship between hydrogel characteristics and HAp formation was studied (115). It was revealed that there were two factors (the bound water content and the swelling ratio of a hydrogel) that affect HAp formation. The higher bound water content will provide a large number of nucleation sites for HAp on/in a hydrogel. On the other hand, the higher the swelling ratio becomes, the larger amount of ions is supplied into a hydrogel matrix from a solution in order to grow HAp nuclei on/in a hydrogel.

## VI. SUMMARY

Hydrogels have been studied as biomaterials in the medical field, but the clinical applications are very limited. The continuous advances in biology and medicine will produce further demand for biomaterials, and hydrogels could be a practical answer, especially in the field of tissue engineering and drug delivery systems.

## Mucoadhesive Polymers

**Andreas Bernkop-Schnürch**

*University of Vienna, Vienna, Austria*

### I. INTRODUCTION

In the early 1980s, academic research groups pioneered the concept of mucoadhesion as a new strategy to improve the therapeutic effect of various drugs. Mucoadhesive polymers are able to adhere on the mucus gel layer that covers various tissues of the body. These mucoadhesive properties are in many cases advantageous rendering such polymers interesting tools for various pharmaceutical reasons:

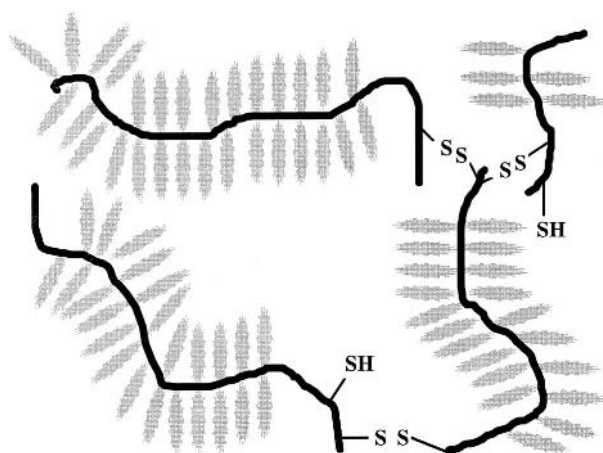

1. Mediated by mucoadhesive polymers, the residence time of dosage forms on the mucosa can be prolonged, which allows a sustained drug release at a given target site in order to maximize the therapeutic effect. Robinson and Bologna, for instance, have reported that a polycarbophil gel is capable of remaining on the vaginal tissue for 3 to 4 days and thus provides an excellent vehicle for the delivery of drugs such as progesterone and nonoxynol-9 (1).
2. Furthermore, drug delivery systems can be localized on a certain surface area for purpose of local therapy or for drug liberation at the “absorption window,” e.g., the absorption of riboflavin, which has its absorption window in the stomach as well as the small intestine, could be strongly improved in human volunteers by oral administration of mucoadhesive microspheres versus nonadhesive microspheres (2).
3. In addition, mucoadhesive polymers can guarantee an intimate contact with the absorption membrane providing the basis for a high concentration gradi-

ent as driving force of drug absorption; for the exclusion of a presystemic metabolism such as the degradation of orally given (poly)peptide drugs by lumenally secreted intestinal enzymes (3,4); and for interactions of the polymer with the epithelium, such as a permeation enhancing effect (5,6) or the inhibition of brush border membrane-bound enzymes (7,8).

Because of all these benefits, research work in the field of mucoadhesive polymers has strongly increased within the last two decades resulting in numerous promising ideas, strategies, systems, and techniques based on a more and more profound basic knowledge. An overview reflecting the status quo as well as future trends concerning mucoadhesive polymers should provide a good platform for ongoing research and development in this field.

### II. MUCUS GEL COMPOSITION

As mucoadhesive macromolecules adhere to the mucus gel layer, it is important to characterize first this polymeric network representing the target structure for mucoadhesive polymers. The most important component building up the mucus structure are glycoproteins with a relative molecular mass range of  $1\text{--}40 \times 10^6$  Da. These so-called mucins possess a linear protein core, typically of high serine and threonine content that is glycosylated by oligosaccharide side chains that contain blood group structures. The protein core of many mucins exhibits furthermore N and/or C ter-

**Figure 7.1** Schematic presentation of the three-dimensional network of the mucus gel layer; protein core; ; glycosidic side chains, .

minally located cysteine-rich subdomains, which are connected with each other via intra- and/or intermolecular disulfide bonds. This presumptive structure of the mucus is illustrated in Fig. 1. The water content of the mucus gel has been determined to be 83% (9). Generally, mucins may be classified into two classes, secretory and membrane-bound forms. Secretory mucins are secreted from mucosal absorptive epithelial cells as well as specialized goblet

cells. They constitute the major component of mucus gels of the gastrointestinal, respiratory, ocular, and urogenital surface. The mucus layer based on secretory mucins represents not only a physical barrier but also a protective diffusion barrier (9,10). Membrane-bound mucins possess a hydrophilic membrane-spanning domain and are attached to cell surfaces. Up to now, eight different types of human mucins have been discovered and characterized, which are listed in Table 1.

Secreted mucins are continuously released from cells as well as glands undergoing immediately thereafter a polymerization process mainly based on an intermolecular disulfide bond formation. This so-formed mucus layer, on the other hand, is continuously eroded by enzymatic and mechanical challenges on the luminal surface. Although the turnover time of the mucus gel layer seems to be crucial in order to estimate how long a mucoadhesive delivery system can remain on the mucosa in maximum, there is no accurate information on this time scale available. A clue was given by Lehr et al., who determined the turnover time of the mucus gel layer of chronically isolated intestinal loops in rats to be in the order of approximately 1–4 h (21). Both mucus secretion and mucus erosion, however, are influenced by so many factors, such as mucus secretagogues, mechanical stimuli, stress, calcium concentration, and the enzymatic activity of luminal proteases leading to a highly variable turnover time a time scale is therefore quite complex and difficult to evaluate.

**Table 7.1** Synopsis of Human Mucins

Mucin	Characteristics	High-level expression	Cysteine-rich subdomains	Reference
MUC1	Membrane-bound epithelial mucin	Breast, pancreas		12
MUC2	Secreted intestinal mucin	Intestine, tracheobronchus	Yes	13
MUC3	Secreted intestinal mucin	Intestine, gallbladder, pancreas	Yes	14
MUC4	Tracheobronchial, secretory mucin	Tracheobronchus, colon, uterine endocervix		15
MUC5A/C	Secretory mucin	Tracheobronchus, stomach, ocular, Uterine endocervix	Yes	16
MUC5B	Secretory mucin	Tracheobronchus, salivary	Yes	17
MUC6	Major secretory mucin of the stomach	Stomach, gallbladder	Yes	18
MUC7		Salivary		19
MUC8		Tracheobronchus, reproductive tract		20

### III. PRINCIPLES OF MUCOADHESION

Since the concept of mucoadhesion was introduced into the scientific literature, considerably many attempts have been undertaken in order to explain this phenomenon. So far, however, no generally accepted theory has been found. A reason for this situation can be seen in the fact that many parameters seem to have an impact on mucoadhesion (Fig. 2), which makes a unique explanation impossible. Although there are many controversies over which theories should be favored, at least two basic steps are generally accepted. In step I, the *contact stage*, an intimate contact between the mucoadhesive and the mucus gel layer is formed. In step II, the *consolidation stage*, the adhesive joint is strengthened and consolidated, providing a prolonged adhesion.

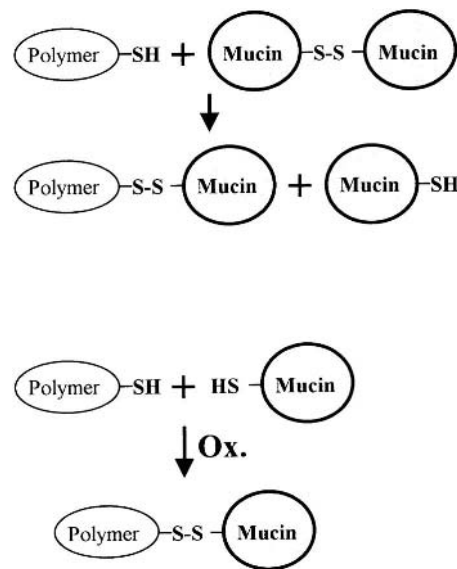

#### A. Chemical Principles

##### 1. Formation of Noncovalent Bonds

Noncovalent chemical bonds include *hydrogen bonding*, which is based on hydrophilic functional groups such as hydroxylic groups, carboxylic groups, amino groups, and sulfate groups; *ionic interactions*, such as the interaction of the cationic polymer chitosan with anionic sialic acid moieties of the mucus; and *van der Waals forces*, based on various dipole-dipole interactions.

##### 2. Formation of Covalent Bonds

In contrast to secondary bonds, covalent bonds are much stronger and are not any more influenced by parameters such as ionic strength and pH value. Functional groups that are able to form covalent bonds to the mucus layer are over

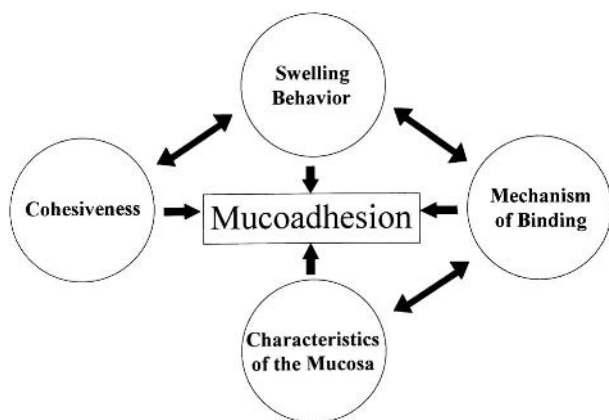

**Figure 7.3** Thiolated polymers forming covalent bonds with the mucus layer.

all thiol groups. The way such functional groups can form covalent bonds with mucus glycoproteins is illustrated in Fig. 3. Thiolated polymers are able to mimic the naturally occurring mechanism whereby mucus glycoproteins are immobilized in the mucus.

#### B. Physical Principles

##### 1. Interpenetration

One theory explaining the phenomenon of mucoadhesion is based on a macromolecular interpenetration effect. The mucoadhesive macromolecules interpenetrate with mucus glycoproteins as illustrated in Fig. 4. The resulting consolidation provides the formation of a strong stable mucoadhesive joint. The theory can be substantiated by the observation that chain flexibility favoring a polymeric

**Figure 7.2** Schematic presentation of effects influencing mucoadhesion. (From Ref. 22.)

**Figure 7.4** Interpenetration of a mucoadhesive matrix tablet (.....) and the mucus gel layer (—).

interpenetration is a crucial parameter for mucoadhesion. The crosslinking of various polymers or the covalent attachment of large sized ligands (23) leading to a reduction in chain flexibility results in a strong decrease in mucoadhesive properties.

Rheological approaches (discussed in detail later on) demonstrate a synergistic increase in the resistance to elastic deformation by mixing mucus with mucoadhesive polymer. Attenuated total reflection Fourier transform infrared (ATR-FTIR) studies showing changes in the spectrum of a poly(acrylic acid) film because of interpenetrating mucin molecules within 6 min (24) provide further evidence for this theory.

Objections to the interpenetration theory, however, are provided mainly by electron microscopy studies giving no evidence of interpenetration in the micrometer range (25) and the strong adhesion of mucoadhesive polymers to plane solid surfaces where the opportunity for macromolecular interpenetration is obviously marginal.

## 2. Mucus Dehydration

Dehydration of a mucus gel layer increases its cohesive nature, which was shown by Mortazavi and Smart (26). Dehydration essentially alters the physicochemical properties of a mucus gel layer, making it locally more cohesive and promoting the retention of a delivery system. The theory can be substantiated by studies with dialysis tubings. Bringing dry mucoadhesive polymers wrapped in dialysis tubings into contact with a mucus layer leads to its dehydration rapidly (26). Dehydrating a mucus gel increases its cohesive nature and subsequently its adhesive behavior, which could be shown by tensile studies (26). An objection to the theory that no interpenetration but exclusively mucus dehydration occurs is given by various rheological studies and tensile studies carried out by Caramella et al. (27), who observed a significant increase in the total work of adhesion (TWA) by mixing the polymer directly with mucin before tensile measurements. It is therefore likely that glycoproteins of the mucus are carried with the flow of water into the mucoadhesive polymer which leads to the already described interpenetration, an explanation which allows the combination of both the interpenetration and mucus dehydration theory.

## 3. Entanglements of Polymer Chains

The mucoadhesive as well as cohesive properties of polymers can also be explained by physical entanglements of polymer chains. The difference in cohesive as well as mucoadhesive properties of lyophilized and precipitated mucoadhesive polymers gives strong evidence for this theory. Whereas precipitated polymers display high cohesive as well as mucoadhesive properties with a likely high number

of polymer chain entanglements, these properties are comparatively lower for the corresponding lyophilized polymers, which do not exhibit such a high extent of entanglements (28).

## IV. METHODS TO EVALUATE MUCOADHESIVE PROPERTIES

### A. In Vitro Methods

The selection of the mucoadhesive material is the first step in developing a mucoadhesive drug delivery system. A screening of the adhesive properties of polymeric materials can be done by various in vitro methods such as visual tests, tensile studies, and rheological methods, which are often accompanied by additional spectroscopic techniques. Apart from these well-established methods, which are described in detail in this section, some novel methods such as magnetic (29) and direct force measurement techniques (30) have been introduced into the literature as well.

#### 1. Visual Tests

##### a. Rotating Cylinder

In order to evaluate the duration of binding to the mucosa as well as the cohesiveness of mucoadhesive polymers, rotating cylinder seems to be an appropriate method. In particular, tablets consisting of the test polymer can be brought into contact with freshly excised intestinal mucosa (e.g., porcine) that has been spanned on a stainless steel cylinder (diameter, 4.4 cm; height, 5.1 cm; apparatus, 4-cylinder, USP XXII). Thereafter, the cylinder is placed in the dissolution apparatus according to the USP containing an artificial gastric or intestinal fluid at 37°C. The experimental set-up is illustrated in Fig. 5. The fully immersed cylinder is agitated at 250 rpm. The time needed for de-

**Figure 7.5** Schematic presentation of the test system used to evaluate the mucoadhesive properties of tablets based on various polymers. **c** = cylinder; **if** = intestinal fluid; **m** = porcine mucosa; **t** = tablet.

tachment, disintegration, and/or erosion of test tablets can be determined visually (22).

### b. Rinsed Channel

At this method, freshly excised mucosa is spread out on a lopsided channel with the mucus gel layer facing upwards and placed in a thermostatic chamber, which is kept at 37°C. After applying the test material on the mucosa, the rinse is flushed with an artificial gastric or intestinal fluid at a constant flow rate, and the residence time of the mucoadhesive polymer is determined visually. The experimental set-up is illustrated in Fig. 6 (31,32).

## 2. Tensile Tests

### a. Tensile Studies with Dry Polymer Compacts

Test polymers are thereby compressed to flat-faced discs. Tensiometer studies with these test discs are carried out on freshly excised mucosa. Test discs are therefore attached to the mucosa. After a certain contact time between test disc and mucosa, the mucosa is pulled at a certain rate (mm/s) from the disc. The total work of adhesion representing the area under the force–distance curve and the maximum detachment force (MDF) are determined. The experimental set-up is illustrated in Fig. 7. It represents one of the best established *in vitro* test systems used by numerous research groups (23,33,34).

### b. Tensile Studies with Hydrated Polymers

In order to minimize the influence of an “adhesion by hydration,” tensile studies can also be carried out with hydrated polymers, as described by Ch’ng and coworkers (35). Hydrated test polymers are thereby spread in a uniform monolayer over excised mucosa which has been fixed on a flat surface. In an artificial gastric or intestinal fluid

**Figure 7.6** Experimental set-up in order to evaluate the mucoadhesive properties of test formulations on a freshly excised mucosa spread out on a lopsided channel.

**Figure 7.7** Experimental set-up for tensile studies with dry polymer compacts.

at 37°C, the hydrated polymer is brought in contact with the mucus layer of a second mucosa, which is fixed on a flat surface of a weight hanging on a balance. The TWA and MDF are then determined as already described.

### c. Tensile Studies with Microspheres

Tensile studies as described are not designed for measuring microscopic interactions such as those that may occur between microparticles and the mucus gel layer. Hence, a method was developed for measuring mucoadhesive properties of microspheres. *In vivo* interactions are thereby mimicked utilizing a miniature tissue chamber, which is heated by a water jacket. Thermoplastic microspheres are mounted to the tips of fine iron wires using a melting technique. The nonloaded ends of the wires are then attached to a sample clip and suspended in the microbalance enclosure. The freshly excised section of mucosa is clamped in the buffer-filled chamber at 37°C, and the microsphere is brought into contact with the tissue. To fracture the adhesive interactions, the tissue is pulled off the microsphere and certain mucoadhesive parameters are calculated and graphs of force versus position and time are plotted using appropriate software for the microbalance. The method provides valuable information concerning the adhesive properties of microspheres. So far, however, it is limited to microspheres not smaller than 300 μm (36).

## 3. Rheological Techniques

During the chain interpenetration of mucoadhesive polymers with mucin macromolecules, physical entanglements, conformational changes, and chemical interactions occur. Thereby, changes in the rheological behavior of the two macromolecular species are produced. An evaluation of the resulting synergistic increase in viscosity, which is supposed to be in many cases directly proportional to results

obtained with tensile studies (37), can be achieved by mixing the mucoadhesive polymer with mucus and measuring viscosity. The rheological behavior can be determined either by a classical rotational viscometry test at a certain shear rate or by dynamic oscillatory measurements, which give useful information about the structure of the polymer–mucin network.

#### 4. Spectroscopic Techniques

Since mucoadhesive properties of polymers have been investigated, these tests were accompanied by additional spectroscopic analyses (38). Kerr et al. (39), for instance, using  $^{13}\text{C}$  nuclear magnetic resonance spectroscopy have provided evidence of hydrogen bonding between mucus glycoproteins and the carboxylic acid groups of polyacrylic acid. Moreover, Tobyn et al., using Fourier transform infrared spectroscopy, reported also interactions between the pig gastric mucus glycoproteins and the test mucoadhesive (40). Jabbari et al. could confirm the chain interpenetration theory by investigating a mucin and polyacrylic acid interface via attenuated total reflection Fourier transform infrared spectroscopy (24). Mortazavi et al., using infrared and  $^{13}\text{C}$  NMR spectroscopy, suggested the formation of hydrogen bonds between the mucoadhesive polyacrylic acid and the terminal sugar residues on the mucus glycoprotein (41). In another study, the nature of interactions between the mucus gel and polyacrylic acid was investigated by tensile studies, dynamic oscillatory rheology, and  $^{13}\text{C}$  NMR spectroscopy as well. The addition of hydrogen bond breaking agents resulted thereby in a decrease in mucoadhesive strength, a reduction in viscoelastic properties of polymer–mucin mixtures, and a positional change in the chemical shift of the polyacrylic acid signal (42).

#### B. In Vivo Methods

To date, the mucoadhesion of dosage forms in the body has been evaluated by direct observation and by gamma scintigraphy. For both methods, either the time period of mucoadhesion is determined or in case of the GI tract to what extent the transit time of the mucoadhesive dosage form can be prolonged.

The direct observation offers the advantage that radionuclides are not needed and that a pretreatment of the test formulation is in most cases not necessary. The technique can be used to evaluate mucoadhesion on various tissues in animal studies. Akiyama and Nagahara for instance, administered mucoadhesive microspheres orally to rats. After 2.5 h, the extent of the adhesion of these microspheres to the gastric mucosa was evaluated visually, demonstrating a high amount of mucoadhesive microspheres being present in the stomach compared to nonadhesive microspheres

(2). For human studies, however, the direct observation is limited only to a few mucosal tissues such as the oral cavity. Bouckaert et al., for instance, determined the adhesion of tablets in the region of the upper canine. Test tablets were thereby fixed for 1 min with a slight manual pressure on the lip followed by moistening with the tongue to prevent sticking of the tablet to the lip. The adhesion time was defined as the time after which the mucoadhesive tablet was no longer visible under the lip upon control at 30-min intervals (43). In another study, which was carried out in the same way, volunteers participating in this study were asked to record the time and circumstances of the end of adhesion (erosion or detachment of the tablet) (44).

In contrast, no tissue limitations seem to exist for gamma scintigraphic methods. Using these techniques makes it even possible to evaluate the increase in the GI transit time of mucoadhesive formulations. Radionuclides used for imaging studies include  $^{99}\text{Tc}^m$ ,  $^{111}\text{In}^m$ ,  $^{113}\text{In}^m$ , and  $^{81}\text{Kr}^m$ . Among them technetium-99m represents the most commonly used radionuclide, as it displays no beta or alpha radiation and a comparatively short half-life of 6.03 h. Indium-113m, which has an even shorter half-life of 1.7 h has a different energy to technetium-99m and can therefore be used in double-labelling studies. For many applications the longer lived isotope indium-111m (half-life 2.8 days) seems to be more appropriate. Whereas a strongly prolonged GI transit time of mucoadhesive polymers was demonstrated in various animal studies (35), the same effect could not be shown in human volunteers (45,46).

### V. MUCOADHESIVE POLYMERS

A system for mucoadhesive polymers can be based on their origin (e.g., natural/synthetic), the type of mucosa on which they are mainly applied (e.g., ocular/buccal), or their chemical structure (e.g., cellulose derivatives/polyacrylates). Apart from these approaches, mucoadhesive polymers can also be classified according to their mechanism of binding as shown within this chapter.

#### A. Noncovalent Binding Polymers

According to their surface charge, which is important for the mechanism of adhesion, they can be divided into anionic, cationic, nonionic, and amphiphilic polymers.

##### 1. Anionic Polymers

For this group of polymers mainly  $-\text{COOH}$  groups are responsible for their adhesion to the mucus gel layer. Carbonic acid moieties are supposed to form hydrogen bonds with hydroxyl groups of the oligosaccharide side chains on mucus proteins. Further anionic groups are sulfate as

well as sulfonate moieties, which seem to be more of theoretical than of practical relevance. Important representatives of this group of mucoadhesive polymers are listed in Table 2. Among them one can find the most adhesive noncovalent binding polymers such as polyacrylates and NaCMC (33,58). Because of their high charge density, these polymers display a high buffer capacity, which might be beneficial for various reasons as discussed in Section VI.C. In contrast to nonionic polymers, their swelling behavior, which is also crucial for mucoadhesion (Fig. 2), strongly depends on the pH value. The lower the pH value, the lower is the swelling behavior, leading to a quite insufficient adhesion in many cases. The correlation between the pH value of an anionic polymer and its swelling behavior is illustrated in Fig. 8. On the contrary, a too rapid swelling of such polymers at higher pH values can lead

to an overswelling, which causes a strong decrease in the cohesive properties of such polymers. Even if the polymer sticks to the mucus layer, in this case, the drug delivery system won't be any more mucoadhesive, as the adhesive bond fails within the mucoadhesive polymer itself. This effect is illustrated in Fig. 9. A further drawback of anionic mucoadhesive polymers, however, is their incompatibility with multivalent cations like  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ , and  $\text{Fe}^{3+}$ . In the presence of such cations, these polymers precipitate and/or coagulate (61), leading to a strong reduction in their adhesive properties.

## 2. Cationic Polymers

The strong mucoadhesion of cationic polymers can be explained by ionic interactions between these polymers and

**Table 7.2** Anionic Mucoadhesive Polymers

anionic substructures such as sialic acid moieties of the mucus gel layer. In particular, chitosan, which can be produced in high amounts for a reasonable price, seems to be a promising mucoadhesive excipient. Apart from its mucoadhesive properties, chitosan is also reported to display permeation-enhancing properties (62,63). The most important cationic mucoadhesive polymers are listed in Table 3. Their swelling behavior is strongly pH dependent as well. In contrast to anionic polymers, however, their swelling behavior is improved at higher proton concentrations. Chitosan, for instance, is hydrated rapidly in the gastric fluid, leading to a strong reduction of its cohesive properties, whereas it does not swell at all at pH values above 6.5, causing a complete loss in its mucoadhesive properties.

**Figure 7.9** Adhesive bond failure in case of insufficient cohesive properties of the mucoadhesive polymer.

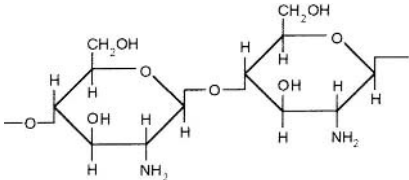

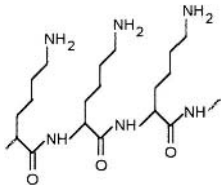

### 3. Nonionic Polymers

The adhesion of anionic as well as cationic polymers strongly depends on the pH value of the surrounding fluid. On the contrary, non ionic mucoadhesive polymers are mostly independent from this parameter. Whereas the formation of secondary chemical bonds due to ionic interactions can be completely excluded for this group of polymers, some of them such as poly(ethylene oxide) are capable of forming hydrogen bonds. Apart from these interactions, their adhesion to the mucosa seems to be rather based on an interpenetration followed by polymer chain entanglements. These theoretical considerations are in good accordance with mucoadhesion studies, demonstrating almost no adhesion of nonionic polymers if they are applied to the mucosa already in the completely hydrated form, whereas they are adhesive if applied in dry form (64). Hence, nonionic polymers are in most cases less adhesive than anionic as well as cationic mucoadhesive polymers. Well-known representatives of this group of mucoadhesive polymers are listed in Table 4. In contrast to ionic polymers, nonionic polymers are not influenced by electrolytes of the surrounding milieu. The addition of 0.9% NaCl, for instance, to carbomer leads to a tremendous decrease in its cohesiveness and subsequently to a strong reduction of its mucoadhesive properties, whereas these electrolytes have no influence on nonionic mucoadhesive polymers.

### 4. Ambiphilic Polymers

Ambiphilic mucoadhesive polymers display cationic as well as anionic substructures on their polymer chains. On one hand, mucoadhesion of the cationic polymers is said to be caused by electrostatic interactions with negatively charged mucosal surfaces. For anionic polymers, on the other hand, mucoadhesion can be explained by the formation of hydrogen bonds of carboxylic acid groups with the mucus gel layer. The combination of positive as well as negative charges on the same polymer, however, seems to compensate both effects, leading to strongly reduced adhesive properties of ambiphilic polymers. Mucoadhesion studies of chitosan–EDTA conjugates with increasing amounts of covalently attached EDTA can clearly show this effect. Whereas the exclusively anionic chitosan–EDTA conjugate (Table 2) exhibiting no remaining cationic moieties and the exclusively cationic polymer chitosan displayed the highest mucoadhesive properties, the mucoadhesion of chitosan–EDTA conjugates showing both cationic moieties of remaining primary amino groups and anionic moieties of already covalently attached EDTA was much lower. In addition, Luessen et al. could show a strongly increased intestinal busserelin bioavailability in

**Table 7.3** Cationic Mucoadhesive Polymers

Polymer	Chemical structure	Additional information	References
Chitosan		Primary amino groups can be acetylated to some extent	3, 60
Polylysine			57

rats using chitosan HCl as mucoadhesive excipient. A mixture of this cationic polymer with the anionic polymer carboxymethylcellulose, however, led to a significantly reduced bioavailability of the therapeutic peptide (66). Representatives of this type of mucoadhesive polymer are mainly proteins such as gelatin, which is reported as mucoadhesive in various studies (58,67).

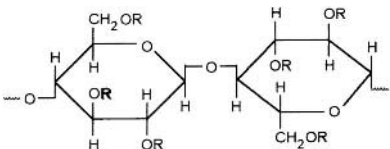

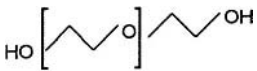

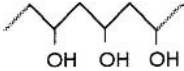

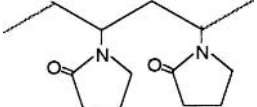

Due to the combination of cationic as well as anionic mucoadhesive polymers leading to ionic interactions, however, the cohesiveness of delivery systems can be strongly improved (53,57). If the adhesive bond of a delivery system fails within the mucoadhesive polymer itself rather than between the polymer and the mucus layer as illustrated in Fig. 9, this effect is more important than the mu-

cohesive properties of the polymer in order to improve the adhesiveness of the whole dosage form.

**B. Covalent Binding Polymers**

Recently, a presumptive new generation of mucoadhesive polymers has been introduced into the pharmaceutical literature (68). Whereas the attachment of mucoadhesive polymers to the mucus layer has to date been achieved by noncovalent bonds, these novel polymers are capable of forming covalent bonds. The bridging structure most commonly encountered in biological systems—the disulfide bond—has thereby been discovered for the covalent adhesion of polymers to the mucus layer of the mucosa. Thio-

**Figure 7.10** Thiomers (thiolated polymer): mucoadhesive polymers which display thiol moieties bearing side chains.

lated polymers, or so-called thiomers, are mucoadhesive basis polymers that display thiol-bearing side chains (Fig. 10). Based on thiol/disulfide exchange reactions, as illustrated in Fig. 11, and/or a simple oxidation process, disulfide bonds are formed between such polymers and cysteine-rich subdomains of mucus glycoproteins (see Table 1). Hence, thiomers mimic the natural mechanism of secreted mucus glycoproteins, which are also covalently anchored in the mucus layer by the formation of disulfide bonds. Due to the covalent attachment of cysteine to polycarbophil, for instance, the adhesive properties of this polymer could be strongly increased. Whereas the unmodified basis polymer displayed a total work of adhesion of  $104 \pm 21 \mu\text{J}$ , it was

**Figure 7.11** Schematic presentation of disulfide exchange reactions between a (poly)peptide and a cysteine derivative according to Snyder (69). The (poly)peptide stands here for a mucin glycoprotein of the mucus, and the cysteine derivative is a polymer–cysteine conjugate. (**R** = mucoadhesive basis polymer) (Adapted from Ref. 68.)

**Figure 7.12** Comparison of the adhesive properties of polycarbophil–cysteine conjugates displaying increasing amounts of covalently attached cysteine (32:1 up to 1:4) and controls of unmodified polycarbophil. $280 \pm 67 \mu\text{J}$  for a corresponding polymer–cysteine conjugate. The results of this study are shown in Fig. 12. Apart from these improved mucoadhesive properties, which could meanwhile also be shown for various other thiolated polymers, thiomers exhibit strongly improved cohesive properties as well. Whereas, for example, tablets consisting of polycarbophil disintegrate within 2 h, tablets based on the corresponding thiolated polymer remain stable even for days in the disintegration apparatus according to the Pharmacopoea Europea (70). The result, as shown in Fig. 13, can be explained by the continuous oxidation of thiol moieties on thiomers which takes place in aqueous solutions at pH values above 5. The decrease in sulfhydryl groups, i.e., the formation of inter- and/or intramolecular disulfide bonds within a sodium carboxymethylcellulose–cysteine conjugate, is illustrated in Fig. 14. Due to the high density of negative charges within anionic mucoadhesive polymers, they can also function as ion exchange resins displaying a high buffer capacity (see Section VI.C). According to this, the formation of disulfide bonds within polymer–cysteine conjugates can be controlled by adjusting the pH value of the system a priori. Adhesion of many quick swelling polymers, as already mentioned, is limited by an insufficient cohesion of the polymer, resulting in a break within the polymer network rather than

**Figure 7.13** Comparison of the disintegration behavior of matrix tablets (30 mg; 5 mm i.d.) containing indicated lyophilized polymers. (PCP = polycarboxiphil; CMC = carboxymethylcellulose; PCP-Cys = polycarboxiphil-cysteine conjugate; CMC-Cys = carboxymethylcellulose-cysteine conjugate.) Studies were carried out with a disintegration test apparatus (Pharm. Eur.) in 50 mM TBS, pH 6.8, at 37°C. Indicated values are means  $\pm$  S.D. of at least three experiments. Polycarboxiphil-cysteine tablets did not disintegrate even after 48 h of incubation. (From Ref. 70.)

**Figure 7.14** Decrease in thiol groups of 0.5% (m/v) (○) and 1.0% (m/v) NaCMC-cysteine conjugate (●, ■), in 50 mM phosphate buffer pH 6.8 (○, ●) and 50 mM acetate buffer pH 5.0 (■), at 37°C. Indicated values are means  $\pm$  S.D. of at least three experiments. (From Ref. 70.)

between the polymer and mucus layer (Fig. 9). Although thiolated polymers are rapidly hydrated, they are able to form highly cohesive and viscoelastic gels due to the formation of additional disulfide bonds. The formation of an overhydrated slippery mucilage can thereby be excluded completely. Using the rotating cylinder (Section IV.A.1) in order to evaluate the mucoadhesive properties of various formulations, for instance, revealed a comparatively much longer adhesion of tablets consisting of thiolated polymers (22). Meanwhile, various anionic as well as cationic thiolated polymers have been synthesized, as listed in Table 5. They all display strongly improved mucoadhesive properties compared to the corresponding unmodified basis polymers.

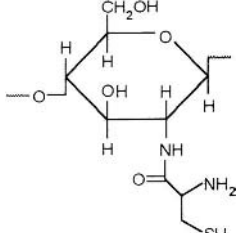

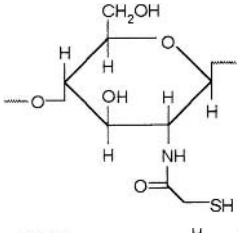

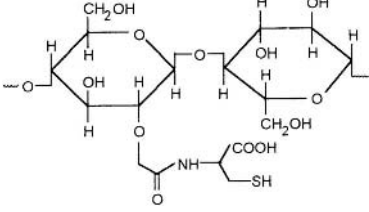

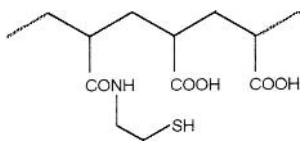

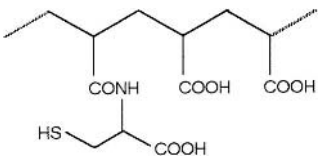

## VI. MULTIFUNCTIONAL MUCOADHESIVE POLYMERS

Whereas in the 1980s the adhesive properties of polymers played a central role in the field of mucoadhesion, numerous scientists began in the 1990s to focus their interest also on additional features of mucoadhesive polymers. These properties include enzyme inhibition, permeation enhancement, high buffer capacity, and controlled drug release. For some of these properties, mucoadhesion is substantial; for others, various synergistic effects can be expected due to adhesion.

### A. Mucoadhesion and Enzyme Inhibition

Due to the great progress in biotechnology as well as genetechnology, the industry is capable of producing a large number of potential therapeutic peptides and proteins in commercial quantities. The majority of such drugs are most commonly administered by the parenteral routes that are often complex, difficult, and occasionally dangerous. Besides so-called alternative routes of application such as the nasal or transdermal route, there is no doubt that the peroral route is one of the most favored, as it offers the greatest ease of application. A presystemic metabolism of therapeutic peptides and proteins caused by proteolytic enzymes of the GI tract, however, leads to a very poor bioavailability after oral dosing. Attempts to reduce this barrier include the use of analogs; prodrugs; formulations such as nanoparticles, microparticles, and liposomes that shield therapeutic peptides and proteins from luminal enzymatic attack; and the design of delivery systems targeting the colon where the proteolytic activity is relatively low. Moreover, considerable interest is shown in the use of mucoadhesive polymers, since due to such excipients various in vivo studies could demonstrate a significantly

**Table 7.5** Thiolated Mucoadhesive Polymers

Polymer	Chemical structure	Additional information	References

improved bioavailability of peptide and protein drugs after oral dosing.

As formulations containing mucoadhesive polymers provide an intimate contact with the mucosa, a presystemic degradation of these drugs on the way between the delivery system and the absorbing membrane can be excluded. Takeuchi et al., for instance, demonstrated a significantly stronger reduction in the plasma calcium level after oral administration of calcitonin-loaded liposomes which were coated with a mucoadhesive polymer in comparison to the same formulation without the mucoadhesive coating (4).

In recent years it could be demonstrated by various studies that certain mucoadhesive polymers display also an enzyme inhibitory effect. In particular, poly(acrylic acid) was shown to exhibit a pronounced inhibitory effect

toward trypsin (74,75). Additionally, the immobilization of enzyme inhibitors to mucoadhesive polymers acting only in a very restricted area of the intestine seems to be a promising approach in order to improve their enzyme inhibitory properties. Due to the immobilization of the inhibitor, it remains concentrated on the polymer, which should certainly make a reduced share of this auxiliary agent in the dosage form sufficient. Side effects of the inhibitor such as systemic toxicity, a disturbed digestion of nutritive proteins, and pancreatic hypersecretion caused by a luminal feedback regulation can be avoided. Hence, the covalent attachment of enzyme inhibitors to mucoadhesive polymers, such as shown in Fig. 15, represents the combination of two favorable strategies for the oral administration of (poly)peptide drugs, offering additional advantages

**Figure 7.15** Example for a mucoadhesive polymer inhibitor conjugate. The elastase inhibitor elastatinal is thereby covalently attached via a C8 spacer to polymers like polycarbophil or NaCMC. (From Ref. 76.)

compared to a simple combination of both excipients without the covalent linkage. So far, various polymer–inhibitor conjugates have been generated as listed in Table 6. Their efficacy could be verified by *in vivo* studies in diabetic mice showing a significantly reduced glucose level after the oral administration of insulin tablets containing a CMC–Bowman Birk inhibitor conjugate and a CMC–elastatinal conjugate. The results of this study are shown in Fig. 16 (83).

### B. Mucoadhesion and Permeation Enhancement

A number of mucoadhesive polymers also have promising effects on the modulation of the absorption barrier by opening of the intestinal intercellular junctions (63,84). In contrast to permeation enhancers of low molecular size such as sodium salicylate and medium-chain glycerides (85,86), these polymers might not be absorbed from the intestine, which should exclude systemic side effects of these auxiliary agents. Permeation studies, for instance, carried out in Ussing chambers on Caco-2 monolayers demonstrated a strong permeation-enhancing effect of chitosan and carbomer (84,87). This permeation-enhancing effect of these mucoadhesive polymers can even be significantly improved due to the immobilization of cysteine on these polymers (5,71). Results demonstrating this permeation-enhancing effect of a thiolated polymer are shown in Fig. 17. This improved permeation across the mucosa was accompanied by a decrease in the TEER, indicating a loosening of the tightness of intercellular junctions, i.e., the opening of the paracellular route across the epithelium for otherwise nonabsorbable hydrophilic compounds such as peptides. Mechanisms which are responsible for the

permeation-enhancing effect of mucoadhesive polymers, however, are still unclear. As anionic polymers such as polyacrylates display a high binding capacity for  $\text{Ca}^{2+}$  ions, their permeation-enhancing effect might be based on the depletion of this cation. The theory relies on the knowledge that on the one hand many complexing agents like EDTA display a permeation-enhancing effect (88), and  $\text{Ca}^{2+}$ , on the other hand, plays an essential role concerning the gate fence function of the tight junctions being responsible for their closing (89).

In contrast, the permeation-enhancing effect of cationic polymers like chitosan might be based on the positive charges of these polymers which interact with the cell membrane, resulting in a structural reorganization of tight junction-associated proteins (90).

In case of thiolated polymers, protein tyrosine phosphatase might be involved in the underlying mechanism. This thiol-dependent enzyme mediates the closing process of tight junctions by dephosphorylation of tyrosine groups from the extracellular region (91). The inhibition of PTP by specific inhibitors such as vanadate or pervanadate causes an enhanced opening of the tight junctions. As it is also inhibited by sulfhydryl compounds such as glutathione forming a mixed disulfide with Cys 215 (92), it is likely that thiolated polymers might also lead to an inhibition of this enzyme.

### C. Mucoadhesion and Buffer System

A further advantage of mucoadhesive polymers can be seen in the high buffer capacity of ionic polymers. As these polymers can act as ion exchange resins, they are able to maintain their pH value inside the polymeric network over a considerable period of time. Matrix tablets based on neutralized carbomer, for instance, can buffer the pH value inside the swollen carrier system even for hours in an artificial gastric fluid of pH 2 (93). The results of this study are shown in Fig. 18. This high buffer capacity seems to be highly beneficial for various reasons. For example, the epidermal growth factor (EGF) is recognized as an important agent for acceleration of ulcer healing and has a peculiar biological property to repair tissue damage by an enhanced proliferation and differentiation of epithelial tissues (94). Itoh and Matsuo demonstrated in a double-blind controlled clinical study the enhanced healing of rat gastric ulcers after oral administration of EGF. This effect could even be drastically increased by using the mucoadhesive polymer hydroxypropyl cellulose as drug carrier matrix (95). As EGF is strongly degraded by pepsin (96), the use of mucoadhesive polymers providing an additional protective effect toward pepsin degradation might therefore be helpful. It can be achieved by a comparatively

Polycarbophil–cysteine	Carboxypeptidase A/B		++++	73

Note: Mucoadhesive properties are classified as poor (+), good (++), very good (+++), and excellent (++++).

<sup>a</sup> Antipain/chymostatin/elastatinal.

<sup>b</sup> Bowman Birk inhibitor.

higher pH value inside the drug carrier matrix based on its high buffer capacity at which penetrating pepsin is already inactive.

Apart from this likely advantage for the (poly)peptide administration, the high buffer capacity of neutralized anionic polymer might also be highly beneficial in treatment of *Helicobacter pylori* infection in peptic ulcer disease, as common antibiotics such as amoxicillin or metronidazole display poor stability in the acidic pH of the stomach. The incorporation of these therapeutic agents in mucoadhesive polymers displaying a high buffer capacity might improve their stability in the acidic milieu.

#### D. Mucoadhesion and Controlled Release

If the therapeutic agent is incorporated in the mucoadhesive polymer, the excipient can act both as mucoadhesive

and as a matrix system providing a controlled drug release. The release behavior of drugs embedded in mucoadhesive polymers depends thereby mainly on their molecular size and charge. According to the equation determining the diffusion coefficient, in which the radius of a molecule indirectly correlates with the diffusion coefficient, small-sized drugs will be released faster than larger ones. Apart from their size, the release of therapeutic agents from mucoadhesive polymers can be simply controlled by raising or lowering the share of the polymer in the delivery system. Whereas a low amount of the mucoadhesive polymer in the carrier matrix can guarantee a rapid drug release, a sustained drug release can be provided by raising the share of the polymer in the delivery system (77). In addition, the drug release from mucoadhesive polymers can also be controlled by the extent of crosslinking. The higher the polymer is crosslinked, the lower is the release rate of the

**Figure 7.16** Blood glucose level of diabetic mice after oral administration of insulin microtablets containing mucoadhesive polymer-inhibitor conjugates (□) versus control (●). Values are means ± S.D.; n = 10; \* differs from control p < 0.05; \*\* differs from control p < 0.001. (From Ref. 83.)

**Figure 7.18** Buffer capacity of mucoadhesive polymers; matrix tablets consisting of carbomer (□); matrix tablets consisting of NaCMC (○); control (▲). (Adopted from Ref. 93.)

**Figure 7.17** Permeation-enhancing effect of polycarbophil and thiolated polycarbophil; polycarbophil-cysteine conjugate (■); polycarbophil (○); control without polymer (◆). (From Ref. 5.)

**Figure 7.19** Release profile of insulin from tablets consisting of 3.3% insulin, 30% mannitol, and 66.7% carbomer (C934P), which had been crosslinked with lysine. Tablets were incubated in 10 mL release medium (20 mM Tris-HCl, pH 7.8) on a waterbath-shaker (100 rpm) at 37 ± 0.5°C. Indicated values are means ± S.D. of at least three experiments. (From Ref. 28.)

drug. Such a crosslinking can be achieved by the formation of covalent bonds, e.g., the crosslinking of gelatin with glutaraldehyde (67), or on the basis of ionic interactions. The release rate of insulin from matrix tablets consisting of the anionic mucoadhesive polymer carbomer (C934P), for instance, can be strongly reduced by the addition of the divalent cationic amino acid lysine (28). The results of this study are shown in Fig. 19. In the case of ionic drugs, a sustained release can also be guaranteed by the use of an ionic mucoadhesive polymer displaying the opposite charge of the therapeutic agent. On the basis of an ion exchange resin, for instance, a sustained release of the therapeutic agent  $\alpha$ -lipoic acid over a period of more than 12 h can be provided by the incorporation of this anionic drug in the cationic mucoadhesive polymer chitosan (97).

## VII. CONCLUDING REMARKS

Motivated by the great benefits that can be provided by mucoadhesive polymers, such as a prolonged residence time and an intimate contact of the dosage form on the mucosa, considerably intensive research and development has been performed in this field since the concept of mucoadhesion had been pioneered in the early 1980s. Merits of these efforts are the establishment of various useful techniques to evaluate the mucoadhesive properties of different polymers as well as the design of novel polymers displaying improved mucoadhesive properties. In addition, the development of multifunctional mucoadhesive polymers also exhibiting features such as enzyme inhibitory properties, permeation enhancing effects, high buffer capacity, and the possibility to control the drug release make them even more promising auxiliary agents. Although there are already numerous formulations based on mucoadhesive polymers on the market, the number of delivery systems making use of these advantages will certainly increase in the near future.

# Polymers for Tissue Engineering Scaffolds

**Howard W. T. Matthew**

*Wayne State University, Detroit, Michigan*

### I. INTRODUCTION

#### A. Tissue Engineering and the Concept of the Scaffold

In general terms, the goal of tissue engineering is to develop materials and approaches which can be used to facilitate repair, regeneration, or replacement of damaged or diseased tissues. In some applications, reconstitution of tissue function outside the body is the desired goal. In the repair/regeneration scenario, the goal is to enhance or improve upon natural repair processes which often produce non-functional or poorly functional scar in place of normal tissue. In the replacement scenario, the tissue “foundation” may be assembled in vitro and subsequently implanted. This approach may employ a cellular component together with an appropriately shaped structural template or scaffold. Alternatively, a material scaffold may be implanted directly into the desired tissue site and colonized by the target cells. Most tissues are not merely collections of randomly arranged cells, but possess highly detailed organizational features which are closely tied to tissue function. The tissue engineer typically seeks to restore this tissue-specific architecture, and the use of a scaffold provides the means to this end. In order to achieve restoration of tissue architecture, the tissue scaffold may be required to perform a variety of tasks. A porous microstructure which allows cellular ingrowth and scaffold colonization is almost a universal requirement. Enhancements to the microstructure may include spatial variations in pore morphology to help

orient cells or variations in material surface properties to facilitate selective cell adhesion and/or migration. In contrast, inhibition of cell adhesion may be an important performance characteristic for certain locations. Similarly, the scaffold material must be either overtly biodegradable or at least amenable to long-term integration with the host tissue. Biodegradability allows the gradual and orderly replacement of the scaffold with functional tissue, and also prevents the development of adverse chronic responses to the artificial structure. The scaffold material may be required to deliver biologically active agents (for example, growth factors or genes) to the target tissue. The material itself may be required to possess intrinsic biological activity to elicit specific migration or proliferation responses in adjacent cell populations. To this list of cell interaction characteristics may be added certain physical properties such as precise matching of the following: tissue mechanical properties, macromolecular permeability, protein binding or repulsion, tissue adhesion or lubricity, and ease of processing. Since restoration of normal tissue architecture and function is the ultimate goal, the scaffold is usually considered to be a temporary structure. Thus the ability to tune degradation rates to achieve an optimal degradation time profile may greatly broaden the applicability of a particular material.

Given the variety of target tissues, possible scaffold microstructures, and technical approaches, it is unlikely that a single polymeric material can meet the requirements of all systems. In keeping with this idea, a variety of polymers have been and continue to be evaluated for tissue engi-

neering applications, and new or modified materials are constantly under development. In this chapter, the chemistry and properties of some of the more widely used or promising biodegradable materials are surveyed.

## B. Polymers for Tissue Engineering

At the most fundamental level, biodegradable polymers used in engineered implants can be broadly classified as either natural or synthetic. In general terms there are advantages and disadvantages associated with both types of materials. For example, natural polymers provide the clear advantage of possessing specific molecular recognition features which generally translate into specific biological activities. They are usually enzymatically degradable to nontoxic subunits which can be utilized by adjacent cells. Furthermore, these materials are amenable to both cell-mediated remodeling and direct integration into neotissue. The disadvantages of such natural materials include source-associated variability and contamination; limited control over parameters such as molecular weight; the potential for adverse immunological responses; variations in degradation rates due to differences in host enzyme levels; and, in some cases, inferior mechanical properties. In contrast, synthetic polymers can be synthesized in pure form with complete control over molecular and physical properties. Degradation usually occurs via passive hydrolysis, thus ensuring uniform *in vivo* degradation rates from one host to another. These polymers also usually permit a wider range of processing options. However, they generally lack intrinsic biological activity. Introduction of bioactivity, by side chain grafting, for example, may also be limited by molecular properties or incompatibility. The degradation products may be toxic or may drastically alter the local microenvironment (e.g., pH). Surface hydrophobicity may also mediate protein denaturation in the vicinity of the implant, and may thus play a role in triggering fibrous encapsulation of the implant.

## II. COLLAGENS

### A. General Overview

The collagens are a family of fibrous proteins that occur in almost all mammalian tissues. They are particularly abundant in load-bearing tissues such as tendon and bone. Skin is also rich in this protein. The structure, sequence, and biology of the many types of collagen, as well as its use in tissue repair, have been extensively reviewed elsewhere (1–3). Because of the relative ease of extraction and its abundance, collagens in both their native and denatured forms have had a long history of use as implantable materi-

als. Its use has been facilitated by the fact that its sequences are highly conserved across species boundaries. Thus, collagens from xenogeneic sources (e.g., bovine collagen) generally produce only mild immune response. To date, 14 types of collagen have been identified. The form that has been most investigated for tissue scaffold purposes is Type I collagen, which is also the most abundant form.

In its native form, collagen exists as three similar polypeptide chains arranged into a triple helical structure. Each polypeptide chain has the general sequence (glycine–X–Y)<sub>n</sub>, where X and Y can be any amino acid but are often proline and hydroxyproline, respectively. Hydrogen bonding by these two amino acids serves to stabilize the helix. As synthesized, the ends of the polypeptide chains (i.e., the N and C termini) deviate from the three–amino acid repeat structure and therefore are not helical. These regions are up to 26 amino acid residues in length and are termed telopeptides. The triple helical collagen molecule is the main functional subunit, and has the unique ability to self-assemble into fibrils of extraordinary strength. The fibrils are further strengthened by the formation of intermolecular crosslinks between adjacent telopeptide regions. This crosslinking generally takes place as a postsecretion, enzymatic process in the extracellular space. Nonenzymatic crosslinking processes such as glycation (4–6) also contribute to postsecretion fibril strengthening. Fibrils may be further assembled into bundles to form collagen fibers, which are the main tensile load-bearing component in non-ligamentous tissues.

Collagen (Type I) is typically isolated by either enzymatic digestion or salt or acid extraction from collagenous animal tissues. Enzymatic digestion (e.g., via pepsin) cleaves the crosslinked telopeptide regions, thus producing soluble triple helices lacking the telopeptides; the so-called atelocollagen. Salt or acid extraction disrupts intra- and intermolecular hydrogen bonds, leading to swelling and subsequent dissolution of the structure. Reversion to a physiological environment restores conditions suitable for collagen fibril self-assembly. Hence an acidic solution of collagen can be induced to form fibrils *in vitro* by imposing conditions of physiological pH, temperature, and ionic strength. The formation of a fibril network is usually manifested by gelation of the solution.

### B. Biological Properties

Since collagen serves as a structural component in almost all tissues and is present to some degree in all basement membranes, it stands to reason that most anchorage-dependent cells express receptors for one or more epitopes of the molecule. As a result, collagen gels and fibers are excellent substrates for cell attachment and migration. Numerous ex-

perimental studies have used collagen as a culture surface for *in vitro* maintenance of a wide variety of primary cell types (3,7–11). Cell attachment is usually mediated by integrins which recognize specific amino acid motifs of the molecule, such as the Arg-Gly-Asp (RGD) sequence. Attachment to this natural substrate and the associated transmembrane signalling events have been associated with improved cell metabolism, proliferation, and longevity, as well as maintenance of superior differentiated function. In particular, it has been demonstrated that embedding some highly differentiated cell types within a collagen gel allows the cells to maintain their differentiated phenotype, including high levels of metabolic function, for long durations in culture (12,13).

Collagen has long been recognized as a hemostatic agent, *i.e.*, a material which stimulates blood coagulation. As such, it has enjoyed a long history of use during surgical procedures as a tool to stop hemorrhaging from injured tissue. Blood clotting is stimulated by platelet binding to collagen via a number of receptors (14–16). This is quickly followed by platelet activation and degranulation events leading to the classical coagulation pathway. The provisional matrix laid down during the first stages of wound healing consists mainly of crosslinked fibrin clot. As healing progresses this initial matrix is replaced with a more complex system using collagen fibers as the main structural element. Given this natural progression it is possible that tissue repair processes could be accelerated by intervening to install an advanced collagen-based tissue scaffold. This fundamental idea led to the use of collagen as tissue repair material in the form of sutures and sponges and as a biocompatible coating on nondegradable implants such as vascular prostheses.

### C. Collagen Scaffolds

For tissue scaffold applications, collagen has been utilized in several forms, most notably, sponges, woven and nonwoven meshes, gels, decellularized tissue matrices, and porous composites. Porous collagen matrices have been prepared as both sponges and as woven and nonwoven (feltlike) fabric structures. These constructs have been applied both as classical tissue scaffolds for delivering cultured cells and generating new tissue *in vivo*, and as materials for physically repairing traumatized tissue (1,8,17–20). The porous structure provides a three-dimensional framework for developing a multilayered tissue from either a seeded single cell suspension or migrating cells from adjacent tissue, while simultaneously providing initial organization and mechanical integrity. Collagen gels have been utilized mainly as cell delivery and localization agents in cases where initial mechanical functionality is not a major

concern. Because of its thermally induced gelation characteristics, this collagen form has the added advantage of conforming to fill available tissue spaces. As a result, gels can be used to engineer space-filling connective tissue structures without the need for prefabricated scaffold shapes. The high water content and low density of a typical collagen gel also facilitates cellular migration and matrix remodeling and reorganization. This type of remodeling is mainly accomplished by invading (or seeded) fibroblasts and may be associated with extensive contraction of the gel, resulting in significant shape and volume alterations postimplantation.

While collagenous tissues tend to have high strength, the lack of long-range fibril organization in synthetic collagen constructs usually results in these materials (in particular, gel-based systems) having fairly low mechanical strength. However tensile strength can be augmented through chemical crosslinking. For example, glutaraldehyde has long been used to strengthen collagen-based materials used in surgery (21–28). In particular, the non-enzymatic crosslinking mechanism of glycation has been successfully used to strengthen cell-seeded, collagen-based scaffolds without compromising cell viability or function (29). Glycation is a complex crosslinking reaction which occurs mainly in collagen-rich tissues and is mediated by reducing sugars (4–6,30,31).

Decellularized tissue matrices are prepared by a combination of enzymatic and detergent treatments of collagen-rich tissues such as porcine heart valves or small intestinal submucosa (SIS). The treatment removes cellular material as well as most of the potentially antigenic noncollagenous proteins. The remaining material is composed mainly of collagen and elastin with some associated extracellular matrix polysaccharides. The mechanical properties and degradation kinetics of this material can be subsequently modified by chemical crosslinking with an agent such as glutaraldehyde. Constructs of SIS have been studied for the repair of heart valves, blood vessels, and intestinal tracts (23,32–37).

Collagen *in vivo* is often found in association with extracellular matrix polysaccharides, termed glycosaminoglycans (GAGs). This association is mediated by both electrostatic and covalent linkages and is most notable in basement membranes and cartilage. In fact soluble collagens are known to form ionic complexes with soluble GAGs under appropriate conditions. This interaction has been used to generate collagen–GAG composite materials as tissue scaffolds. Porous microstructures were generated by controlled freezing of the hydrated complexes followed by lyophilization (38–41). The constructs were then stabilized by chemical crosslinking. The resultant scaffolds have been successfully applied as skin repair/regeneration

aids and are being studied for cartilage repair and as conduits for nerve regeneration (18,42,43).

### III. POLYSACCHARIDES

#### A. General Overview

While polysaccharides have enjoyed popularity for certain specialty applications, they have generally been underutilized in the biomaterials field. Recognition of the potential utility of this class of materials is growing however, and the field of polysaccharide biomaterials is poised to experience rapid growth. Four factors have specifically contributed to this growing recognition of polysaccharide potential. First is the longstanding recognition that the oligosaccharide components of most glycoproteins are absolutely essential for normal function of these molecules. This has been coupled with a large and growing body of information pointing to the critical role of saccharide moieties in numerous cell-signaling schemes and in the area of immune modulation in particular. Second has been the realization that the so-called extracellular matrix polysaccharides play critical roles in modulating the activities of signaling molecules as well as mediating certain intercellular signaling directly. Third is the recent development of powerful new synthetic techniques with the potential for automated synthesis of biologically active oligosaccharides. These techniques may allow researchers to finally decode and exploit the “language” of oligosaccharide signaling. The fourth factor is the explosion in tissue engineering research and the associated need for new materials with specific, controllable biological activity and biodegradability.

Polysaccharides in general share a number of features which make them as a class particularly desirable starting materials for a number of biomaterials applications. The numerous hydroxyl groups present on the typical molecule, in addition to providing the means for the stereospecific biological activity, also provide numerous sites for the attachment of side groups. Such groups can provide specific functionality and biological recognition features, or may serve simply to modulate mechanical or biological properties of the parent molecule. Polysaccharides are also hydrophilic, and many have the potential to be processed as hydrogels of various densities as well as denser structures. This feature has made some members of the family highly sought after as drug delivery matrices and components of drug formulations. The charged members of the polysaccharide family possess additional features which may facilitate the development of useful materials. Such materials may be held together by ionic interactions. The ionic functional groups also play a significant role in some

of the more useful known biological activities involving charge-based binding of proteins ranging from growth factors to matrix proteins such as collagens.

With few exceptions, natural polysaccharides and their constituent monomers and degradation products can generally be considered to be either nontoxic or of low toxicity. Furthermore, while all polysaccharides can be considered biodegradable, mammals do not possess the enzymatic machinery to rapidly degrade many of the structural plant and marine varieties. However, most are susceptible to poorly understood, slow enzyme-mediated cleavage processes as well as free radical-based chain scission.

Polysaccharides can be classified into several groups in a number of different ways. This review will focus on polysaccharides of major significance in the biomaterials arena—in particular, marine polysaccharides of algal and animal origin and extracellular matrix polysaccharides of mammalian origin. It should be noted here that certain polysaccharides are synthesized by more than one type of organism, thus alginates are made by both algae and bacteria, and chitin/chitosan can be obtained from both arthropods and fungi.

Polysaccharides are polymers of five-carbon (pentose) or six-carbon (hexose) sugar molecules. As such, the term glycopolymers is often used to describe these substances. The polymers may be linear or branched depending on the polysaccharide, and linkage between subunits occurs via a condensation reaction between hydroxyl groups, resulting in the formation of an etherlike glycosidic bond.

Most nonsubstituted monosaccharides possess four or five hydroxyl groups capable of forming glycosidic linkages. Furthermore, each hydroxyl group can exhibit two optical isomeric configurations, leading to a large number of theoretically possible ways in which two different sugars can be linked to form a disaccharide. This feature, together with interactions mediated by charged substituent groups, leads to a range of chain configurations found in various polysaccharides. These configurations range from rigid rod conformation to flexible coil to random coil to globular. As expected, the chain configuration plays a major role in defining the physical properties of polysaccharide solutions, gels, and solids. The abundant hydroxyl groups in these molecules are capable of forming intermolecular hydrogen bonds and are the main contributor to both the solubility of many of these substances and their ability to form gels. It is the gel-forming capabilities that drew initial attention to this class of compounds for biotechnology applications. More recently, the cellular recognition features and the attendant biological activity have sparked renewed interest in their therapeutic and biomaterials potential.

Polysaccharide gel formation is generally of two types.

Hydrogen bonded gels are typical of molecules such as agarose and neutral chitosan, whereas ionically bonded gels are characteristic of alginates and carrageenans. The distinction is, however, limited since many charged polysaccharides will exhibit hydrogen bonded gel formation under neutralizing conditions.

The polar nature of the hydroxyl groups together with the presence of ionizable functional groups in some species means that polysaccharides are intrinsically hydrophilic and most are soluble in aqueous media. The exceptions to this rule tend to be species which form ordered structures with a high degree of crystallinity in the solid state. These exceptions include the crystalline polysaccharides chitin and cellulose. The conversion of these insoluble native forms to soluble derivatives generally involves the addition of charged or bulky side groups which disrupt the crystal structures and thus facilitate solvent penetration. Because of their high molecular weights, extended chain configurations, and the high degree of interchain hydrogen bonding potential, most polysaccharides form highly viscous solutions. This property ultimately limits the solution concentrations attainable in practice and also makes these molecules ideal for viscosity enhancement and gel formation.

The growing interest in polysaccharide-based drugs and biomaterials is partly fueled by the recognition that many biological recognition events at both the cellular and molecular levels are mediated or at least modulated by polysaccharide or oligosaccharide moieties. As a result, these molecular features and interactions form attractive targets for a variety of therapeutic interventions and also raise the possibility of developing polysaccharide biomaterials with a variety of useful biological activities. Within the tissue engineering paradigm there is a constant search for new materials which are biodegradable and which also possess targeted biological activity. In the sections which follow we describe the features and potential of some of the more promising polysaccharide biomaterials.

## B. Alginates

### 1. Chemical and Physical Properties

Alginic acids, or alginates, are isolated from several species of brown algae (e.g., *Macrocystis pyrifera*). Alginates are composed of two monomers,  $\alpha$ -L-guluronic acid (G) and  $\beta$ -D-mannuronic acid (M) (Fig. 1). The polymer is structured as a block copolymer with blocks of G and M alternating. Within the blocks, residues are linked by  $\alpha(1 \rightarrow 4)$  and  $\beta(1 \rightarrow 4)$  glycosidic bonds, respectively. In some regions single M and G units may alternate, giving rise to MG blocks. Within these MG blocks, the two bond types also alternate. Sizes of the three blocks can vary over a wide range, giving rise to alginates of different properties.

Figure 8.1 Alginate monosaccharide components.

Most notably, gels of alginate richer in the G blocks have a higher elastic modulus and also show higher solute diffusivities. These observations suggest a more open and more ordered polymer network for G-rich alginate gels. Average molecular weights range from 200 to 500 kDa.

Chain flexibility is a function of the block sizes and the relative quantities of the three block types. G blocks have the highest stiffness and MG blocks the lowest. Industrially, different alginates are often referred to by their M:G ratio. Thus, alginates with low M:G values (i.e., high G content) have chains which tend more toward the rigid rod conformation, while high M:G material tends to the flexible coil type conformation.

Within the biomaterials sphere, alginates have been extensively investigated for their gelation capabilities. The molecules have an extraordinarily high exclusion volume, which is evidenced by their high intrinsic viscosity. Alginates gel in the presence of divalent cations. The most widely used agents are calcium ions. Upon addition of  $\text{Ca}^{2+}$  to an alginate solution, the chains undergo rearrangement to form the so-called egg-box structures (Fig. 2), where groups of chain segments align with several intercalating  $\text{Ca}^{2+}$  ions. These structures are formed by the G blocks and serve to ionically crosslink the molecules in solution. As can be expected, the greater the G block con-

Figure 8.2 Alginate "egg box" structure.

tent of an alginate, the more crosslinks are formed and the stronger and stiffer the gel.

The excellent gellation ability has led to the use of alginates for entrapment of cells within gel beads. Cells so entrapped maintain viability and metabolic function and are capable of secreting a variety of protein products into the external medium. This scenario can be and has been used for the transplantation of cells for restoration of metabolic function. The strength of the techniques arises from the fact that xenogeneic entrapped cells can be protected from immune attack by controlling the density and permeability of the gel. Permeability parameters can be set to exclude immune cells and antibodies while allowing both nutrient access and the outward diffusion of smaller, desirable cell products. In an enhancement of the technique, the outermost layers of alginate in the beads are ionically crosslinked by reacting with a polycationic species such as poly-L-lysine (PLL) (44,45). The ionic complexes formed are stable over a wide range of pH and ionic strength conditions and are also calcium independent. This then allows the use of a calcium chelating agent such as EDTA or citrate to dissolve the inner gel regions of the bead, thus producing a hollow capsule enclosed in an ionic complex membrane. The complex formation provides an additional degree of freedom with regard to setting and controlling both the permeability and the strength of the capsule membrane. These capsules have been studied for use in a wide variety of cell transplantation and bioreactor design scenarios (44–46).

Alginates have been extensively researched for the encapsulation of pancreatic islet cells for controlled release of insulin to treat Type 1 diabetes. The research in this area has focused on modifying the properties of the semi-permeable membrane coating the alginate capsule in an effort to reduce pericapsular fibrosis and to control the diffusion rate of nutrients to the islets and insulin from the islets. This application of alginates has been extensively reviewed (46–48). Encapsulation is conducted by suspending the islets in a solution of sodium alginate which is sprayed into a container of calcium chloride solution using a droplet-forming device. The droplets are then surface reacted with a poly-L-lysine solution to form a semi-permeable complex membrane, after which the internal gel is dissolved by treatment with a calcium chelating solution. The alginate–PLL membrane allows small molecules such as insulin and glucose to pass into and out of the capsule, but presents a barrier to immune cells and large molecules such as immunoglobulins.

The mechanical properties of calcium alginate gels vary greatly with the composition of the alginate. The highest mechanical strengths are achieved using alginate with a G content higher than 70% and an average G block length of

approximately 15 residues. For alginate molecular weights above some critical value, the mechanical strength of gels is determined mainly by chemical compositions and block structure and is independent of molecular weight. For low molecular weight alginates, however, molecular weight is still a major determinant of gel strength. The critical molecular weight depends on the concentration of alginate (48).

## 2. Drug Delivery Potential and Bioactivity

The ability to control alginate gel permeability means that these materials have significant potential for controlled release applications. Ionically crosslinked alginate gels have been used to incorporate a variety of proteins for controlled release. These have included TGF- $\beta_1$ , the TNF receptor, and angiogenic molecules such as EGF and bFGF. Because alginate is an anionic polymer at physiological conditions (pH 7.4), proteins with a net positive charge can ionically bond to the polymer and thus exhibit reduced bioactivity upon incorporation into an alginate delivery system. TGF- $\beta_1$ , with a pI of 9.8, is one such example (49). The porosity of alginate gels can be controlled by varying alginate concentration, M:G ratio, and calcium concentration. In this way the release kinetics of entrapped solutes can be controlled (50–53).

In general, alginates exhibit minimal intrinsic biological activity and therefore are employed mainly as inert matrices for delivery of cells or therapeutic agents. However, as with most polysaccharides, the hydroxyl and carboxyl groups provide attractive derivatization sites through which specific bioactive groups can be immobilized. Thus, bioactive peptides such as the fibronectin-derived adhesion sequence RGD have been covalently attached to alginate gels to provide cell adhesion properties (54).

## 3. Immunology and the Tissue Response

The biocompatibility of alginate materials is also dependent on the composition of the alginates. In vivo studies with empty alginate–PLL capsules have shown that the cellular overgrowth on capsules implanted intraperitoneally was composed of fibroblasts in cases of alginate with intermediate G content. But the overgrowth was mainly composed of macrophages when high-G alginate was used. There was no evidence of other immune cell elements such as B or T lymphocytes (55,56). In other studies, purified alginates with a high M content (68%) showed no fibrotic reaction after 3 weeks of implantation (57).

One of the issues facing the use of alginates and other polysaccharide biomaterials in vivo is the presence of impurities in commercial alginate preparations. These impurities may include contaminating algal or bacterial pro-

teins, endotoxin, and other trace polysaccharides. It is quite possible that the biocompatibility difference between high and low guluronate alginates may in fact be partly due to different affinities for the contaminants exhibited by M and G blocks. Such contaminants have been implicated in the severity of the tissue response to alginate implants, fibrotic overgrowth, and general failure of the transplanted cells within the implant. It has been suggested that some of the contaminants are mitogenic in nature and may be directly responsible for fibrotic tissue overgrowth (58). Alternatively, an inflammatory response to contaminating elements would result in the local release of endogenous mitogens, again leading to cellular overgrowth of the implants. These issues have been addressed by the introduction of purification strategies involving the separation of alginates from more soluble contaminants using multistep precipitation and extraction procedures (56,59). The purified material was shown to elicit a minimal fibrotic response in vivo.

### C. Chitosan

#### 1. Chemical and Physical Properties

Chitosans are partially or fully deacetylated derivatives of chitin, the primary structural polymer in arthropod exoskeletons. From the biomaterials standpoint, chitosans are the most promising polysaccharides, with great potential for development of resorbable, biologically active, implant materials (60,61). The primary source for chitin/chitosan is shells from crab, shrimp, and lobster. Shells are ground, demineralized with HCl, deproteinized with a protease or dilute NaOH, and then deacetylated with concentrated NaOH. Structurally, chitosans are very similar to cellulose. The polymer is linear, consisting of  $\beta(1 \rightarrow 4)$  linked D-glucosamine residues with a variable number of randomly located N-acetyl-glucosamine groups (Fig. 3). In essence, chitosan is cellulose with the 2-hydroxyl group replaced by an amino or acetylated amino group. Depending on the source and preparation procedure, molecular weight may range from 50 to 1000 kDa. Commercially available preparations have degrees of deacetylation ranging from 70 to 90%. As an additional method of property control, chitosan

**Figure 8.3** Structure of chitosan. One acetylated residue is shown linked to a deacetylated residue.

can be stoichiometrically depolymerized by reacting in solution with nitrous acid (62).

Chitosan is a crystalline polysaccharide and the degree of crystallinity is a function of the degree of deacetylation. Crystallinity is maximum for both chitin (i.e., 0% deacetylated) and 100% deacetylated chitosan. Minimum crystallinity is achieved at intermediate degrees of deacetylation. Because of the stable, crystalline structure, chitosan is normally insoluble in aqueous solutions above pH 7. However, in dilute acids, the free amino groups are protonated and the molecule becomes fully soluble below  $\sim$ pH 5. The high charge density causes the linear chitosan chain to extend into a semirigid rod conformation. Upon raising the pH, amino groups are increasingly deprotonated and become available for hydrogen bonding. At some critical pH, the molecules in solution develop enough hydrogen bonds to establish a gel network. The pH at which this transition occurs is dependent upon both the degree of deacetylation and the average molecular weight. For a typical 86% deacetylated commercial chitosan with an average molecular weight of 300 kDa, gellation occurs at about pH 6. As the pH is raised further, deprotonation continues and the molecules establish additional hydrogen bonds, ultimately rearranging to establish miniature crystalline domains. This effect results in an increase in gel stiffness and can be associated with minor gel contraction. Chitosan's pH-dependent solubility provides a convenient mechanism for processing under mild conditions. Viscous solutions can be extruded and gelled in high-pH solutions or baths of nonsolvents such as methanol. Such gel fibers can be subsequently drawn and dried to form high strength fibers. The polymer has been extensively studied for industrial applications based on film and fiber formation, and the preparation and mechanical properties of these forms have been reviewed previously (63,64). Woven and nonwoven fiber-based structures and materials have potential for applications as implantable biomaterials and have been investigated to a limited extent (65).

#### 2. Interactions with Biomolecules and Cells

Much of chitosan's biomaterial potential stems from its cationic nature and high charge density in solution. The charge density allows chitosan to form insoluble ionic complexes with a wide variety of water-soluble anionic polymers. Complex formation has been documented with anionic polysaccharides such as heparin and alginates, as well as synthetic polyanions like poly(acrylic acid) (66–69). Because the chitosan charge density is pH dependent, transfer of these complexes to physiological pH results in dissociation of a portion of the immobilized polyanion. This property can be used as a technique for local delivery

of biologically active polyanions such as heparin and other glycosaminoglycans or even DNA. Heparin release from ionic complexes may enhance the effectiveness of growth factors released by inflammatory cells in the vicinity of an implant (70). In the case of DNA, complexation with chitosan has been shown to protect plasmids from degradation by nucleases and also facilitates cellular transfection by poorly understood interactions with cell membranes (71–73). Chitosan's positive charge also mediates nonspecific binding interactions with a variety of proteins. Since the majority of soluble proteins carry a negative charge at physiological pH, many of these molecules can be expected to bind with varying affinities to chitosan-based materials. The N-acetyl-glucosamine moiety in chitosan is also a structural feature found in the extracellular matrix polysaccharides termed glycosaminoglycans. These molecules are discussed later, but their properties include many specific interactions with growth factor receptors and adhesion proteins. This suggests that the analogous structure in chitosan may also have related bioactivity. In fact, chitosan oligosaccharides have been shown to have a stimulatory effect on macrophages, and the effect has been linked to the acetylated residues (74). Furthermore, both chitosan and its parent molecule chitin have been shown to exert chemoattractive effects on neutrophils *in vitro* and *in vivo* (75–78).

Chitosan is hydrolyzed enzymatically *in vivo*. The primary agent is lysozyme, which appears to target acetylated residues (79). The degradation products are chitosan oligosaccharides of variable length. The degradation kinetics appear to be inversely related to the degree of crystallinity. Crystallinity in the chitin–chitosan family of materials exhibits a minimum at intermediate levels of deacetylation, with chitin and fully deacetylated chitosan showing the highest levels of crystallinity. In fact, the low degradation rate of highly deacetylated chitosan implants (several months *in vivo*) is believed to be due to the inability of hydrolytic enzymes to penetrate the crystalline microstructure. This issue has been addressed by derivatizing the molecule with side chains of various types (80–84). Such treatments alter molecular chain packing and increase the amorphous fraction, thus allowing more rapid degradation. They also inherently affect both the mechanical and solubility properties.

Chitosan has been widely studied for applications in systems for the controlled release of various drugs and therapeutic agents. These applications have been extensively reviewed by others (49,64,85).

### 3. Immunology and the Tissue Response

A number of researchers have examined the tissue response to a variety of chitosan-based implants (60,61,69,

83,84,86–95). In general, these materials have been found to evoke a minimal foreign body reaction. In most cases, no major fibrous encapsulation developed. Formation of normal granulation tissue, often with accelerated angiogenesis, appears to be the typical course of healing. In the short term (<10 days), significant accumulation of neutrophils in the vicinity of the implants is often seen, but this dissipates rapidly and a chronic inflammatory response does not develop. The stimulatory effects of chitosan and chitosan fragments on immune cells mentioned, may play a role in inducing local cell proliferation and ultimately integration of the implanted material with the host tissue.

In the area of blood interactions, chitosan has been shown to have a strong hemostatic capacity. Blood coagulation occurs rapidly even under conditions of heparin anticoagulation. The process involves fibrin-independent aggregation of erythrocytes and appears to involve direct chitosan interactions with erythrocyte membranes (96–98). This type of reaction can be abrogated by acylating the free amino groups (81,99). In contrast, water-soluble, sulfated chitosan derivatives have been shown to have anticoagulant activity even higher than that of heparin (100–103).

As was discussed for alginates, contaminants within a chitosan preparation can dictate the nature of the tissue response, and an otherwise biocompatible material may exhibit adverse bioactivity in terms of a severe and possibly chronic inflammatory response accompanied by excessive fibrosis. The typical problem impurities are residual tissue proteins from the source organism and bacterial cell wall components. Thus care must be taken to ensure that chitosan for implant use is of a highly purified medical grade. Alternatively, the general purification methods used for alginates may be modified for application to chitosan. Chitosans also have the added feature of precipitating as gels with a relatively small change in pH. This characteristic can be used as an additional method of separating the polymer from more soluble contaminants. It should be noted that the highly deacetylated (>86%) chitosan forms are less likely to contain peptide contaminants since few peptides could withstand the harsh processing conditions needed to attain high degrees of deacetylation.

### 4. Formation of Tissue Scaffolds

One of chitosan's most promising features is its excellent ability to be processed into porous structures for use in cell transplantation and tissue regeneration. The tissue engineering approach to the repair and regeneration of damaged or diseased tissues relies on the use of polymer scaffolds which serve to support and organize the regenerating tissue (104–106). There is a continuous ongoing search for materials which either possess particularly desirable tissue-

specific properties or which may have broad applicability and can be tailored to several tissue systems. Chitosan may be one such broadly applicable material. Porous chitosan structures can be formed by freezing and lyophilizing chitosan solutions in suitable molds (107). During the freezing process, ice crystals nucleate from solution and grow along the lines of thermal gradients. Exclusion of the chitosan salt from the ice crystal phase and subsequent ice removal by lyophilization generates a porous material whose mean pore size can be controlled by varying the freezing rate. Figure 4 illustrates tissue scaffold pore morphologies which can be produced by this simple technique. Pore orientation can be directed by controlling the geometry of

**Figure 8.4** Porous chitosan tissue scaffolds produced by controlled rate freezing and lyophilization of chitosan solutions.

the temperature gradients during freezing. The structures resulting from lyophilization of chitosan solutions are actually composed of the chitosan salt, for example, chitosan acetate if an acetic acid solution was used. The acid component must be neutralized or otherwise removed prior to rehydrating the scaffold. This can be accomplished by direct neutralization and rehydration in a basic solution such as dilute ammonia or NaOH.

The mechanical properties of chitosan scaffolds formed in this way are mainly dependent on the pore sizes and pore orientations. Tensile testing of hydrated samples shows that porous membranes have greatly reduced elastic moduli (0.1–0.5 MPa) compared to nonporous chitosan membranes (5–7 MPa). The extensibility (maximum strain) of porous membranes varied from values similar to nonporous chitosan (~30%) to greater than 100% as a function of both pore size and orientation. The highest extensibility was obtained with a random pore orientation structure frozen rapidly at  $-78^{\circ}\text{C}$  to give pores 120  $\mu\text{m}$  in diameter. Porous membranes exhibited a stress–strain curve typical of composite materials with two distinct linear regions: a low modulus region at low strains and a transition to an approximately twofold higher modulus at high strains (Fig. 5). For all pore orientations, membranes formed at lower freezing rates exhibited higher moduli in both curve regions. The differences were most notable for samples with a random pore orientation. This suggests that in addition to larger pores, the lower freezing rate produces a more crystalline (and hence stiffer) chitosan phase. The tensile strengths of these porous structures were in the range 30–60 kPa.

**Figure 8.5** Tensile stress–strain plot for a porous chitosan membrane.

#### 4. Modified Chitosans

Several chitosan derivatives have already been mentioned. Generally speaking, derivatization provides a powerful technique for generating new biological activities and for controlling chitosan's fundamental materials properties. The primary amino groups on the molecule are reactive and provide a means for side group attachment using very mild conditions. The general effect of side chain addition is to disrupt the material's crystal structure and hence increase the amorphous fraction. This modification generates a material with lower stiffness and often greater solubility. The precise nature of chemical and biological property changes will of course depend on the form of the side group. Thus, N-alkyl derivatives can exhibit reduced solubility and micellar aggregation in solution for alkyl lengths greater than five carbons. The character of chitosan as cationic, hemostatic, and insoluble at high pH can be completely reversed by sulfation, which, as described, can render the molecule anionic, anticoagulant, and water soluble. The variety of groups which can be attached to chitosan is almost unlimited, and side groups can be chosen to provide specific chemical functionality, alter biological properties, or modify physical properties. As an example, simply grafting on randomly distributed polyethylene glycol (PEG) side chains to the chitosan molecule reduces the elastic modulus of cast chitosan membranes in direct proportion to the PEG content (Fig. 6). Since PEG is a neutral, water-soluble, inert polymer with a large excluded volume, the grafted side chains serve to mask the chitosan surface in addition to reducing membrane stiffness. This masking

**Figure 8.6** Effect of grafted polyethylene glycol side chains on the elastic modulus of dense chitosan membranes. Increasing PEG levels decreases membrane crystallinity, resulting in a reduction in elastic modulus. Membranes were tested in a hydrated state.

effect has been shown to reduce the spreading and proliferation of endothelial and smooth muscle cells seeded onto PEG chitosan membranes as compared to unmodified chitosan membranes.

#### E. Glycosaminoglycans

##### 1. General

Glycosaminoglycans are polysaccharides which occur ubiquitously within the extracellular matrix (ECM) of most animals. They are unbranched heteropolysaccharides, consisting of repeated disaccharide units, with the general structure [uronic acid–amino sugar]<sub>n</sub>. In their native form, several GAG chains are covalently linked to a central protein core, and the protein–polysaccharide complex is termed a proteoglycan. Proteoglycans play a major role in organizing and determining the properties and functionality of the ECM, and the GAGs are the major factor in determining proteoglycan properties.

There are six different types of glycosaminoglycans: chondroitin sulfates, dermatan sulfate, keratan sulfate, heparan sulfate, heparin, and hyaluronic acid. Table 1 lists the component monosaccharides, primary source tissues, and molecular features of the commonly occurring GAGs. The monosaccharides in GAGs are sulfated to varying degrees, with the exception of hyaluronic acid, which is not sulfated. Unlike the other GAGs, hyaluronate exists as a free, high molecular weight molecule with no covalently attached protein. Figure 7 illustrates the repeating structures of hyaluronate and chondroitin-6-sulfate and a disaccharide segment of the variable heparin structure.

The GAGs are usually obtained as salts of sodium, potassium, or ammonia, and in this form they are all water soluble. The presence of strongly ionizing sulfate groups means that the charge density of these molecules is much less pH dependent than in the case of chitosan, and as a result these molecules are soluble over a wide pH range. The disaccharide repeat structure and the resultant alternating glycosidic bond types (analogous to the MG blocks of alginate) prevent this family of materials from forming high strength, crystalline structures in the solid state, and the dried or precipitated GAGs are essentially amorphous. The three-dimensional configurations which do form in solution tend to be flexible coil structures, extended as a result of the charge effects. Heparin for example is known to form single chain helical structures in solution. The only GAG with significant gel-forming ability is hyaluronate. This high molecular weight molecule is the primary gelling agent in the vitreous humor of the eye and can form very high viscosity solutions at concentrations as low as 0.3 wt%.

The biomaterials potential of the GAGs stems not from their intrinsic physical properties but from their biological

**Table 8.1** Glycosaminoglycan Sources and Molecular Properties

Glycosaminoglycan	Source tissues	Molecular weight (kDa)	Charges per disaccharide	Component monosaccharides
Hyaluronate	Vitreous humor, cartilage	250–8000	1.0	N-acetyl-D-glucosamine D-glucuronic acid
Chondroitin 4-sulfate	Cartilage, cornea, skin, artery	5–50	1.1–2.0	N-acetyl-D-galactosamine D-glucuronic acid
Chondroitin 6-sulfate	Cartilage, cornea, skin, artery	5–50	1.2–2.3	N-acetyl-D-galactosamine D-glucuronic acid
Dermatan sulfate	Skin, heart valve, tendon, artery	15–40	2.0–2.2	N-acetyl-D-galactosamine L-iduronic acid D-glucuronic acid
Keratan sulfate	Cartilage, cornea, vertebral disks	2.5–20	0.9–1.8	N-acetyl-D-glucosamine D-galactose
Heparan sulfate	Lung, artery, cell surfaces	5–50	1.1–2.8	D-glucosamine N-acetylglucosamine L-iduronic acid D-glucuronic acid
Heparin	Mast cells in: lung, liver, skin, intestinal mucosa	5–25	3–5	D-glucosamine L-iduronic acid D-glucuronic acid

**Figure 8.7** Repeating structures of representative glycosaminoglycans.

activity, which is a direct result of their numerous interactions with many important biomolecules. The biological activities described subsequently can be exploited by binding, complexing, or covalently linking GAG moieties to other polymers with superior structural or mechanical characteristics. Suitable polymers may include ECM proteins such as collagen, polysaccharides like chitosan, or a variety of synthetic polymers. Formation of composites of this type can endow the structural polymer with desirable tissue interaction properties and drastically improve its overall biocompatibility. Some of the better known GAG biological activities are described herein.

## 2. Interactions with Enzymes

These are the most extensively characterized of all GAG–protein interactions. In particular, the anticoagulant activity of heparin, via the activation of the protease inhibitor antithrombin III (ATIII), has been thoroughly characterized (108,109). Antithrombin III inactivates several proteases in the coagulation cascade, the most important of which is thrombin. Binding of heparin to ATIII increases the inactivation kinetics by as much as 2000-fold. Binding and activation of ATIII involves highly specific recognition of a pentasaccharide sequence found in both heparin and heparan sulfate. Heparin and heparan sulfate are also known to bind and activate the enzyme lipoprotein lipase (110–112). This property facilitates hydrolysis of triglyc-

erides in lipoprotein particles in peripheral tissues. The fatty acids so formed are then available for uptake by adjacent cells. Lipoprotein lipase is normally found bound to heparan sulfate on endothelial cell surfaces where it is active. The soluble enzyme is inactive in the absence of GAG. This property has been used to reduce the levels of circulating lipoprotein by activating inactive lipase via injections of soluble GAG.

### 3. Interactions with Polypeptide Growth Factors

A wide variety of polypeptide growth factors bind avidly to heparin and heparan sulfate. Lower affinity binding also occurs with some other GAGs. Members of the fibroblast growth factor (FGF) family have been most extensively studied, but heparin/GAG affinity has been demonstrated with EGF, VEGF, a variety of interleukins (e.g., IL-3), as well as hematopoietic factors such as GM-CSF (113–122). Glycosaminoglycan binding can have a variety of effects on growth factors depending on the ratios of the two molecular species and the binding environment. Growth factors can be bound and sequestered in the extracellular matrix by GAGs. In the bound state, the polypeptides are often protected from proteolytic attack, and can be subsequently released from the ECM under the action of GAG lyases, matrix metalloproteinases, or changes in ionic strength. Growth factor binding to GAGs can also induce conformational changes which enhance receptor-growth factor binding. The GAGs may also enhance growth factor activity indirectly by mediating the clustering of growth factors or receptor–ligand complexes on the cell surface.

### 4. Interactions with Extracellular Matrix Proteins

Most ECM proteins have at least one GAG binding domain and many have several. These polypeptides bind heparin and heparan sulfate with the highest affinities, but binding of other GAGs is also known. The GAG–protein interaction may serve to facilitate the aggregation and organization of matrix proteins into ordered structures such as fibrils. Alternatively, the interaction may inhibit matrix protein organization. As an example, soluble GAG interactions can inhibit the assembly of Type I collagen fibrils from a collagen solution at physiological pH, while ionic GAG–collagen complexes are precipitated under acidic conditions. Binding of heparan sulfate to fibronectin may affect the conformation of the protein and thereby regulate its function. Furthermore, the binding of fibronectin to collagen *in vitro* is stabilized by the presence of heparin. Similarly, the apparent affinity of fibronectin for its cell surface receptors on rat hepatocytes and peritoneal macrophages is increased in the presence of heparan sulfate (123).

### 5. The Tissue Response to GAG-Containing Biomaterials

Because of their tissue origins, the GAGs are intrinsically biocompatible. Furthermore, because of their biological activity, interest in GAGs as components of implantable materials has been growing, particularly in recent years. Attention has focused mainly on heparin and hyaluronate. Heparin is being examined as the GAG of choice for tissue regeneration and wound healing applications primarily for two reasons. First, compared to other GAGs, it generally exhibits the highest level of biological activity with the broadest set of biological systems (124). Second, it is readily available at fairly low cost, in contrast to its less sulfated counterpart heparan sulfate. For wound healing and regeneration applications, heparin is generally complexed with or covalently linked to another biopolymer which serves as the main structural component. Both chitosan (70,94) and collagen (18,42) have been used for this purpose. Under these circumstances, the heparin can exert a number of influences dictated by the biological activities described previously. Thus growth factors released in the vicinity of the implant by neutrophils and macrophages may be sequestered and stabilized within the implant structure by immobilized heparin and subsequently released and utilized by ingrowing tissue cells. The bound heparin may also facilitate the binding and organization of deposited ECM components to the implant and consequently enhance the integration of the implant with neotissue and existing tissue. Alternatively, heparin released from an implant may activate and protect growth factors from degradation in the vicinity of the implant, a phenomenon which may lead to accelerated healing and/or enhanced angiogenesis. The typical outcome of these implantation studies is formation of new tissue in and around the implant which is histologically and functionally intermediate between normal tissue and scar. Although heparin has garnered the most interest for tissue repair, the other sulfated GAGs have also been applied with similar goals (69). In particular, crosslinked collagen–chondroitin sulfate complexes have demonstrated superior healing and regeneration in skin and nerve applications (18,42).

In contrast to heparin, hyaluronic acid is usually employed as a structural component in its own right because of its high molecular weight and gel-forming ability. The properties of the molecule may be broadly altered by chemical modification. For example, partial esterification of the carboxyl groups reduces the water solubility of the polymer and increases its viscosity. Extensive esterification generates materials that form water-insoluble films or swellable hydrogels (125). One of hyaluronate's main roles in tissue is as an organizer of the ECM. It appears

to be particularly important during development of embryonic tissues. In addition, its importance in wound healing is emphasized by its transient elevation during the granulation phase (126). Ethyl- and benzyl-esterified hyaluronate membranes have demonstrated excellent healing responses and biodegradability *in vivo*. The fully esterified membranes had *in vivo* lifetimes of several months, whereas the partially esterified forms degraded within a few weeks. This type of degradation behavior has also been seen *in vitro* (127). The esterified hyaluronate derivatives undergo spontaneous de-esterification in aqueous environments. However, the hyaluronate backbone is very stable under the same conditions. As with all GAGs, degradation of the backbone occurs mainly by enzymatic depolymerization.

Hyaluronate-based materials may range from high viscosity solutions to low density hydrogels to high density hydrogels to dense but swellable hydrophilic polymers. The precise properties depend on the degree of esterification. Esters have been extruded into fibers and woven into fabrics for wound dressing applications. Dehydrated membranes and fibers may resemble similar structures made from synthetic polymers. They exhibit good mechanical and physical properties compared to other biological materials such as collagen. However, because the polysaccharide backbone retains its hydrophilic nature even at 100% esterification, these materials do exhibit some water absorption, swelling, and associated reductions in the mechanical properties.

#### IV. POLY( $\alpha$ -HYDROXY ACIDS)

Currently, the poly( $\alpha$ -hydroxy acids), specifically poly(lactic acid) (PLA), poly(glycolic acid) PGA (Fig. 8), and copolymers of the two are the most widely used synthetic polymers in the tissue engineering arena. These polymers have gained popularity because they offer the typical synthetic polymer advantages of high purity, convenient processing, and good mechanical properties, in addition to their biodegradability. Furthermore, since these materials have been used for over 25 years as resorbable sutures and fixation devices, they are already approved for *in vivo* hu-

**Figure 8.8** Repeating structures of the two most commonly used poly( $\alpha$ -hydroxy acids).

man use in several forms and formulations. Polymerization can be induced either by direct condensation reactions between the acidic monomers or by catalytic ring-opening polymerization reactions of cyclic precursors.

Degradation of these polymers occurs by passive hydrolysis, with the monomeric acids as the final metabolizable products. The degradation rates are functions of polymer molecular weight, degree of crystallinity, and surface-to-volume ratio. Poly(glycolic acid) is generally available in a highly crystalline form. As such it possesses a high melting point ( $\sim 300^\circ\text{C}$ ) and overall low solubility in organic solvents. However, its hydrophilic nature allows rapid absorption of water leading to rapid degradation within a few weeks. In contrast, poly(lactic acid) is available as fully crystalline or fully amorphous forms depending on the relative levels of the D and L optical isomers of lactic acid present in the molecule. Thus poly(D-lactide) and poly(L-lactide) are both highly crystalline, whereas the racemic copolymer poly(D,L-lactide) is completely amorphous. The presence of a methyl group makes PLA more hydrophobic than PGA, resulting in lower water absorption rates and correspondingly slower degradation, on the order of months. In both PLA and PGA, hydrolysis is accelerated by a reduction in pH. Thus, accumulation of acidic degradation products in the vicinity of the implant can have an autocatalytic effect, increasing the degradation rate. The effect is more pronounced in thicker samples since the outward diffusion of low molecular weight products is slower, leading to a drop in pH within the material and enhanced hydrolysis.

Neither PGA nor PLA possess intrinsic bioactivity. Cellular responses to implants of these polymers are mediated mostly by surface adsorbed proteins, surface topography, and the pH effects of degradation products. It is noteworthy that there is an effect of crystallinity on cell adhesion to these materials (128). The effects are believed to be a result of differences in protein conformation stemming from variations in binding to amorphous versus crystalline polymer surfaces. The chirality of crystalline regions may also play a role in controlling cellular response, but the detailed mechanisms of these effects are not fully understood.

Given the stability of these synthetic polymers, they are amenable to a wide variety of processing procedures for fabricating tissue scaffolds. They can be melt-spun into fibers which can be subsequently assembled into woven or nonwoven (i.e., felted) fabrics (129). Thin films can be directly cast from polymer melts or solutions in volatile organic solvents. Bulk porous scaffolds can be prepared using the porogen leaching procedure (130–132).

In this method, water-soluble porogen particles (e.g., sodium chloride crystals) are blended into a viscous poly-

mer solution in a volatile organic solvent. The solution is then cast as a slab, and after evaporation of the solvent the slab is soaked in an aqueous solution to dissolve and leach out the porogen. Removal of the porogen leaves behind a porous matrix suitable for cellular ingrowth. Control of pore size and connectivity can be achieved by varying the porogen particle size and volume fraction, respectively.

An alternative fabrication procedure uses supercritical carbon dioxide as a foaming agent (133). In this approach, a nonporous slab of polymer is equilibrated with supercritical carbon dioxide under conditions of elevated temperature and pressure. Subsequent release of the pressure induces nucleation and expansion of gas bubbles within the polymer matrix, resulting in a closed cell polymer foam being formed. An open cellular architecture can be generated if the salt leaching method is combined with the gas foaming method.

More recently, freezing of polymer solutions followed by solvent removal under vacuum has been employed to generate macroporous scaffolds with a defined nanoscale fibrous architecture (134). This advance may represent a potentially useful technique for influencing cell behavior on these materials without altering the material chemistry or incorporating extrinsic biologically active molecules.

## V. PSEUDOPOLY(AMINO ACIDS)

In this recently developed family of polymers, amino acid derivatives are assembled into polymers using either non-amide linkages for homopolymers or a combination of amide and nonamide bonds for heteropolymers. Unlike the previously developed poly(amino acids), which are in essence synthetic proteins, these materials can be generated as dimensionally stable thermoplastics. The most promising family of these materials examined to date are the tyrosine-based polymers. Desaminotyrosine is esterified with a tyrosine ester to form a diphenolic compound with an internal amide bond. This diphenol can be subsequently polymerized by linking the phenolic groups through a variety of chemistries (Fig. 9). Linkage of phenols via a carbonate group gives a tyrosine-derived polycarbonate such as poly(DTH carbonate) (135–140). Alternatively, a dicarboxylic acid may be used as the linking agent to give copolymers consisting of an alternating sequence of a diphenol and a diacid. By varying the length of the dicarboxylic acid and the type of tyrosine ester used to form the diphenol, a combinatorial library of related polymers was produced with physical and associated biological properties spanning a broad range (141). The chemical properties of the tyrosine-derived monomers impart thermoplastic behavior and water insolubility to this family of materials. In contrast to the poly(amino acids), the pseudopoly(amino

**Figure 8.9** Tyrosine derivatives and the repeating structure of the polycarbonate-type pseudopoly(amino acid) resulting from polymerization of their diphenolic dimer.

acids) are thermally stable and can be processed using standard synthetic polymer techniques. They exhibit particularly high strength and stiffness and have been considered for use as bone substitutes and fixation devices (142). In animal studies, poly(DTH carbonate) scaffolds have exhibited good integration with regenerating bone without triggering a fibrous encapsulation response (142,143).

## VI. POLYETHYLENE GLYCOL

Polyethylene glycol, also known as polyethylene oxide, is a petroleum-derived synthetic polymer that has garnered much attention in recent years. It is a linear polymer with the structure  $\text{HO}-(\text{CH}_2\text{CH}_2\text{O})_n-\text{OH}$ . The presence of the backbone oxygen makes the molecule water soluble, and its high hydration volume and molecular mobility in solution cause it to exhibit negligible binding interactions with proteins. Thus, PEG-modified surfaces have been shown to resist protein adsorption and cellular attachment (144–147). The molecule is nontoxic and nondegradable under physiological conditions. Polyethylene glycol possesses no biological activity and in soluble form it is rapidly excreted by the kidneys without undergoing any transformation or chemical modifications. The terminal hydroxyl groups have low reactivity but can be activated under rigorous conditions. Thus they can be used as attachment sites for a variety of other more reactive or polymerizable groups. It is the end-modified PEG derivatives which have shown promise as tissue scaffolds. Derivatives such as PEG–diacrylate can be crosslinked under mild photoinitiated polymerization conditions to form crosslinked hydrogels which

are nondegradable and completely inert. The mildness of the crosslinking procedures allows cells to be entrapped within these gels without toxic side effects. The power of this method stems from the fact that these inert hydrogels can be designed to incorporate cell adhesion factors such as the RGD peptide as well as other bioactive agents. This then allows the researcher complete and independent control over the physical gel properties as well as the biological properties. For example, biodegradable PLA oligomers or peptide sequences have been incorporated into PEG hydrogels to allow them to degrade or to allow cell migration through the gel structure (148–155). Apart from its direct use as a scaffolding material, PEG has also been used to modify a variety of biosurfaces. Its ability to resist protein binding led to its use as a modification for prolonging the lifetime of various peptide drugs in blood. Polyethylene glycol has also been examined as a nonfouling, covalently grafted surface layer on various medical materials (145). Such layers can improve the blood compatibility of procoagulant surfaces by preventing the adsorption and denaturation of plasma proteins. This type of modification also reduces or inhibits cell adhesion and migration on the modified surfaces and in principle can be used to modulate the level of interaction between tissue and implant materials.

# Chitosan: Structure–Properties Relationship and Biomedical Applications

Alain Domard and Monique Domard

*University Claude Bernard Lyon I, Villeurbanne, France*

## I. INTRODUCTION

### A. Definition of Chitosan

Chitosan is a naturally occurring polysaccharide whose commercial forms are essentially produced from N-deacetylation of chitin. Chitin and chitosan can be represented by a unique structure, shown in Fig. 1. This structure corresponds to the series of the copolymers of  $\beta$  (1  $\rightarrow$  4) linked glucosamine, and N-acetyl-glucosamine. They can be considered as belonging to the family of glycosaminoglycans (GAGs), a family to which also belong chondroitin sulfates, hyaluronic acid, and heparine. Glycosaminoglycans are particularly interesting since they seem to be alone among the polysaccharides that express the property of bioactivity.

The difference between chitin and chitosan is essentially related to the possibility to solubilize the polymer in dilute acidic media. Thus, when the structure can be dissolved in this kind of solvent, it corresponds to chitosan; in the reverse case, to chitin. Therefore the degree of acetylation (DA), which is related to the balance between the two kinds of residues, is essential to define these two terms. When chitin is deacetylated in heterogeneous conditions, the solubility in water is only achieved for DA generally below 30% (1). Nevertheless, on reacetylating chitosan in homogeneous conditions, it is possible to observe a solubilization up to DA close to 60% (2,3). As a consequence, the frontier between chitin/chitosan can be located at a DA

of 60%. As we shall see, DA is also an interesting adaptable parameter whose simple modification allows us to provide this series of copolymers with a very great variety of properties. In numerous circumstances, this opportunity gives the advantage of avoiding some difficult and expensive chemical modifications.

### B. Origin

The production of chitin in biomass has been evaluated to be as abundant as that of cellulose, with a yearly production within  $10^{10}$ – $10^{12}$  T (4,5). This polymer is present in most of the families of living species (5). Thus, it constitutes the structure polymer of the cuticles of all the arthropods and the endoskeletons of all the cephalopods. It is also very often present at the cell wall and in the extracellular matrix of most fungi. It is encountered in numerous microorganisms, in some algae, etc. Chitosan is much less present in living media and to date it has only been observed in some microorganisms, particularly of fungal nature (6). This lack of occurrence explains why the latter polymer, whose direct applications are much more important than that of the former, is essentially produced from chitin. It is noteworthy that both chitin and chitosan in their polymeric form are completely absent in numerous animals including mammals. Nevertheless, the N-acetyl-glucosamine unit is largely widespread in the chemical structure of the other GAGs and the glycoconjugates such as glycoproteins and glycolipids (7). On the other hand,

Figure 9.1 Chemical structure of chitin and chitosan.

the nearly total absence of chitosan in living media must be regarded as an interesting opportunity for numerous possible applications, especially if we consider that it corresponds to a more or less charged polycation, a chemical structure totally absent in nature.

A brief summary of the origin of chitin and chitosan from a historical point of view is also interesting. Chitin was discovered in 1811 by H. Braconnot during his studies on mushrooms and was termed *fungine* (8). This discovery occurred approximately 30 years before that of cellulose. The term *chitin* was first proposed by C. Odier in 1823 (9), who ignored the works of Braconnot and found chitin in the elytrum of the cockchafer beetle. In 1859, C. Rouget discovered chitosan after he treated chitin in hot and concentrated KOH. He logically proposed to name this new product “modified chitin” (10). Unfortunately, in 1894, F. Hoppe-Seyler, ignoring the works of Rouget proposed to term this derivative *chitosan* (11). This name, which is now strongly anchored in the scientific language, is at the origin of an important problem of nomenclature since we have one chemical structure but, depending on DA, two names.

Surprisingly, the modern development of the research on chitin and chitosan was not initially related to an important discovery but to governments concerned with the production of food processing of crabs and shrimps, specifically to solve the problem of the significant amount of waste related to this process. Grants were offered to try to valorize this waste. Thus, the beginning of modern research on chitin/chitosan is situated at the beginning of the 1970s. The continuously increasing amount of research on these polymers, especially chitosan, signifies their importance. Before 1970 there were less than 10 papers per year abstracted in *Chemical Abstracts*. For 1999, they number more than 2000.

### C. Production

Chitin is produced essentially from the cuticles of crustaceans, especially from crab and shrimp shells. Another in-

teresting source is represented by the endoskeletons of cephalopods. The method is relatively simple and consists of two successive extractions. The first is a demineralization related to the presence of a more or less significant amount of calcium carbonate in the shells (5). This step is performed by means of mineral acids. It must be performed with care, particularly for medical applications for which the mineral part must be eliminated but also because polysaccharides are well known to be easily hydrolyzed in acidic media. The second step is a deproteinization, which consists of placing the material in alkaline media of sufficient concentration associated with a moderate heating (5). There also, the complete deproteinization is very important in the case of medical uses. Endoskeletons of calmars such as squid pens are particularly interesting for their very low mineralization with a content of calcium carbonate generally below 1% (w/w) (12). In this case, the demineralization step can be avoided. This source is probably the most interesting for the preparation of the polymers with the highest molecular weights. Some recent papers propose an enzymatic method for this step (13).

Chitosan is obtained from the N-deacetylation of chitin. All the methods are derived from the descriptions given in two patents (14,15) and consist in the use of highly concentrated solutions of sodium hydroxyde (30–50%) at temperatures over 90°C for times over 1 h. For mild conditions, these methods allow us to reach in one step DA close to 10–15%. If repeated one time, the deacetylation can be within 96–95%. Nevertheless, each step operated in relatively drastic conditions contributes to an important decrease of the molecular weight. Thus, if a complete deacetylation can be achieved with a three-step process, the chain length becomes relatively low at the end of the treatment. In order to avoid this problem, the use of sodium thiophenolate has been proposed, allowing both the catalysis of the reaction and the protection of the polymer chains from degradation. This method allows us also to considerably decrease the amount of sodium hydroxyde used (16). There also, endoskeletons of calmars are very interesting. Indeed, their crystalline parts are different from those of the cuticles of crustaceans. They are more accessible to reactives and thus the reaction of deacetylation is achieved more easily (12). For this additional reason, the molecular weight of chitosans produced from these sources are much higher.

## II. THE THREE PHYSICAL STATES OF CHITOSAN

### A. Solutions

Solutions of chitosan correspond to the most important physical state for this polymer, either from a fundamental

point of view or for the very great number of applications obtained from this physical form. Indeed, in the dry solid state, although unknown, the temperatures of glass transition and melting of chitosan are certainly, as for cellulose, higher than its temperature of thermal decomposition, whose beginning is generally found to be close to 180°C (17). As a consequence, except for the native forms, the solid and gel states of chitosan are necessarily processed from solutions.

From a fundamental point of view, solution behavior of chitosan is informative of the properties of this polymer. Indeed, it reflects the role of the structural parameters and the molecular weight distribution, based on the interactions with the solvent and on the molecular and supramolecular organization. It also allows us to understand the various interactions in which these polymers can be involved. It is also very important to remember that the origin of the starting material and the quality of the industrial processes necessary for the production of these polymers play very important roles in determining their properties.

Considering the chemical structure schematized in Fig. 1, it is highly functionalized with a great variety of functions and atoms. When the glucosamine residues are in the free amino form, these structures are strongly involved in the formation of three-dimensional networks thanks to hydrogen bonding and hydrophobic and van der Waals interactions. The consequence is a full insolubility of this series of copolymers whatever the solvent or the degree of acetylation. Nevertheless, the solubilization can be achieved thanks to an influx of energy which depends on parameters such as the degree of acetylation, the molecular weight, and various environmental parameters.

### 1. Role of DA

When DA is below 60%, the polymer is soluble in dilute acidic solutions. This behavior is related to the fact that the protonation of the amino groups of glucosamine residues contributes to the disruption of hydrogen bonding, the solvation of the cationic sites, and then to the solubilization when the balance between solvent/polymer and polymer/polymer interactions becomes favorable. This limit is tightly related to the value of the intrinsic  $pK_a$  ( $pK_0$ ) of chitosan, which is found to be close to 6.5 for DA below 25% (18). For a given molecular weight (out of the range of the oligomers), the pH range where chitosan is soluble increases with the degree of acetylation when DA increases from 0 to 50% (19). This variation can be attributed to two contributions. One is related to the increase of the  $pK_0$  value when DA becomes over 25%. This value should tend toward that of the monomer, close to 7.7 (20) and then contribute to an increase in solubility. The second is related to the increase of the stiffness of the polymer chain

on increasing DA, in relation with an increase of the steric hindrance of acetylated residues and then to an increase of the excluded volume (3). The consequence is that when DA equals 0, which corresponds to a fully deacetylated structure, the polymer is only soluble in water for a range of pH within 2–6 (18), although when DA is close to 50%, the polymer becomes soluble whatever the pH.

When DA becomes over 60%, we enter the range of chitin and the chains become completely insoluble in water. This insolubility has to be related to the numerous hydrogen bonds occurring between the alcohol, amide, and ether functions distributed on the repeating units all along the polymer chains. They also correspond to hydrophobic interactions due to the presence of the methyl groups of the acetamide functions and to the  $-\text{CH}$  and  $-\text{CH}_2$  of the glucosidic rings. Nevertheless, there also the solubilization can be achieved thanks to the use of hydrogen-bonding ruptors such as complexing agents of alcohol functions. Lithium ions are well known for this kind of interaction and contribute to destabilize the crystalline domains. The adjunction of some solvents such as *N,N'*-dimethylacetamide (DMAc) or *N*-methylpyrrolidone (NMP) allows the complete solubilization (21). Nevertheless, these solutions are not true solutions and contain an important amount of aggregates and microgels.

### 2. Role of Molecular Weight

For thermodynamic reasons, the solubility of neutral polymers is known to decrease with an increase of their molecular weight (22). In the case of chitosan, two factors play an additional role, the possibility of interchain association by hydrogen bonding and the polyelectrolyte character. The former behavior has been identified in the case of high molecular weight chitosan, whose aggregation capacity increases with molecular weight (23). The latter is classical and explains why chitosan is insoluble at low pH. Indeed, in these conditions, the ionic strength becomes sufficiently high to favor the condensation of the counterions. For these three reasons it is difficult to prepare high concentrations of chitosan chains. Another limitation is the increase of viscosity with the molecular weight, especially due to the electroviscous effects. Therefore, it is often difficult to prepare solutions with a concentration over 2–3% (w/w). On the contrary and for the same reasons, it is possible to increase the concentration on decreasing the molecular weight. In the case of very low molecular weight oligomers, for degree of polymerization (DP) below 8, the oligomers are highly soluble whatever the pH and DA (24). In this case, the increase of the  $pK_0$  value (20) contributes to the enlargement of the pH range of solubility. In the case of intermediate molecular weights, for DP within 15–50, the behavior is similar to that of the high molecular

weights as concerns the pH range of solubility, but the viscosity remains much lower and thus we can considerably increase the concentrations up to 20–30%. In the same range of DP, we also observe a typical behavior for fully deacetylated molecules. In this case, solutions preserve the memory of the crystalline organization in the solid state (25), especially when the molecules have been isolated in the free amino form. Thus, a monodisperse sample of a given molecular weight, after isolation in the free amino form and a storage of a few days, leads to a chromatographic analysis exhibiting a distribution showing several peaks corresponding to molecular weights multiple of the initial molecule (monomer, dimer, trimer, etc.) This behavior depends on the DP, the concentration, and the degree of crystallinity before dissolution. It does not change with time contrary to a classical process of aggregation. It is interesting to remember that this kind of molecular weight crystallizes very easily (26) and has the dimensions that avoid the folding of the chains to build the crystallites. Therefore, in this case, the chains which have the same dimensions are packed in the crystallites in parallel. When these systems are placed in a solvent, the amorphous parts lead to isolated chains, although molecules constituting the crystalline parts are only partly dissociated and constitute arrangements of two, three, four chains, etc., which are either packed in parallel or attached together by their chain ends (25).

### 3. Role of Other Parameters

The solubility of chitosan is essentially governed by the possibility of formation of inter- and intramolecular hydrogen bonds. Then, all factors contributing to the contrary of this kind of interaction can contribute to solubilization. This is the case of a decrease of pH which allows the protonation of the amino sites. In the free amino form, we could consider the case of the complexation/solvation mentioned for chitin. Nevertheless, this situation does not operate with chitosan, certainly in relation with the too high polarity of water compared to solvents such as DMAc or NMP. We could also consider the formation of soluble complexes with some metals. Unfortunately, all the known complexes of chitosan in the free amino form are neutral, involving hydroxylated forms of metals which can also contribute to reinforce the network of hydrogen bonding (27).

Ionic strength is also a disfavorable parameter since it contributes to reduce the Debye atmosphere of the ionized sites of the polycationic chains and then to favor the ionic condensation, thus reinforcing the depletion of the polymer chains. This behavior is quite well illustrated when we study the hydrolysis of chitosan in acidic media. Indeed,

initially, the polymer chains are not soluble in relation with the polyelectrolyte behavior just described. On decreasing the molecular weight, the total ionic strength does not change, but the electrostatic potential of the chains decreases considerably and contributes to a critical molecular weight below which the chitosan molecules become soluble.

The dielectric constant of the media can also play an important role. Indeed, polar solvents favor dipolar and ionic interactions and should contribute to solubilize chitosan. The experimental results show that this parameter is not sufficient alone to induce the solubilization. The case of solvent blends is particularly interesting. In some conditions it can give rise to the gelation of chitosan instead of precipitation. This is particularly the case when solvents such as DMSO (16) or others (28) are added to a solution of chitosan in water. The decrease of the dielectric constant disfavors the ionization and ionic interactions, especially the protonation of the amino sites. This behavior is emphasized when a weak acid has been chosen to prepare the solution. The consequence is that, for a given concentration of the less polar solvent, the number of free amino groups becomes sufficient to allow the formation of a network of chitosan chains in which hydrogen bonds constitute the physical links. This situation is often metastable and turns to precipitation on increasing the concentration of the solvent of weaker polarity.

The solubility of chitosan can also be constrained by the use of acids which can interact with chitosan in a particular way. The most typical behavior is that of sulfate ions, which interact with chitosan according to two modes. The first is related to the very high salting out (dehydrating) power of these ions, as has been evaluated by the scale of Hofmeister (29). The second is that chitosan would form a typical complex with sulfate ions through intermolecular crosslinking (5). Although the latter point remains unclearly demonstrated, we can observe that chitosan is not soluble in the presence of sulfate ions.

The origin and the quality of the materials and processes can also play an important role on the solubility of chitosan. There are several sources of chitin and several recipes for the preparation of chitosan (5). Contrary to the wrong ideas published in the past, it is now definitely decided that the chemical structure is independent of the source. The only differences we can observe concern the values of DA and molecular weight. They can be related to the origin, but the most important parameter is the quality of the treatment. Thus, if the raw material is selected in order to eliminate the too highly pigmented part of the shells, the corresponding chitosan is less colored. The coloration can also be related to a too high temperature of deacetylation. As a consequence, the less colored chitosans are those obtained

taking into account these parameters, and the best materials are logically those produced from endoskeletons of cephalopods which are not pigmented. The second problem concerns the presence of insoluble parts corresponding to particles or colloidal forms. The first case is due to impurities or a bad deacetylation; the second is essentially related to the possible presence of silica or lipids. There also, the quality of the process is important. A sufficient washing of the raw material can eliminate completely solid impurities. The elimination of organic colloids possibly due to the presence of residual lipids is more difficult to solve. Some methods used by producers consist of a washing with organic solvents or detergents before the last washing and drying. Endoskeletons of cephalopods are there also the most promising materials.

#### 4. Molecular and Supramolecular Organizations in Solution

The conformation of chitosan in solution is not completely known. This polymer, depending on the parameters already discussed, is generally considered as adopting a disordered conformation with a certain stiffness (3). This stiffness is related to the relatively constrained  $\beta$  ( $1 \rightarrow 4$ ) backbone, less flexible than  $\alpha$  ( $1 \rightarrow 4$ ) chains. Various models have been proposed in the literature to evaluate the stiffness. The Kuhn model consists in the definition of an equivalent statistical segment  $A_m$  (30), but is limited to conformations of relatively low stiffness. Beyond this limit, the “wormlike” model (31) defining a persistence length  $P_L$  is preferred. For moderate stiffnesses, the two models are equivalent. The values reported in the literature are generally deduced from viscometric measurements at various concentrations and ionic strengths. We can mention a value of the Kuhn segment found to be close to 23 nm (32) at a low ionic strength, and a value of the persistence length extrapolated near to 4.2 nm at infinite ionic strength (33). The stiffness of the chitosan chains is confirmed by the values of the Mark–Houwink–Sakurada exponent, which is located within 0.9–1.1 (23), values in agreement with semirigid conformations. As a conclusion, we can consider that the stiffness of chitosan in solution decreases with the deacetylation, ionic strength, and temperature (32), although no conformational transition order/disorder can be observed (33).

No ordered conformation has ever been observed in chitosan solutions at low concentration. Nevertheless, a kinetic process of aggregation has been identified by light scattering studies and steric exclusion chromatography (16). These aggregates are characterized by very high apparent molecular weights. The structure of these aggregates has not yet been described. Nevertheless, the pres-

ence of a supramolecular organization in these molecular associations has been reported (34).

#### 5. Stability of Chitosan Solutions

We already mentioned the two limitations related to the polyelectrolyte character of chitosan in aqueous solution, in particular the possible precipitation at more or less high ionic strength and the viscosity which depends on the molecular weight and charge density.

As for all polysaccharides, the glycosidic linkage is sensitive to acidic hydrolysis, a phenomenon which depends on concentration, temperature, and pH (24). The consequence is a continuous decrease of the molecular weight of chitosan chains in solution. As for all natural polymers, there is also a possible contamination of the chitosan solutions by microorganisms specific to their chemical structure. As a consequence, in order to avoid these problems it seems better to limit the storage of these solutions and to work with the readily soluble forms of this polymer represented by chitosan salts.

#### 6. Applications of Chitosan Solutions

Solutions of polysaccharides are necessary for the processing of articles for various uses either in solid form or as gels. Nevertheless, these solutions find many direct uses, and the literature is filled with several thousands of papers and patents reporting on these applications (5,35,36).

### B. Hydrogels

Most of the polysaccharides are known to undergo gel formation. These gels are only obtained in the presence of an important proportion of water and belong to the family of hydrogels. They can be of either chemical or physical nature. In the first case, the three-dimensional network of the polymer chains responsible for the gel formation is due to covalent crosslinks and, as a consequence, these gels are not reversible. In the second case, the junctions between the chains are due to two kinds of interactions. In a first case, they can correspond to low energy interactions such as hydrogen bonding or van der Waals or hydrophobic interactions. In another case, they are due to the presence of some conformations stabilized by ionic interactions such as in the case of pectins and alginates (38). For most of the applications in which we are interested in this book, only physical gels can be considered as interesting. These gels are generally solvo- and thermoreversible.

#### 1. Physical Gels

Physical gels have the advantage of being reversible in some conditions. They also correspond to molecular sys-

tems which have fully preserved their chemical structure of origin. Except in the case of gels stabilized by some ionic species, the biological properties of the polymer in the gel form are very close to that of the polymer in the solid or solution state. These gels are superabsorbants since they are generally prepared in conditions where the concentration of the polymer network is below 5% (w/w). They have a soft consistency and in numerous cases are highly transparent to the visible spectra.

## 2. Physical Gels Formed from Chitosan Solutions

### a. Pure Chitosan Gels

If we consider chitosan solutions, the gel formation needs to be at a concentration sufficiently high to favor the chain entanglement useful for the formation of a continuous gel instead of microgels or aggregates. This critical concentration is well known as  $C^*$  and is easily deduced from the inverse of the intrinsic viscosity  $[\eta]$ .

The second parameter corresponds to the balance between attractive and repulsive interactions along the polymer chains and the ability to favor the formation of junction points by means of ordered domains. This balance can be influenced in different ways. We can play on the dielectric constant of the media. Then, a weak decrease of this parameter, associated with a control of the ionization state of the amine groups, favors the formation of hydrophobic interactions and hydrogen bondings. The latter constitute the junction points on chains where numerous hydrophilic interactions still exist and contribute to the existence of the chain segments between the junction points (28). The presence of ordered conformations as well as order-disorder transitions has never been identified in chitosan solutions (5). Moreover, the absence of any information on the presence of ordered domains in chitosan gels led us to suppose that gel formation from a chitosan solution could be due to a statistical reticulation.

The crosslinking of chitosan chains can also be achieved thanks to interchain ionic bridging. This behavior has been described in the case of various multivalent ions such as oxalates, sulfonates, or molybdates (38–40).

Whatever the case, in some circumstances, the gels are thermoreversible. They can be also fully regenerated in the form of pure chitosan gels after a complete exchange of the components of the initial media of their formation (38). Unfortunately, after this exchange, they become thermostable. This behavior must necessarily be related to the generation of other junction points than those initially responsible for gelation. These pure chitosan gels have then the same properties as chitosan both in solution and in the solid state.

### b. Chitin Gels

The last possibility to play on the balance between segments/segments and segments/solvent interactions is to chemically modify the polymer chains by introduction of chemical groups as generators of hydrophobic interactions and hydrogen bonding. The most well-known physical gels formed by chemical modifications of chitosan in aqueous solutions are chitin gels. They were described for the first time in the literature by Hirano et al. (41). They observed their formation in the course of the reaction of acetylation of chitosan in aqueous media in the presence of acetic anhydride. These gels were described as rigid, thermostable, and soluble in formic acid. Unfortunately, in these conditions, both N- and O-acylations occurred. They were discarded to the benefit of true chitin gels discovered by the same authors. The presence of a hydroalcoholic media allowed them to avoid the O-acylation (42).

The formation of this kind of gel can only be achieved when chitosan is initially in the form of a salt of a weak acid such as acetic acid. Then, if chitosan is in the form of hydrochloride, the gel formation is not observed. This behavior must be related to the fact that the reaction of acylation needs the presence of free amino groups and that gelation only occurs at DA over 80%. In addition, as already mentioned, the value of  $pK_0$  increases with DA. This is the reason why a weak acid favors gelation contrary to strong acids whose salts are always completely formed. As a consequence, the reacetylation in the case of a chitosan hydrochloride does not overcome 60% and then remains below the critical DA of gelation (43). The gel formation is obviously dependent on the molecular mobility of the polymer chains in solution and on the extent of acylation. This is to be related to the high DA necessary for gelation. It is interesting to notice that this value is independent of the nature of the alcohol (43). In fact, the role of the alcohol is only to reduce the dielectric constant of the media since it has no chemical function to play. According to its viscosity, it can operate in a role on the kinetics of gelation (43). The relatively high level of the acetylation degree necessary for gelation confirms a statistical process of gelation related both to the fact that no ordered conformation is generated and that no long-range homogeneously acetylated sequences are observed. It also shows that when the hydrophobic sites are short enough, the repulsive forces (electrostatic, steric hindrance) and the solvation by water molecules play very important roles. This kind of mechanism was confirmed by the fact that the initial value of the DA has no influence on the DA at which gelation occurs (43). Another confirmation was given by the fact that when the chain length of the acyl group increases, the value of the critical DA necessary for gelation decreases. It has

also been shown that the molecular weight has no effect on the critical DA of gelation (43). Nevertheless, the kinetics of gelation increase with the molecular weight certainly in relation with a decrease of both the molecular mobility and the solubility parameter on increasing the molecular weight. It was also shown that below DP 280, only microgels were formed instead of a macrogel, and that no gel at all was observed for an oligomer of DP 7. These results confirm the mechanism of a statistical gelation with a probability to form a stable reticulation which is relatively weak when the concentration of polymer is below  $C^*$ .

### c. *Specific Properties of Chitin Gels*

Hydrogels are known to undergo the classic process of syneresis. This phenomenon is typically of thermodynamic origin and depends on the molecular mobility of chain segments between two junction points. As acetylation proceeds, the solubility of these segments decreases and the polymer network excludes progressively the solvent to favor segment–segment interactions with, as a consequence, a more or less important depletion of the gel. All parameters contributing to decrease this solubility contribute to this phenomenon (44). Syneresis is sensitive to the density of reticulation, which for reasons of van der Waals and electrostatic interactions disfavors this phenomenon. The consequence is that for high concentrations of polymer or low DA (near the limit of gelation), no syneresis is observed. External parameters such as pH, ionic strength, the dielectric constant, or temperature can also influence the solvent exclusion. In this case, the laws of electrostatic and osmotic mechanisms are generally followed. Then, according to the DA, the content of the gel, and the nature of the external media in which the gel is placed, we can observe either a swelling or a depletion of the gel (44). The relaxation of chain segments must also be considered for the understanding of the syneresis. Indeed, when the gel is formed, the chain segments between two reticulation points are necessarily stressed and then, for entropic reasons, they obey a relaxation process up to an equilibrium state with the thermodynamic parameters.

The mechanical properties of chitin gels are very interesting for their numerous possible applications. As for all gels, they obviously depend on the density of reticulation, the polymer concentration in the gel, and the molecular weight. The limitation comes from the fact that the best gels are necessarily obtained from the highest molecular weights, the highest DA, and the highest polymer concentrations. The consequence is that it is difficult to prepare chitin gels containing more than 2% polymer in relation with too high viscosities and kinetics of gelation.

These gels have the interesting property of being completely exchangeable in pure water with no major alteration of their properties (43,44). Thus, the initial hydroalcoholic media containing (after gelation) acetic acid is easily replaced by pure water after a sufficient contact with this solvent. This property reveals that the physical reticulation is not sensitive to this important change. It also signifies that these gels can be considered as having a very large potential of applications in the fields of cosmetics, biotechnology, biomaterials (45), pharmacology and so on.

These gels are certainly formed mainly due to the conjugation of hydrogen bonding and hydrophobic interactions. According to the value of DA, they also contain ionizable amino sites. From a physical point of view, in addition to their good mechanical properties, in relation to a relatively high polymer concentration, they necessarily have a high porosity (44). The consequence is that these gels are highly interactive and can be used to interact with a great variety of molecules.

## C. **Solid State**

Chitosan exists in the solid state in various forms such as films, fibers, sponges, flakes, powders, and microparticles.

Its properties in this state depend on the origin of the material and on the method of processing. As for the other physical states, they also depend on DA and the molecular weight distribution. Moreover, they depend on whether chitosan is used as received from the manufacturer or it has been regenerated after solubilization. In the former case, the material has the memory of the crystalline organization in the cuticle since all along the industrial process of production the material has never been solubilized. In the latter case, the solubilization destroys this organization.

### 1. **Crystallinity of Chitosan**

The solid state of chitosan can vary first from a morphological point of view. This is obvious when we compare the micrographs of a sample of chitosan as received from the manufacturer to a lyophilizate of the same chitosan after dissolution with hydrochloric acid (Fig. 2) (46). In the case of the sample as received from the manufacturer, we observe a succession of dark and clear striations which correspond to the differences of opacity to electrons characteristic of the cholesteric geometry. This morphology is exactly that we observe in the cuticles of crab or shrimp. In this case, the material has never been dissolved during the industrial process and this result agrees with the fact that the material has maintained the supramolecular organization all along the process of extraction of chitin, then of deacetylation. Therefore, the material has physical behaviors re-

**Figure 9.2** (a) Ultrafine cut of a sample of chitosan initially in the free amine form, as received from the manufacturer. TEM observation after contrasting with uranyl acetate ( $\times 30,000$ ). (b) Ultrafine cut of a sample of chitosan lyophilized in the hydrochloride form, observed in the same conditions as for (a).

lated to this morphology. Thus, it remains highly crystalline with degrees of crystallinity close to 40% with relatively large crystallites (46). The consequence is a relatively low porosity of the material, which is essentially due to fractures of the supramolecular organization initially present in the cuticles or formed in the course of the industrial process. This kind of material has a relatively low accessibility and its hydration is particularly slow to be fully achieved (46).

In the case of the sample in the hydrochloride form, obtained after dissolution then lyophilization, the morphology represented in Figure 2.a shows the absence of a long-range supramolecular organization. The material appears as a sponge in which the periodic structure has completely disappeared. The volumic mass is only  $0.016\text{--}0.02\text{ g/cm}^3$  although it is measured as close to  $0.12\text{ g/cm}^3$  in the initial material (46). In the lyophilizate, the porosity is very high

and the crystallinity is only 10%. This important decrease is also followed by a decrease of the length of the crystallites. The consequence of these important changes is an easy dispersion of this material in water with a relatively fast hydration certainly followed with a complete destruction of the crystallites (27).

The crystallographic structure of chitosan is necessarily related to the crystalline organization of chitin. Chitin exists under three allomorphs termed  $\alpha$ ,  $\beta$ , and  $\gamma$ . Only the first two are now completely accepted.  $\alpha$  chitin, the most abundant structure, is present in the cuticles of all arthropods and fungi. It is characterized by an orthorhombic unit cell in which chains are arranged in an antiparallel manner following the  $b$  axis (47). This structure is stabilized thanks to numerous hydrogen bondings according to the three axes ( $a$ ,  $b$ , and  $c$ ) of the unit cell.  $\beta$  chitin is much less widespread in the biomass. The most important source is represented by the endoskeletons of cephalopods such as squid pens. The main difference with  $\alpha$  chitin is the parallel arrangement of the polymeric chains whatever the axis,  $a$  or  $b$ . This organization contributes to reduce the length of the  $b$  axis and to slightly increase that of the  $a$  axis (48). We also notice an important difference due to the absence of hydrogen bondings between the chains, along the  $b$  axis. The consequence is that this chitin is chemically more accessible than  $\alpha$  chitin (12).

According to the literature, the polymorphism of chitosan is more important than in the case of chitin. Its structure can be more or less modified by the insertion in the unit cell of small molecules such as water, some metals, or salts. Degree of acetylation and the salt or the free amine form are also important parameters (49). In the free amino form, two allomorphs are described. When chitosan is obtained from  $\alpha$  chitin or when it has been regenerated after precipitation of a solution, the solid state corresponds to the allomorph “tendon,” which is a hydrated form (49). When this form, especially when it corresponds to a fully deacetylated chitosan, is heated up to  $240^\circ\text{C}$ , we observe another allomorph named “annealed,” whose main difference to the previous one is having no water in the unit cell. Nevertheless, this transition is never total and we always observe a mixture of the two allomorphs.

In the case of salt forms, two other kinds of allomorphs have been proposed. These salts can be obtained in sufficiently concentrated solutions of various acids thus avoiding the dissolution of chitosan. Salts of various acids have been tested, especially those prepared from  $\text{HNO}_3$ ,  $\text{HBr}$ ,  $\text{HI}$ ,  $\text{HF}$ ,  $\text{HCl}$ , and  $\text{H}_2\text{SO}_4$  (50). For the first three acids, the structure is that of a helix  $2_1$  and contains no water. Nevertheless, these structures show some differences especially along the  $a$  or  $b$  axis, although the length of the  $c$  axis is preserved. This behavior must certainly be

related to the fact that the protonation of the amine groups, its solvation, and the inclusion of anions in the structure only are contrary to the hydrogen bondings according to the *a* and *b* axes of the unit cell and have no great influence on the length of the chain axis essentially stabilized by a hydrogen bond between the —OH of C<sub>2</sub> and the heterocyclic oxygen atom. Another difference between the crystalline structures of these salts is that in the case of the two first salts, the unit cell is orthorhombic although it is monoclinic for the last one. In the case of the three last acids, the structures of the salts correspond to a monoclinic unit cell with polymer chains adopting a more extended conformation identified as a 8<sub>3</sub> helix. The cell unit, according to the salt, is more or less hydrated, but the number of water molecules included in the structure has not been really determined. For all the salts, the regeneration of the free amino form after dipping in a solution of sodium hydroxide leads to a mixture of the allomorphs tendon and annealed in a proportion which depends on the nature of the acid. Thus, it seems that HF and H<sub>2</sub>SO<sub>4</sub> favor the annealed structure more than the others. On the other hand, the proportion of the annealed structure seems to be dependent on the length of the chains. Thus, for DP within 30–50, it is possible to obtain monocrystals of the annealed structure (26).

The modification of the crystalline structure of  $\alpha$  chitin during the process of deacetylation in NaOH at 95°C has been studied by x-ray diffraction (51). The authors observed the progressive disappearance of the pics characteristics of the allomorph  $\alpha$  to be progressively replaced by those specific of the allomorph tendon of chitosan. Nevertheless, in the course of this heterogeneous process of deacetylation one peak characteristic of the chitin structure persists up to degrees of deacetylation of 70% (51–53). Some authors have also observed a decrease of the degree of order during the conversion of chitin into chitosan (54) with, moreover, the quasicomplete disappearance of the 020 crystallographic plan associated to an anisotropic resistance of the network toward the stretching stresses. It has finally been proposed that the chains could be arranged differently whether the amino form is regenerated by precipitation of a solution or is obtained from a film dried in the salt form then neutralized in alkaline media (55,56).

This information on the morphology and the crystallography of chitosan is necessary for the understanding of the properties of this polymer in the solid state.

## 2. Solid Forms of Chitosan

### a. Flakes and Powders

For a long time chitosan has been commercialized in the physical state achieved at the end of the process of deacety-

lation. This state corresponds to flakes of various forms and dimensions whose average length is generally close to 4–5 mm. These particles are the result of the treatment in heterogeneous media of the cuticles of shrimp or crab without any dissolution. These particles have the advantage of being easily manipulated, in particular in the case of their washing, filtration, collection, and drying. Their morphology and crystallinity have been described previously. This kind of particle presents several disadvantages. First, their volumic mass is relatively low and this fact contributes to increase the cost of their transportation. This form cannot be used for the filling of small volumes such as capsules. It is also disfavorable for direct uses of chitosan, especially those for which the specific area plays an important role. This is the case when chitosan is used for the sorption of chemical species such as metal ions (46). For these various reasons, all the manufacturers recently decided to commercialize chitosan in the solid state in the form of powders. In all cases, these powders are obtained by grinding the flakes described. In most processes, this grinding is not performed under a rigorous control of the local increase of temperature, which can be at the origin of a superficial thermal decomposition of the material associated with a yellowing. The best way consists of grinding in liquid nitrogen which completely avoids this problem. The particles can then be passed on sifters of different mesh allowing the preparation of particles of selected granulometry according to the application considered. Chitosan which has never been dissolved can be considered as a true porous material. Then, when particles of such material are used as sorbents of various types of molecules such as metal ions, the total specific area, which includes the sum of the porous area plus the superficial area, plays an important role in the kinetics of sorption (57). It can be easily increased by decreasing the dimensions of the particles. Nevertheless, there is a limit to the grinding related to the difficulty to collect small particles in a dispersed state. The specific area is certainly an important parameter for the circumstances in which chitosan has to be modified in heterogeneous media.

### b. Films

Chitosan, as all members of the family of linked  $\beta$  (1  $\rightarrow$  4) polysaccharides, is known for its very good film-forming ability. The films are usually obtained from a solution of the polymer in the salt form. The solution is then cast on a surface such as a sheet of polystyrene. After evaporation of the solvent, we obtain a film which is easily detached from the support. The film can be regenerated in the free amino form after it has been subjected to an alkaline solution. The thickness of these films can be controlled either

by the polymer concentration or by the height of the liquid to be evaporated.

The mechanic characteristics of chitosan films depend on various parameters. The most important is the hydration. Thus, for a chitosan film in anhydrous conditions, the stress at break can be relatively high and close to 83 MPa (58) with a stretching close to 33% and a Young modulus near 3620 MPa. After an immersion one night in deionized water, we observe an important loss of the mechanical properties: 99% for the Young modulus and 88% for the stress at break. The behavior in aqueous media depends on the conditions of preparation of the membrane (59). Then, the elastic modulus increases with the concentration of the solution used for the preparation of the film. It also depends on the chemical structure of the acid used for the preparation of the solution. For the authors, the nature of the interactions, the concentration of chitosan, and the nature of the acid used could influence the conformation of the polymer chains during the formation of the film and, as a consequence, the density of entanglement of the chains in the solid state. Indeed, a densification of the material induces necessarily a decrease of the molecular mobility and then of the stress relaxation responsible of an increase of the elastic modulus. Nevertheless, the differences of behavior according to these parameters, in most cases, remain relatively low. It has also been demonstrated that a storage of the films at 23°C, 1 atmosphere, and 50% relative humidity had no particular influence on the mechanical properties of the films (60).

Membranes of chitosan show other physical properties, especially their very high impermeability to various gasses in their dehydrated form. The permeability depends on various parameters such as DA, the crystallinity, and the degree of hydration (28). These membranes of chitosan show a selectivity for the transport of some gasses, for example, toward CO<sub>2</sub> compared to O<sub>2</sub> (61). They are effective in applications of pervaporation of water–alcohol mixtures (62). The permeability of these membranes in aqueous media has also been studied, especially in the case of the diffusion of vitamin B12 (63).

All the properties of chitosan membranes associated with their physicochemical and biological properties are particularly interesting for various biomedical applications, such as for pharmaceuticals, wound coverings and tissue engineering.

#### *c. Chitosan Fibers*

The filmogenic properties of chitosan must necessarily be associated to its easy spinning. Due to the properties already mentioned, the spinning of chitosan is only possible by the method of wet spinning. Mild conditions of solutions of chitosan at concentrations close to 5–6% (w/w)

prepared with acetic acid. This highly viscous collodion is pushed through a spinneret and the filaments are coagulated in an alkaline bath. After washing and drying we can obtain very nice chitosan fibers (64) whose tenacity in the dry state can be close to 2 g/Denier with an elongation at break near 14% and a Young modulus of 73.27 g/Denier (65). Chitosan fibers can then be processed in the form of yarns with direct applications or used to prepare woven or nonwoven fabrics with particularly interesting biological properties.

#### *d. Chitosan Sponges*

The filmogenic properties of chitosan can also be associated with its capability to form spongelike materials. These materials are easily formed from a solution or a dispersion of chitosan with a concentration located within 0.5–2%, followed by a lyophilization. These materials are highly expanded systems with open pores. Their volumic mass can be very low and close to only 0.016 g/cm<sup>3</sup> (46). Their porosity can be calculated from SEM studies, and parameters such as the concentration and the temperature of freezing considerably influence this parameter (66). It is then possible to prepare materials with average pore sizes varying within 20–250 μm. In fact, there are several levels of pore size depending on the scale of observation. Thus, the walls of the pores seen by SEM when observed by TEM reveal a secondary porosity due to the fibrous structure of these walls which is below 50 nm (46). When they are hydrated, these lyophilizates become very brittle and can be used as a source of particles when they are dispersed in water under heavy stirring. At higher densities, they can also constitute materials operating as a sponge with interesting biological properties.

#### *e. Microparticles of Chitosan*

Microparticles, especially microspheres of chitosan, can also be obtained from the method of emulsification, followed by an extraction/evaporation. Typically, the inner phase is constituted by a solution of chitosan in a mixed solvent such as acetic acid/acetone. This solution is emulsified in an outer phase constituted with a vegetal oil to which an emulsifier is added. Afterward, the solvent of the inner phase is evaporated and finally extracted up to completion leading to microspheres of diameter generally below 10 μm (67).

### III. PHYSICOCHEMICAL PROPERTIES

If we consider the chemical structure of chitosan shown in Fig. 1, it bears atoms and functions allowing this structure to give rise to all the known interactions of chemistry.

The nature of these interactions depends particularly on two parameters, the degree of acetylation and the degree of ionization of the ionizable functions, i.e., the amine and alcohol functions.

### A. Hydrogen Bonding

Alcohol, amine, amide, and ether functions present in the structure of chitosan can be involved in the formation of hydrogen bonds either with various substrates or by means of inter- and/or intramolecular bonding.

The most important substrate in the formation of this kind of interaction is water. It participates in the formation of hydrogen bonds responsible for the solubility of chitosan in water. Nevertheless, the competition between inter- and intramolecular bonding is always present. This competition is regulated by the balance between attractive and repulsive interactions. Here, the degree of ionization and DA can play an important role. When DA and the ionization degree are close to 0, the possibility of hydrogen bonding should be minimum. Nevertheless, we always observe the formation of aggregates. If DA increases, the stiffness increases but the second virial coefficient decreases in relation with the increase in the ability to form aggregates by intermolecular hydrogen bonds between the polymer chains. These aggregates have been described as corresponding to relatively ordered supramolecular organizations (35). Aggregation is a kinetic process which can be compared to crystallization (16). When the degree of ionization decreases, the repulsive interactions decrease, thus favoring the formation of hydrogen bonding leading to precipitation.

Other substrates can give rise to hydrogen bonding with chitosan. It is the case of some dyes (5) or polymers. In the latter case, we can mention the interaction of chitosan with collagen (68). Thus, when a very great excess of chitosan (over 200%, w/w) is added to a solution of collagen, we observe the formation of a precipitate in which the interactions between the two kinds of polymer chains are essentially due to hydrogen bondings. The complex can contain up to 85% (w/w) chitosan, which is largely beyond the maximum theoretical value (28.5%) calculated for a pure polyelectrolyte complex (PEC). The formation of such a complex is confirmed by IR spectroscopy analyses. It also allows us to show that this interaction is very strong and induces the denaturation of collagen characterized by the transformation of the threefold helices into single helices. This behavior is confirmed by the fact that this complex is not hydrolyzed by collagenases which specifically recognize the threefold helix (69).

Hydrogen bondings also plays an important role in the gelation process of chitosan (43).

In the solid state, the role of hydrogen bonding is very

important. It is responsible for the stability of the ordered structures in the crystalline domains and of the interchain interactions which reinforce the stability of these domains. In some circumstances, hydrogen bonding with water can be observed in the unit cell (49).

### B. Hydrophobic and van der Waals Interactions

This kind of interaction is often used to interpret some results especially in the case of amphiphilic polymers such as biopolymers. Thus, if we consider the structure of chitosan, the  $-\text{CH}$ ,  $-\text{NH}_2$ ,  $-\text{CH}_2$ , and  $-\text{CH}_3$  groups are hydrophobic. The conformation of chitosan in solution is relatively stressed and the stiffness increases with DA. As a consequence, The deprotonation of amine groups and the increase of DA, temperature, and dielectric constant contribute to influence not only the hydrogen bonding, but also this kind of interaction. Thus, when we increase the temperature of chitosan, we contribute to decrease its solubility by the disruption of hydrogen bonding with water and increase the interactions mentioned previously. This behavior is emphasized when the dielectric constant of the media is decreased by addition of a solvent of lower dielectric constant such as an alcohol (43).

### C. Electrostatic Interactions

#### 1. General Aspects

These interactions are due to the ammonium form of the glucosamine residues and then to the charge density of the polymer chains. This property is quite well illustrated by the Katchalsky equation (70):

$$\text{pK}_a = \text{pH} + \frac{\log(1 - \alpha)}{\alpha} = \text{pK}_0 - \frac{\epsilon \Delta \Psi(\alpha)}{KT} \quad (1)$$

The polyelectrolyte character of chitosan is illustrated by the second term on the right part of the equation which depends especially on the charge density of the polymer chains. From a theoretical point of view, if we assume the crystallographic parameters, the projection of the repeating unit on the chain axis is at least 0.512 nm (26). As a consequence, the charge density is relatively low and precludes the phenomena of ionic selectivity and ionic condensation.

The low value of  $\text{pK}_0$  already mentioned (6.5) provides chitosan with interesting properties when it is in the salt form. Thus, in the case of a strong acid, the salt is quite stable and cannot be easily displaced. In the case of acetic acid, or weaker acids, the salt is not completely formed and then can be displaced especially in the presence of a stronger acid or simply by elimination of the free acid. This behavior is illustrated especially when this salt is iso-

lated in the solid form. In the case of acetate, the acid is weak, weakly soluble in water, and has a relatively low boiling point compared to other acids. The consequence is that if we prepare a film from a solution of chitosan in acetic acid, the solid obtained after evaporation is only partially in the acetate form, and if we let this film in ambient conditions, after a few days the free amine form is completely regenerated (17). This behavior is lowered in the case of higher molecular weight carboxylic acids in relation with the increase of their boiling points. A particular case is observed with  $\alpha$ -hydroxyacids which can form stable complexes with chitosan, although their  $pK_a$  is higher than that of acetic acid (17).

## 2. Interaction with Lipids

The interaction of chitosan with lipids is particularly interesting if we consider the biological properties of chitosan or the role of this polymer as a food additive, allowing a decrease of the metabolization of lipids, especially fatty acids, triglycerides, and cholesterol.

First, salts of chitosan and lipids can be formed (71). When chitosan is added to solutions of lipids such as undecylenic acid, it induces an important decrease of the critical concentration of micellization, which is thus divided by three. In addition, the presence of chitosan is responsible for a phenomenon of flocculation dispersion of lipidic aggregates. In the case of undecylenic acid, the flocculation is maximum for a ratio glucosamine mole/fatty acid mole ranged near 0.25. On increasing the concentration of chitosan, we observe a strong redispersion which is much more stable than initially. The maximum of flocculation is then close to the maximum redispersion. This phenomenon is dependent on the ionic strength, pH, and concentration of lipid. Therefore, the maximum flocculation occurs sooner on increasing the ionic strength and decreasing the concentration. It is optimal at pH 5.8, which corresponds to the maximum electrostatic charge of the whole system. The particle size is minimum at the maximum of redispersion and depends also on these parameters (71).

It was also shown that for the optimal pH, the interaction between chitosan and the lipidic particles is essentially of electrostatic nature and is directly related to the DA of chitosan (72). The molecular weight plays another important role in the mechanism of flocculation dispersion. When the molecular weight increases, less chitosan is necessary to flocculate/redisperse the system, and the size of the redispersed particles increases. Adsorption studies based on the Langmuir model show that within a wide range of molecular weights, one major mechanism of interaction is involved in the process of flocculation, namely, electrostatic interactions of the mosaic type. Above a criti-

cal mass, another mechanism arises which corresponds to the polymer bridging with several particles (72).

Analyses by TEM and SEM (73) reveal that flocs obtained by means of high molecular weight chitosans correspond to catenary fractal structures in agreement with a theoretical model established for the flocculation of spherical particles by polymers. In addition, when chitosan chains are adsorbed on a polymeric surface such as a modified cellulose, the presence of lipids in solution allows the formation of an asymmetric membrane with one side constituted of pure chitosan and the other side of chitosan/lipid aggregates (73).

## 3. Polyelectrolyte Complexes

Another case of electrostatic interactions in which chitosan can be involved corresponds to the formation of polyelectrolyte complexes (PECs) with polyanions. Polycationic polymers are particularly rare in nature and thus chitosan is a very interesting tool for this kind of interaction. This interaction plays an important role in living media and the problem of its possible appearance on introducing chitosan in such media is of particular interest. The formation of a PEC depends essentially on the charge density of each kind of polymer and on the  $pK_0$  of the various ionic sites. If we represent the ammonium sites of the glucosamine residues by  $-NH_3^+$ , the optimal conditions for the formation of such complexes are summarized in the following equation:

where  $A^+$  and  $B^-$  are the counterions of the polyanion and polycation, respectively. Two other reactions must be considered:

From these relations, we deduce that the maximum complexation occurs when the charge densities are maximum for each polymer and when their ionization state is maximum. In these conditions the complete formation of the PEC is achieved when the total amount of negative charges is exactly neutralized by the same amount of ammonium functions. At this point, the medium contains only the complex, which is electrically neutral and insoluble in water, and the stoichiometric amount of the AB salt liberated during the interaction (74). As shown by Eq. (3) and (4), the stability of the complex depends on the  $pK_0$  of the anionic and cationic sites. Thus, when the ionic site corresponds to a weak carboxylic acid, the complex is easily destroyed on decreasing pH. This behavior explains why the PEC is only slightly formed when chitosan in the salt form is added to a solution containing the free acidic form

of a weak polyanion. This situation is observed, for example, when chitosan is mixed with collagen at low pH (75). On the contrary, when the anionic sites correspond to strong acids such as sulfates, whatever the pH, these sites are always protonated and the complex is stable even at low pH as in the case of the sulfate sites of chondroitin sulfates (74). This behavior is also observed in the case of carboxylic sites of low  $pK_0$  as in the case of the uronic residues of hyaluronic acid whose  $pK_0$  is close to 2.9 (76). In this case the complex can be formed even in acidic media (74). Furthermore, we observe a continuous decrease of the pH of the media during its formation related to a progressive deprotonation of the carboxylic sites. This behavior is possible provided that the pH of the media remains over the  $pK_0$  of hyaluronic acid. When the  $pK_0$  of the anionic sites increases, depending on both the concentration of the polymers and  $pK_0$ , we can observe an intermediate situation where only a part of the carboxylic sites initially in the free acidic form are deprotonated. This is the case of the carboxylic sites of chondroitin sulfates whose  $pK_0$  is close to 3.83 (74).

#### IV. BIOLOGICAL PROPERTIES

##### A. Biodegradability

It is important to remember that chitosan is completely absent in mammals. The first interesting biological property of chitosan is its ability to be biodegradable and bioresorbable. Indeed its structure constitutes a source of carbon and nitrogen for various kinds of bacteria. Chitin deacetylases and enzymes hydrolyzing chitosan, such as chitinases, chitobiases, chitosanases, as well as glucosaminidases and N-acetyl-glucosaminidases, are now well known (36,37). If for some of them, the structure is clearly identified, the mechanisms of their activity remain obscure. In mammals, these enzymes seem to be completely absent. Nevertheless, when chitosan is implanted it disappears definitely after more or less time depending on the DA (77). Lysozyme, which is a nonspecific proteolytic enzyme widespread in this category of animals can hydrolyze chitosan, but this activity disappears rapidly when chitosan has a DA below 30% (78). Fully acetylated chitosans are then completely insensitive to this enzyme. In addition, it seems that at least three consecutive N-acetylated residues are necessary to be recognized by this enzyme (79). The degradation of these polymers is nevertheless observed but the mechanism is not really elucidated. It is attributed to the presence of some oxidative agents produced by the immune system in the exudates (80).

It has been shown that whatever the circumstance, the biodegradation of chitosan is a phenomenon depending on

several factors, especially the degree of acetylation, the molecular weight, the degree of crystallinity, the water content, and also the shape and the state of surface of the material (8,82).

##### B. Biocompatibility

###### 1. Oral Administration

The consequence of oral administration of chitosan in humans has been studied in the case of dietetic applications (see Section IV.E). No adverse reaction has been observed for normal conditions of use. In animals, more information was obtained. Thus, in the case of the oral delivery of chitosan in rabbits, no particular adverse response of the host was noticed in normal conditions of administration (83). These conditions corresponded to the use of chitosan as a food additive with a ratio of 2% in the basal ration, for periods of 85 to 189 days. No significant difference of weight, height, color, fat deposition, or any pathology (lung, heart, stomach, intestine, or behavior) were observed. The  $LD_{50}$  was found as over 16 g/day/kg body weight, a dose which is higher than that of sucrose (12 g/day/kg body weight). The same experiments were performed on mice where the  $LD_{50}$  was lower, close to 10 g/day/kg body weight (84). The observation of the digestive organs revealed that chitosan flocculate with feed residues and remains in the duodenum and in the upper part of the jejunum. This observation confirms the effective dissolution of chitosan in the acidic conditions of the stomach (83). The perfect biocompatibility of chitosan after oral administration can also be related to the fact that there is no report mentioning the metabolization of this polymer through the intestinal cells.

###### 2. Hemocompatibility

The hemocompatibility of chitosan is generally accepted. Added to blood, it induces the formation of a coagulum (85). In the case of solid forms of chitosan, the response is related to the surface properties (77). The first important results were obtained from experiments on dogs (86). It was shown that a graft of aorta covered with chitosan allowed a good integration of the synthetic material owing to a local hemostasis on the surface of the material created by the chitosan coating. Autopsies revealed that the graft was covered by normal epithelial cells. In vitro, the hemostatic properties of chitosan have been observed even in severe anticoagulating conditions (87) and in the case of an abnormal activity of platelets (88).

The consequences of direct injections of chitosan in blood have also been studied. In mice, the  $LD_{50}$  was found to be over 10 mg/day/kg body weight. In an experiment

on rabbits, intravenous injections of chitosan oligomers (DP 2–8) were made at a dosage of 4.5 mg/kg body weight. No abnormal physiological symptom was noticed after treatment for 11 days (89). The serum hexosamine value increased on the second day after the last injection and decreased immediately on the next day. This kind of experiment revealed also the increase of the lysozyme activity in blood. Thus, for a dosage of 7.1–8.6 mg/day/kg body weight, the lysozyme activity was more than twice the normal value and was coming back to the normal 5 days after the last day of treatment. In the case of relatively high doses, severe diseases were observed. Thus, 200 mg/kg subcutaneous administration in dogs induces severe hemorrhagic pneumonia (90) and 10 mg/kg induces a systemic activation of chemiluminescence response (CL) in canine circulating polymorphonuclear cells (PMN). The increase of CL response was observed in the PMN recovered from the chitosan treated dogs after incubation with normal plasma and in the PMN of chitosan nontreated dogs after incubation with the plasma recovered from the chitosan treated dogs. When chitosan is administered to subcutaneous tissues of dogs and mice, *in vitro* studies (91) reveal that subcutaneous complement wastes rapidly by contact with chitosan material, due to the plasma C3 increase in these treated animals. On the contrary, when chitosan is administered to human plasma, C3 and C5 are decreased whereas C4 does not change. Therefore, there is no doubt that chitosan activates the complement alternative pathway. Nevertheless, in the alternative pathway, C3b is originated by a C3i enzymatic degradation of C3, but a formation of C3i due to chitosan remains unknown.

A last response concerns the production of interleukins by fibroblasts subjected to chitosan. The activation of the production of IL-8, in relation with the stimulation of both IL-1 and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), has been reported (91).

### 3. Cytocompatibility, Cell Adhesion and Cell Proliferation on Chitosan Films

The cytocompatibility of chitosan films, at physiological pH, toward keratinocytes, fibroblasts, or chondrocytes has been recently studied *in vitro*. In the case of the first two kinds of cells, the role of the degree of acetylation was also investigated (29). The results revealed that whatever the DA, all chitosan films are cytocompatible for these two kinds of cells. In the case of chondrocytes, there also, no cytotoxicity at all was detected in the case of a film with a DA of 2.5% (92). The adhesion tested on the two first types of cells showed that cell adhesion increases considerably on decreasing DA. This increase is important as long as the DA is low. In addition, for a given DA, fibroblasts

appeared to adhere twice as much as keratinocytes on these films. Although alive, fibroblasts do not proliferate on chitosan films. This behavior is related to the too high adhesion of these cells on this surface, which inhibits their development. On the contrary, the proliferation is quite good in the case of keratinocytes. This proliferation increases when the DA of chitosan decreases. All these experiments contribute to show that electrostatic interactions between the negative charges of the cell membranes and the cationic charge of chitosan play the major roles. Thus, the adhesion seems to reach an optimum depending on these parameters.

Some studies were performed *in vitro* on the role of the addition of chitosan solutions to cell suspensions. In the case of fibroblasts, it was observed that the presence of chitosan at low concentration inhibited the proliferation of the cells but did not act as a cell killer (93). Although not claimed by the authors, it seemed that the microscopic views of the cell cultivations agreed with a mechanism of cell agglutination in the presence of chitosan, which in turn could be the reason for the inhibition of cell proliferation without cell death induction (see the discussion in Section IV.B.4).

### 4. Bacterio- and Fungistatic Properties

Chitosan under various physical forms including solutions, powders, and films has been shown as inducing fungi- and bacteriostatic properties. These properties are relatively interesting since chitosan is not considered as toxic. As a consequence, they allow us to consider numerous applications for this polymer in various fields such as biomaterials, textiles, etc. Although extensively studied, these properties remain relatively unexplained with regard to the biological mechanisms involved.

Among the various types of bacteria and fungi, positive and significant results were obtained with the following families.

*Bacteria:* Escherichia (93), Pseudomonas (94), Lactobacillus (94), Staphylococcus (94,95), Micrococcus (94), Enterococcus (94), and Clostridium (94). In this field some antimutagenic activities were reported when chitosan was contacted to Salmonella associated to the mitogene Trp-P-1 (98)

*Fungi and yeasts:* Candida (97), Fusarium (94,97), Scombomorus (99), Pseudosciaena (99), Botritis, Saccharomyces (97), Pyricularia (97), and others

This kind of biological property must be first related to the physicochemical properties, in particular to the possibility for chitosan to flocculate dispersions of particles including cells and to be involved in hydrogen bond formation and polyelectrolyte interactions. The flocculating

properties of cationic polyelectrolytes toward cell suspensions were demonstrated at least 30 years ago (100). An interesting study of the flocculation properties of chitosan in cell suspensions concerns the cases of *Escherichia coli*, *Bacillus subtilis*, and *Zymomonas mobilis* (101). In this study, it was shown that the flocculation properties of chitosan were comparable to those of synthetic molecules known for their high potency to induce this phenomenon. The role of pH showed that the maximum flocculation was located within 5.5–6 for the three kinds of microorganisms. It is interesting to notice that this optimal pH is quite similar to that observed in the flocculation of lipid aggregates (71). Unfortunately the study was limited at high pH by the precipitation of chitosan (over pH 6) where the authors observed a sudden decrease of the flocculation properties. The dose necessary to achieve the maximum property certainly depends on the nature of the cell in relation with the charge density of the cell surface but was comprised between 2 and 3.5 mg chitosan per gram of cells. Whatever the case, we can consider that the cell entrapment in chitosan flocs limits the cell mobility necessary for their division and then to their proliferation. This behavior is quite similar to that mentioned when epithelial cells such as fibroblasts adhere too much on the surface of a chitosan biomaterial. Nevertheless, in the conditions of maximum flocculation, the cells are maintained alive and then chitosan has “cell-static” properties. We can also consider as demonstrated in the case of plant cell suspensions that when chitosan concentration becomes sufficiently high to produce a redispersion of the flocs, the cell surface becomes highly positively charged and leads to the death of the cells (102). Fortunately, in relation with the physiological pH which is generally over 7, this situation cannot occur and chitosan can never be considered directly as a cell killer in vivo.

### C. Bioactivity

Although considered as nontoxic, chitosan is often shown as being a strong elicitor of biological activity whether in plants or in animals. In both cases, the consequence of the contact between chitosan and living media has been extensively studied during the last 20 years. Some results in the case of plants could be used to understand some behaviors observed in animals.

#### 1. “Immune” Response in Plants

Except one case mentioning the possible cell internalization of chitosan oligomers in plant cells (103), the crossing of the cell wall and the plasma membrane of these cells by chitosan has never really been demonstrated. As a con-

sequence, the elicitation of various cell activities must be related to signals coming from the interactions between chitosan and the cell envelope. Among the elicitations reported in the literature, the induction of the production of callose has been the most studied. Thus, when chitosans of various degrees of acetylation and molecular weights were subjected to suspension-cultured cells of *Catharanthus roseus*, the following results were observed (102): The elicitation of the formation of the  $\beta$  (1  $\rightarrow$  3) glucan callose was not observed with low molecular weight oligomers. Callose synthesis increased with the degree of polymerization up to several thousands corresponding to a weight average molecular mass of  $10^6$  g/mol<sup>1</sup>. At a comparable degree of polymerization, the increase of the acetylation degree contributed to decrease the elicitation. In the case of protoplasts, the biological response was greatly emphasized. These results showing the role of the charge density and molecular weight allowed the authors to consider that the primary interaction responsible of the biological signal may be attributed to an electrostatic interaction between the cationic charges of chitosan and the anionic charges of the phospholipidic structure of the cell membrane. This interaction is repressed by the electrostatic barrier constituted by the cell wall. In the case of another kind of cell such as those of *Rubus*, the elicitation of laminarinase was studied. Similar results were obtained with an additional interesting observation showing that the elicitation reached a maximum for a DP close to 3000 then decreased (104). This behavior has to be related to a change in the mechanism of interaction between chitosan and cells. In the first case, several chains can bind at the surface of one cell with a progressive lowering of the number of chains and cationic sites involved on each chain on increasing the molecular weight. In this case we observe a process of cell agglutination of mosaic type where the cell surface is certainly highly stressed. This stress increases with the molecular weight and then favors an increase of the elicitation process. Over a critical chain length, the mechanism becomes of interparticular type. In this situation, one chain can bind several cells. The consequence is a progressive decrease of the cell stress on increasing the molecular weight. In the case of *rubus* cells, a lectin specific for glucosamine oligomers especially of DP 4 was identified (105).

#### 2. Immunological Properties in Animals

The antigenicity of chitosan has not already been demonstrated and antichitosan antibodies are not known. Nevertheless, this state of our knowledge does not signify that they do not exist. The immunologic activity of chitosan is particularly interesting and contributes to potentially very important applications of this polymer in the treatment of

various tumoral afflictions and in the treatment of several pathologies of viral origin. Since chitosan can be degraded in living media, the question remains whether the biological activity is due to the monomer and oligomers or directly to the polymer. It seems that both kinds of involvement must be considered.

The activation of macrophages has been studied by several authors. Thus, the peritoneal exudate macrophage (PEM) chemotaxis has been demonstrated *in vitro* in the presence of chitosan. The experiments show that macrophages migrate in response to a positive gradient of chitosan, thus indicating a true chemotactic effect. Another consequence of this activation concerns the nitrite production by the PEM after preincubation with chitosan. This activity is related to the N-acetylglucosamine residues since the monomer glucosamine, contrary to NAG, has no influence on this response (106). This result is of great importance. It could signify that fully deacetylated chitosan is not biodegradable in mammals. Indeed, lysozyme has no action on it and nitrite production should not be elicited in its presence. On the contrary, the production of nitrite if it were confirmed *in vivo* should be associated with biocompatibility problems. Indeed, NO production contributes to amplify the inflammatory reaction leading to the destruction of both the polymer material and the tissue surrounding the implant. *In vivo* experiments performed by subcutaneous implantation of chitosan in mice reveal adverse inflammatory reactions at the level of the implants. After 2 weeks implantation, the foreign materials are loosely attached to the host tissues showing no integration at a macroscopic level. Histologic studies by TEM demonstrate the penetration and invasion of the cells into the chitosan material. Thus, many migrating macrophages and eosinophils are present inside the material or at the interface between this material and the host tissue in contact. Remnant particles of chitosan can be observed inside and outside the cells (106). Nevertheless, vascularized neotissue is also observed. It can be considered that the complete degradation of the implant produces the progressive normalization of the histological picture with a final wound healing. This behavior explains the numerous results (see Section V.D.2) on the wound healing induced by chitosan following implantations of at least 2 months.

#### *a. Antitumoral and Antiviral Activity*

The antitumoral activity of glucosamine tested *in vitro* on human tumors shows a specific killer activity without any toxicity toward the normal tissues (107).

The antitumoral activity of chitosan oligomers especially the hexamer has been demonstrated in mice. The use of this kind of oligomer is particularly interesting as an

immunotherapeutic agent compared to other polysaccharidic systems. Indeed, their antigenicity has not been demonstrated and their solubility in water associated to their facile biodegradation allow them to be easily eliminated from the human body (108).

The antitumoral properties of the polymeric forms of chitosan are also demonstrated. They are related to the production of tumor necrosis factors, especially cytokines (109). They are also due to activation of macrophages leading to the stimulation of killer cells and T cells by the secretion of lymphokines. It is interesting to notice that it has no particular influence on the production of lymphokines by spleen cells (110).

The antitumoral activity of chitosan inducing the activation of killer cells, especially lymphocytelike cells, led us to consider that it can also act as a killer of virus-infected cells.

## V. APPLICATIONS

### A. Cosmetics

If we consider all the properties of chitosan mentioned, they necessarily predict numerous possible opportunities in the field of cosmetics. Thus, chitosan is a good moisturizer with no allergenic properties and possesses the two fundamental properties for this field of application (considering the nonmedical aspect of this domain). There are several hundred patents reporting on the possible applications of this polysaccharide in the various aspects of this branch. Thus, as mentioned, chitosan can be used as a lipidic dispersant and participates to the formulation of various cosmetic creams. Chitosan has filmogenic properties; it weakly interacts with proteins such as keratine and possesses cationic sites. Therefore, it can be used, especially in the case of low molecular weights, as aftershampoo giving a silky aspect associated with repulsive electrostatic properties. If the molecular weight is sufficiently low, the polymer film will be easily eliminated after a brushing or a new washing. The power to improve the glossiness associated to fixating and comb-out properties was claimed for formulations containing both chitosan and linear block copolymers of polysiloxane and polyoxyalkylene (111). The capability to act as a moisturizer can be illustrated by formulations containing chitosan and organic acids such as gluconic or succinic acids (112). The moisturizing properties of chitosan associated with an emulsifying character were claimed in the case of formulations corresponding to chitosan modified by acylation with fatty acid anhydrides or chlorides (113). The cationic character of chitosan was claimed in other cosmetic formulations for the cleaning and makeup remover of the skin and mucous membrane

(114). Chitosan has been proposed in toothpaste formulations, in the solid state for its abrasive properties associated to its possible anti-dental caries activity (115). Chitosan gels have good skin adhesive properties and could be used in the form of patches for the delivery of various substrates such as caffeine, vitamins, or nicotine. A complex between chitosan and iodine was proposed as a good disinfectant and wound healing system (116). Another interesting patent concerns the use of chitosan powder in the formulation of soaps. A soap was prepared from palm oil, fatty acids, tetrasodium edetate, and chitosan powder (1%, w/w). This preparation was then applied to patients with atopic dermatitis and revealed a decrease of their symptoms and no skin trouble formation (117).

Although the number of patents is very important in this field, surprisingly the number of papers describing the scientific background of cosmetic applications of chitosan is very poor. We can mention the use of chitosan associated with collagen and other glycosaminoglycans in a porous form as a dermal equivalent (DE) and a skin equivalent (SE) (118,119). The DE model was made from this three-dimensional matrix populated with human fibroblasts. The SE corresponded to the DE after seeding with normal human keratinocytes. These systems were then subjected to UVA in order to test *in vitro* the deleterious effects of this radiation. These systems were also tested in the presence of chemicals usually used for skin protection. A good accordance was obtained between the results on the cell viability and the IL-1 alpha release obtained both *in vivo* and *in vitro* with these models. As a consequence, they could be used to test the efficacy and toxicity of sunscreens. We can also note that chitosan could be possibly used itself as a sunscreen since UV spectra of chitosan solutions and films reveal a strong absorption below 200 nm, although it is quite transparent in the visible range (18).

Chewing gum supplemented with low molecular weight chitosans (3%) were used to evaluate the pH response of the human dental plaque (120). Thus, the role of these molecules was tested after an exposure to fermentable carbohydrates by means of a microelectrode. The fermentable substances corresponding to 5% glucose solution or sugared caramel were directly applied. Then, the subjects started chewing gums with or without chitosan. In the former case, the recovery of the normal pH (close to 5.5) was much faster than in the latter. This behavior can be simply related to the fact that chitosan as a polyamine has the potency to actively neutralize acidic media. A comparison was made between the capability of various buffering substances of different  $pK_a$  to inhibit the pH lowering of the dental plaque. Aspartame ( $pK_a = 7.8$ ), phosphate buffer (7.1), low molecular weight chitosan (6.4), and maleate

buffer (6.2) were tested after addition of lactic acid. It was shown that the  $pK_a$  value plays an important role since the most effective inhibition of pH lowering was observed both with chitosan and maleate buffer (121). The findings indicate that low molecular weight chitosans may be used as a food additive or, better, in the formulation of toothpastes to decrease the cariogenicity of foods.

## B. Dietetics

Due to its polycationic character and its amphiphilic structure chitosan allows, as mentioned, the formation of all the known interactions in chemistry. Therefore, it can interact with numerous components of the diet, especially those of lipidic nature. It also exhibits some particular properties which in some cases could be at the origin of adverse responses.

### 1. Effect on Calcium and Vitamin Metabolism

The effect of chitosan intake was investigated in rats fed with diets containing 5% chitosan. The role of chitosan on the decrease of the whole-body retention of  $^{47}\text{Ca}$  was demonstrated, although there was no significant increase of the calcium content in fecal excretions. In fact the  $^{47}\text{Ca}$  elimination was identified by the increase of calcium in urinary excretions. These results suggest that dietary chitosan would affect the calcium metabolism in animals (122). This result was confirmed in the case of mice fed with a continuous and massive dose of chitosan. The decrease of calcium adsorption was characterized by an important decrease of the bone calcium content (123). In the case of the latter experiments, a marked decrease of the serum vitamin E level was also observed.

### 2. Effect on Intestinal Media

The effect of dietary chitosan on the induction and development of colonic precursor lesions was determined in CF1 mice fed with diets containing 2% of low or high molecular weight chitosans for a period of 6 weeks (124). Over a 2-week pretreatment period, one group of mice was treated with azoxymethane (four injections of 5 mg/kg body weight). Whatever the molecular weight of chitosans, an important reduction in the number of aberrant crypt foci cell proliferation, crypt height, and crypt circumference in the colonic epithelium was observed ( $p < 0.05$ ). As a consequence, it seems that dietary chitosan reduces the incidence of early preneoplastic markers of colon carcinogenesis as evidenced by aberrant crypts and mitotic figures and altered crypt morphometrics in the murine colon. This property could be influenced by the molecular weight of chitosan.

### 3. Effect on Intestinal Immune System

Experiments made on rats fed with diets containing 5% chitosan revealed some changes in immune functions. Thus, the serum IgE was significantly lower while the IgM did not differ. IgA, IgG, and IgM in mesenteric lymph node (MLN) lymphocytes were unchanged, although the IgE concentration was also lower. The CD4+/CD8+ T cells in MLN lymphocytes were not affected nor the  $\gamma$ -interferon concentration or the tumor necrosis factor- $\alpha$  (125).

### 4. Hypocholesterolemic Properties

The most important studies on the use of chitosan as a food additive were performed on the effectiveness of this polymer to promote a hypocholesterolemic effect when it is associated with diet. The first results were published in 1978–1979 (126,127). The authors noticed that when rats were fed diets containing additional cholesterol, addition of chitosan induced a marked decrease of liver and plasma cholesterol. The magnitude of the reduction was comparable to that observed with cholestyramine but without any adverse secondary effects. The same authors enlarged their investigations to several series of experiments. They confirmed the first results and added that chitosan seemed to have no effect on bile acids and that the hypocholesterolemic activity had to be related to an increase of cholesterol in fecal excretions. They also mentioned the growth lowering of the rats fed with diets containing chitosan. The role of chitosan was effective from 2% (w/w diet) and the reduction of cholesterol was by 25–30% (128). In another study, these authors mentioned that on a large scale, the chain length does not play a major role. Nevertheless, they observed that the first terms of the series of the oligomers of glucosamine were ineffective (129). Similar experiments performed on rats (130) confirmed the previous results. In addition, it was mentioned that feeding with diets containing chitosan had no effect on hemoglobin and serum iron. The same authors observed that contrary to cholestyramine, there was no mucosal change in the gastrointestinal tract, except an increase of the distal small bowel. The hypocholesterolemic activity of chitosan was also shown in the presence of a hypocholesterolemic substance such as cystine (131). In the same manner, it was observed that the type of dietary fat influences the cholesterol absorption. Thus, the cholesterol uptake was more effective in the presence of sunflower oil than with palm oil (132). The results do not seem to vary considerably with the kind of animal. Thus, similar results were obtained with hens or rabbits where the decrease of the cholesterol was also observed in the blood plasma and liver (133,134). A particular case was mentioned in the second paper con-

cerning rabbits. When these animals were fed with cholesterol enriched diet (up to 9 g/kg), the serum cholesterol and triacylglycerol levels of these high-serum cholesterol rabbits were affected neither by feeding with a 20 g/kg chitosan-supplemented diet nor by intravenous injection with chitosan of low molecular weight or chitosan oligomers daily. These results signify that chitosan has a hypocholesterolemic action only in the intestine.

The first human experimentation was reported in 1993 (135). Three to six grams per day of chitosan introduced in biscuits was given to eight healthy males. Their LDL and total cholesterol level decreased significantly. Moreover, serum HDL cholesterol was increased. In parallel, the excreted amounts of primary bile acids were significantly increased during ingestion of chitosan.

More recent studies concerned the treatment of 100, 90, 80, and 30 adults in four different places in Italy. Contrary to previous experiments, chitosan was directly ingested by means of tablets (four per day) containing 250 mg chitosan each. The experiments were performed in a randomized, double-blind, placebo-controlled trial for 4 weeks. The results confirmed quite well those previously reported (135), but with more details and quantification. Lowering of LDL cholesterol up to 35.1% and increase of HDL cholesterol up to 11.12% were observed. Numerous other benefits related to chitosan ingestion were also mentioned, such as the decrease of arterial pressure and the increase of respiratory rate (136–139).

### 5. Fat Binding and Antilipidic Metabolism

In parallel with the ability to decrease the cholesterol level, numerous papers reported the capability of chitosan to bind fats and thus to decrease their metabolism by animals as well as humans. Thus, in a first report (128) a decrease of the triglyceride level in plasma and liver was observed in rats fed with diets containing chitosan. The inhibition of the absorption of fatty acids, bile acids, and triglycerides was claimed in a first patent in 1980 (140). A study on rats whose gut contents were examined 2 h after feeding with chitosan-containing diets gave interesting results. Thus, the ratio between the content of bile acids and phospholipids in the liquid phase and in the solid phase (after centrifugation) was significantly lowered compared to the control (without chitosan in diets). This result allowed the authors to show the uptake of bile acids and phospholipids by chitosan (141). When an emulsion containing various kinds of oils was introduced intragastrically in rats, the absorption of triglycerides was relatively low, showing that the gastric medium plays a major role on the uptake of triglycerides except for the very first terms of the series of the oligomers of glucosamine, which were inefficient (128). A

synergistic effect related to the association of chitosan and ascorbic acid in diets was investigated in a study made on rats and by the observation of ileal contents (142). It was claimed that this association should allow the uptake of 3.4 g fat per 1 g chitosan. In the same kind of study, the same team showed that both the increase of the viscosity (equivalent to the molecular weight) and the deacetylation of chitosan favor an increase of the fat binding. They also noticed that their results were dependent on the nature of the fat. Thus, the excretion was more significant with corn oil than with lard (143). The hypolipidic capability of chitosan was also demonstrated on broiler chickens fed with diets containing chitosan. This behavior was also associated with a lower weight intake (144).

Human experiments on the lipid uptake by chitosan were more recently reported (136–139). The triglyceride reduction was 26.6% associated with a weight decrease of at least 7.9 kg after 4 weeks of chitosan treatment (four tablets containing 250 mg chitosan per day).

#### 6. Mechanisms of Interaction Between Chitosan and Lipids

The mechanism of inhibition of lipid metabolism by chitosan can be attributed to either physicochemical interactions between chitosan and the substrate or to the inhibition of enzymatic mechanisms. Another question concerns the possible metabolism of chitosan and/or its degradation products. The intravenous injection of low molecular weight chitosan, as mentioned previously, has no influence on the cholesterol level in blood. In addition, although chitosan can be degraded by lysozyme produced by intestinal flora, up to this time there is no evidence of the metabolism of chitosan through the intestinal cells, whatever the molecular weight. Therefore, all the results reported in the literature agree with an effect only to the conditions of the gastrointestinal tract.

An important question concerns the possible involvement of the inhibition of pancreatic lipase by chitosan in the mechanism of antilipidic metabolism. A simple experiment (145) showed that chitosan inhibited the hydrolysis by lipase of triolein emulsified with phosphatidylcholine but not that of triolein emulsified with gum arabic and triton X-100. The conclusion is that the inhibition of lipid absorption by chitosan is essentially due to a physicochemical mechanism.

#### 7. Conclusion

All the papers mentioned agree that chitosan has the capability to reduce significantly the intestinal metabolism of all kinds of lipids. When the absorption of chitosan does not exceed a critical amount, this activity seems to be

achieved without any damage whether to the intestinal flora or to any tissue or mucous membrane in contact with the polymer. It is also interesting to note that chitosan seems to have no effect on the inhibition of lipid-specific enzymes.

The inhibition of lipid metabolism by chitosan seems essentially of physicochemical origin. In absence of chitosan, the metabolism is attributed to the micellization of lipids in the gastrointestinal tract thanks to the presence of micellizing substances such as biliary acids. These aggregates are stabilized by cholesterol and the whole can be then recognized by intestinal cells and transferred in the blood plasma.

When a solution of chitosan is added to a dispersion of lipids at 37°C (for example, oleic acid or various edible oils) in acidic conditions corresponding to the gastric media, no particular phenomena are observed and the dispersion is preserved after incubation during 30 min. If we increase the pH to intestinal conditions, we observe the formation of an impressive fatty coagulum contrary to the control (without chitosan). This fat clot corresponds to a coprecipitation of lipid aggregates formed in the presence of chitosan (see Section III.C.2) in a three-dimensional network. This clot obviously inhibits any possible recognition by lipases and intestinal cells. This mechanism agrees with all the results mentioned, especially the rejection of fatty acids, cholesterol, and triglycerides as well as biliary acids in feces. It also agrees with the noninhibition of lipases and the fact that the antilipidic activity of chitosan is not observed when chitosan is directly subjected to blood. It finally agrees with the fact that the molecular weight of chitosan is not very important except for molecular dimensions below a critical limit where the three-dimensional network cannot be formed. This mechanism, to be really observed, needs the prior solubilization of chitosan. In these conditions, we can observe *in vitro* a lipidic coagulum containing up to 30 g lipid per 1 g chitosan. It is important to remember that chitosan cannot be solubilized at pH below 2, in that case if chitosan is absorbed in a free amine form corresponding to a powder in capsules or tablets, the efficacy is very low and limited to the high intestine at the beginning of the increase of pH. This observation certainly agrees with the low efficacy of most commercial formulations. It is also important to notice that all formulations including polyanions such as ascorbic acid, etc., necessarily contribute to limit this efficacy.

#### C. E-3-Pharmacology

Chitosan has very interesting physical and physicochemical properties which provide it with numerous possible applications in the field of pharmacology. Since another com-

plete chapter in this book is devoted to this application, we will concentrate especially on the physicochemical and physical aspects. Thanks to its properties, chitosan has been extensively studied in the field of vectorization and sustained release of drugs. The bioactivity of this biopolymer has also been shown as favoring the targeting or the induction of some synergistic effects.

### 1. Vectorization

Chitosan is a biodegradable, bioresorbable, biocompatible, and bioactive polymer. Moreover, it is highly functionalized and as a consequence it can be considered as an interesting tool for the vectorization of drugs.

We first mention the simple case of the vectorization of anionic forms of acids (17). Indeed, chitosan is a weak alkali with a  $pK_0$  close to 6.5. Thus, the salts prepared from weak acids and chitosan are easily displaced and anionic forms of acids are then liberated in the media. We have the particular case of  $\alpha$ -hydroxyacids, which are weak acids but are strongly complexed with chitosan by means of hydrogen bonds between OH groups. This simple kind of vectorization can also be observed at physiologic pH where chitosan is essentially in the free amino form and is then a strong complexing agent of metals. These complexes are pending forms (27) and chitosan can be used for the vectorization of some transition or alkaline earth metals and actinides.

An important research activity has been developed during the last 10 years in Japan on the vectorization of 5-fluorouracyl. This drug is well known for its antitumoral activity but unfortunately also for its high toxicity. It was first bound covalently to a hexamethylene spacer by a carbamoyl bond (146), then to chitosan through an amide bond on the amine groups of the glucosamine residues. This system was successfully used to treat various tumors, especially fibrosarcoma cells. After inoculation of these cells to rats, the 5-fluorouracyl–chitosan conjugate was administered to animals at different doses and at various times. On day 30 after inoculation of the tumoral cells, the mice were sacrificed. The inhibition ratio was then measured for the different cases. It is interesting to note that chitosan alone had an antitumoral activity. Also, a synergy was observed with the drug vector compared to treatment with the drug alone. In addition to the biological activity of chitosan, this behavior was attributed to the protecting effect brought about by the polymer avoiding the dilution effect of the drug in the organism and to the targeting property of chitosan toward the tumoral cells whose phospholipidic composition of their membrane is relatively different from that of healthy cells.

Magnetic microspheres of chitosan can be used to entrap some drugs. This complex system has the advantage of being easily transported under a magnetic field toward the site to be treated. We have a sort of a double vectorization. A combined emulsion/polymer crosslinking/solvent evaporation technique was used to obtain chitosan microspheres containing the anticancer drug oxantrazole (147). The particulates were crosslinked to minimize the biodegradation and reduce the porosity. It was possible to entrap up to 3% (w/w) oxantrazole. These particulates were administered to rats intra-arterially with solutions of the same drug as reference. After subjection of the animals to a magnetic field of 6000 G for 30 and 120 s, the observation of different tissues revealed a concentration of the drug in the brain 100-fold greater than that of reference with an ipsilateral repartition. Therefore, there was a targeting effect toward the brain tissues with a maximum efficacy achieved only after 30 s exposure to the magnetic field (148). Chitosan is a good tool for this kind of application involving magnetic particles. Indeed, as mentioned, this polymer has excellent complexing properties especially with metal oxides and hydroxides.

### 2. Chitosan as an Enhancer of the Permeability of Epithelial Tissues

Several experiments reveal the property of chitosan to enhance the permeability of various mucosal surfaces. This property has been tested on intestinal epithelial cells using Caco-2 cell monolayers. Measurements of the transepithelial electrical resistance (TEER) were performed at pH 6.2 after subjection to chitosan hydrochloride at a concentration within 0.25–1.5% (w/v). The presence of chitosan caused an immediate and pronounced lowering in TEER values of 84% after 2 h incubation. The permeability was then tested by means of hydrophilic radioactive markers and revealed a large increase in the permeation of these markers. The increase of the transport of  $^{14}\text{C}$  mannitol was increased 34-fold in the presence of chitosan. In addition, no deleterious effect to the cells could be demonstrated with tripan blue exclusion studies and confocal laser scanning microscopy. The conclusion is that chitosan, due to its chemical structure, especially in the presence of cationic charges even at physiologic pH, contributes to the opening of the tight junctions and allows the paracellular transport of drugs (149).

This kind of property contributed to the recent proposal of chitosan for the nasal drug delivery of insulin (150). Solutions or particulates of chitosan glutamate containing insulin were prepared and administered to sheep. The results showed that in the presence of chitosan, the delivery

of insulin in the blood plasma was multiplied by a factor of 3 compared to the same treatment in absence of this polymer. Moreover, it was observed that the level of delivery was also multiplied by 4 when chitosan was administered in the solid form. These behaviors were attributed to the fact that chitosan can bind to the negative sites of the sialic residues in the nasal lining. Therefore, chitosan favors the paracellular transport of polar molecules thanks to a weakening of the tight junctions between epithelial cells. These interpretations are supported by an effect which increases when DA and pH decrease in relation with an increase of the charge density of the polymer chains.

### 3. Forms of Chitosan Containing Drug Delivery

The conjugation of all the properties of chitosan already mentioned point to this polysaccharide as a polymer of choice for drug delivery, via the two main routes, oral and injectable, or other pathways.

#### *a. Oral Administration*

Oral administration is certainly the most interesting for its easy processing by patients. Nevertheless, it exhibits numerous disadvantages, which in numerous circumstances limits its use. It is for this kind of drug administration that we will find the most important number of available physical forms of chitosan.

Chitosan can be proposed in the formulation of tablets in relation to several of its properties. Chitosan, especially in the salt form, is a strong water absorbent and provides tablets with the property of disintegrant in the gastrointestinal tract (151). Due to its capability to give rise to all the known chemical interactions, it constitutes an interesting binder for the processing of tablets (152). Its antiulcer properties related to its antacid behavior in the free amino form allows its association to the formulations of tablets which can be used for the administration of ulcerogenic drugs such as aspirin (153).

Granules of chitosan-containing drugs have been proposed for their capability to slowly dissolve in the gastric media. The main difference between granules and beads is that in the former case, the disintegration is the major mechanism of drug delivery whereas diffusion is in the latter. These physical forms were tested by several authors *in vitro* and *in vivo* for various drugs such as acetaminophen, ampicillin, indomethacin, nifedipine, prednisolone, sulfadiazine, and theophiline (154–160). *In vivo* experiments all agree and reveal a delayed and prolonged effect and a high blood plasma level of drug quite different to that obtained with other means of administration.

The production of microspheres and microcapsules of chitosan-containing drugs has been extensively described in the literature (161–168). In these papers, many parameters were analyzed concerning their formation, their stability, and their release of drugs. There also, various drugs were tested including aspirin, diclofenac, furosemide, indomethacin, methotrexate, nifedipine, prednisolone, theophiline, and others.

Numerous other kinds of chitosan drug delivery systems were also proposed. Thus, as already mentioned, chitosan favors and stabilizes the micellization of lipids including phospholipids (71–73,169,170). These properties were applied to improve the oral absorption of insulin by means of chitosan-coated liposomes (171). Capsules of chitosan containing R68070 were recently used as anti-inflammatory and for the treatment of ulcerative colitis, especially in the case of colon-specific delivery. A synergistic effect due to chitosan was observed in comparison with carboxymethylcellulose suspensions (172). We can also mention the studies concerning the immobilization of prednisolone (173) and indomethacin (174).

#### *b. Administration by Other Routes*

The oral route is limited by various problems, especially those related to strong irritations, the nonmetabolization through the intestinal mucosis, and the inactivation during transit in the gastrointestinal tract. The injectable, nasal, transdermal, and ophthalmic routes, can also be considered for chitosan-containing drugs. These routes are described elsewhere in this book.

## D. Biomaterials

Chitosan can be processed according to a great variety of physical forms and as a general rule most of the forms used in the field of biomaterials can be processed from either solutions or gels. If we add to this possibility the fact that chitosan has very useful biological properties, we must necessarily also consider that it represents a very interesting tool for many applications in the field of biomaterials. Numerous results in the literature reveal that chitosan is a bioactive material which stimulates cell proliferation and contributes to tissue regeneration for either soft or hard tissues, whatever the nature of the cell constitution.

### 1. Cell Activation

The first important fact is that chitosan has an immunogenic activity, which has been already discussed. Cell activation is another important factor. Cytocompatibility and the cell adhesion observed in the presence of chitosan have

also been addressed already. Administration of chitosan contributes to activate inflammatory cells leading to an enhancement of the antiphlogistic activity (175). In the presence of chitosan, mesenchymal cells generate a well-defined three-dimensional network. For most of the compartments of this scaffold an undifferentiated aspect is observed showing sometimes an endothelial appearance (176). In vivo studies on animals revealed that the organization of chitosan chains when submitted to living media where the polymer is insoluble contributes to stimulate the migration of polymorphonuclear and mononuclear cells (175). In the case of wounds, the presence of chitosan limits the exudates, thus demonstrating a positive response of the biological media (175). In this paper, it was also reported that chitosan is particularly effective in stimulating the formation of granulated tissues.

Chitosan has a chemical structure which is not so far from that of mammal glycosaminoglycans. Thus, it can constitute a material which mimics the extracellular matrix of numerous cells constituted partly of these molecules, alone or included in the structure of glycoproteins

We now examine various examples of applications of chitosan in the field of tissue regeneration.

## 2. Wound Healing of Soft Tissue

Artificial wounds created on animals, for example of 2 cm<sup>2</sup>, were treated by a chitosan material. On day 28 after treatment, a lower level of inflammatory cells than in the control was observed. Moreover, the esthetic quality was much better (177). In another experiment performed on beagles, a cotton fiber type chitosan was applied on open skin wounds for 15 days. On day 3, a severe infiltration of PMN cells was observed with an increase of effusion. Granulation was more important in the presence of chitosan than in the control on days 9 and 15. An increase of the production of collagen III was also noticed. A mitotic effect was apparent on day 6 and was delayed compared to that of the control (178).

An interesting experiment was performed on a model of abscess created experimentally in dogs after a subcutaneous inoculation of *Staphylococcus aureus* T-6, with a 4-cm silk suture (179). After draining the pus, the abscess was treated with a suspension of finely granulated chitosan and other systems. After euthanasia on day 8, the contraction of the wound cavity was as high in the case of dogs treated with a sufficient dose of chitosan (>0.1 mg) than for those treated by ampicillin. Nevertheless the best results of healing on day 8 (90%) were obtained in the group of animals treated with chitosan (only 40% with ampicillin and no healing for the control groups or for those treated with a dose of chitosan below 0.01 mg). Moreover, histological

observation showed the formation of highly vascularized granulation tissue in the group subjected to chitosan from 0.1 mg.

Chitosan was tested in vivo in other difficult conditions of wound healing. We can mention the case of the application of chitosan on wounds of the genitourinary system in dogs. Wounds were created in the kidney, ureter, and penile foreskin. Wound healing was normally achieved and a decrease of fibrosis was seen in the presence of chitosan compared to the control (180). Chitosan in the form of hydrogel obtained in the presence of ascorbic acid was also used for the regeneration of gingival tissue after an important surgical operation consecutive to the formation of dental pockets. After 2 months, the result was quite interesting and showed a very good tissue regeneration with the recovery of the gingival tissue over the level before treatment (181).

All the very good results mentioned concern epithelial tissue regeneration. In the case of endothelial tissues, the results are quite absent in the literature. This fact could be related to the absence of satisfying results in this field. This comment is corroborated by the experiments performed on the eyes of rabbits. Chitosan was applied topically after they had sustained central corneal wounds. Even after 21 days treatment, there were no apparent differences in corneal wound tensile strength between the chitosan-treated and the control eyes (182).

In the presence of cartilaginous material, chitosan can induce typical reactions. Thus, the influence of the injection of a chitosan solution in the rat knee articular cavity was studied up to 6 weeks after injection (0.2 mL of 0.1% chitosan solution). It was noticed that chitosan slows significantly the decrease in epiphyseal cartilage thickness and increases significantly articular cartilage chondrocyte densities. Nevertheless, also observed was an induction of the proliferation of fibrous tissue with abundant fibroblasts, fibrocytes, and monocytes (183). In fact, the latter problem can be related to a possible coprecipitation of chitosan and hyaluronane, proteins, etc., present in the joint cavity by PEC formation. This problem possibly does not exist when chitosan is introduced in the free amine form.

## 3. Osteogenesis by Chitosan

In vitro experiments can show the effect of chitosan on osteoblast differentiation and bone formation. Wells pretreated with chitosan solutions were seeded with stem cells. After 14 days of growth under optimal conditions, histological studies confirmed the bone formation. Image analysis led the authors to consider that chitosan potentiates the differentiation of osteoprogenitor cells and may facilitate the formation of bone (184).

In vivo experiments reveal the osteoinductive property of chitosan. Experiments were performed on rabbits by direct application of a paste made from chitosan and hydroxyapatite after removal of the osteomembrane. After 1 week treatment, immature slender trabecular bone was formed on the surface of the bone. At 2 weeks, the new bone tissue matrix showed a mosaic pattern and osteoblasts were arranged at the surrounding area. At 6 weeks the new bone tissue began to mature and continued its maturation up to 20 weeks. The new bone formation was observed to appear only at the interface between the biomaterial and the bone (185). Our experiment in this field (28) shows that the osteoinduction is due to chitosan and that hydroxyapatite has only a kinetic role on the tissue regeneration.

## VI. CONCLUSION

In this chapter we gave an overview of the properties of chitosan, deliberately neglecting its derivatives. The reason for that is simple: there is no example in the literature showing better results obtained with chitosan derivatives in the field of biomedical applications.

It is very important to understand all the properties of this polymer in order to avoid misapplication or misinterpretation. Also, it is very important to consider that this polymer may interact with numerous substances when is introduced in the living media.

The results of the literature confirm quite well the interest in the use of such a polysaccharide for numerous applications in the life sciences. In the near future, we should see the application of this polymer in various physical forms on the corresponding markets. Some new directions solving the present limitations of its use should appear. To mention a few: the use of chitin and chitosan gels and true nanoparticles (no more than a few tenths of a nanometer).

Another field which is not sufficiently explored concerns the research on the immunogenicity of chitosan, which could give very interesting results from a molecule completely absent in mammals.

# Chitosan-Based Delivery Systems: Physicochemical Properties and Pharmaceutical Applications

Radi Hejazi and Mansoor Amiji

*Northeastern University, Boston, Massachusetts*

## I. INTRODUCTION

### A. Chemical Structure of Chitosan

Chitosan [a (1 → 4) 2-amino-2-deoxy-β-D-glucan] is obtained by the alkaline deacetylation of chitin. Thus, the chitosan molecule is a copolymer of N-acetylglucosamine and glucosamine (Fig. 1) (1–3). The sugar backbone consists of β-1,4-linked glucosamine with a high degree of N-acetylation, a structure very similar to that of cellulose, except that the acetyl amino group replaces the hydroxyl group on the C-2 position. Thus, chitosan is poly(N-acetyl-2-amino-2-deoxy-D-glucopyranose), where the N-acetyl-2-amino-2-deoxy-D-glucopyranose (or Glu-NH<sub>2</sub>) units are linked by (1 → 4)-β-glycosidic bonds (4,5).

### B. Availability of Chitosan

Chitin is the second most abundant polysaccharide in nature, cellulose being the most abundant. Chitin is found in the exoskeleton of crustacea, insects, and some fungi. Chitosan has a rigid crystalline structure through inter- and intramolecular hydrogen bonding. The main commercial sources of chitin are the shell wastes of shrimp, lobster, krill, and crab. In the world, several million tons of chitin are harvested annually (4,6,18).

### C. Chemical Methodology for the Preparation of Chitosan

Shrimp or crab shell proteins are removed by treatment with 3–5% (w/v) NaOH aqueous solution at 80–90°C for a few hours or at room temperature overnight. Afterward, the product's inorganic constituents are removed by treatment with 3–5% (w/v) HCl aqueous solution at room temperature giving a white to beige colored sample of chitin. The treatment of the sample with an aqueous 40–45% (w/v) NaOH solution at 90–120°C for 4–5 h results in N-deacetylation of chitin. The insoluble precipitate is washed with water to give a crude sample of chitosan. The conditions used for deacetylation will determine the polymer molecular weight and the degree of deacetylation. The crude sample is dissolved in aqueous 2% (w/v) acetic acid, then the insoluble material is removed giving a clear supernatant solution which is neutralized with NaOH solution, resulting in a purified sample of chitosan as a white precipitate (7). Further purification may be necessary to prepare medical and pharmaceutical grade chitosan.

### D. Physicochemical and Biological Properties of Chitosan

The word chitosan refers to a large number of polymers which differ in their degree of N-deacetylation (40–98%)

**Figure 10.1** Structures of chitin (A) and chitosan (B).

and molecular weight (50,000–2,000,000 daltons). These two characteristics are very important to the physicochemical properties of the chitosans and, hence, they have a major effect on the biological properties (8).

Chitosan is a weak base with a  $pK_a$  value of D-glucosamine of about 6.2–7 and, therefore, insoluble at neutral and alkaline pH values. It does, however, make salts with inorganic and organic acids such as hydrochloric acid, acetic acid, glutamic acid, and lactic acid. In acidic medium, the amine groups of the polymer are protonated resulting in a soluble, positively charged polysaccharide that has a high charge density (one charge for each D-glucosamine unit). Chitosan can form gels by interacting with many multivalent anions (9–14).

Chitosan salts are soluble in water, the solubility depending on the degree of deacetylation (and thereby the  $pK_a$  value of the D-glucosamine) and the pH. Chitosans with low degree of deacetylation ( $\leq 40\%$ ) are soluble up to a pH of 9, whereas highly deacetylated chitosans ( $\geq 85\%$ ) are soluble only up to a pH of 6.5. Addition of salts to the solution interferes with the solubility of chitosans. The higher the ionic strength, the lower the solubility as charge neutralization occurs by increasing concentrations of counterion. Increasing degree of deacetylation increases the viscosity. This can be explained by the fact that high and low deacetylated chitosan have different conformations. Chitosan has an extended conformation with a more flexible chain when it is highly deacetylated because of the charge repulsion in the molecule. However, the chitosan molecule has a rodlike shape or a coiled shape at low degree of deacetylation due to the low charge density in polymer chain (12,15). The viscosity of chitosan solution is also affected by factors such as concentration and

temperature. As the chitosan concentration increases and the temperature decreases, the viscosity increases. The nearly linear negative dependence of viscosity on temperature could be explained by the enhanced chain flexibility and reduced root-mean-square unperturbed end-to-end distance of the polymer chains with increasing temperature (16).

Chitosan in solution exists in the form of quasiglobular conformation stabilized by extensive intra- and intermolecular hydrogen bonding. The hydrogen bonding that might attribute to the high viscosity of chitosan solutions exists mainly between the amine and hydroxyl groups of the polymer chains. Chitosans with lower degree of deacetylation have lower hydrogen bonding density because of the lower number of amino groups in the polymer chains. Since urea is capable of breaking the hydrogen bonding, the chain conformation of chitosan changes from a spherical structure in acetic acid–NaCl to a random coil conformation in acetic acid–NaCl–urea system (2). Intermolecular hydrogen bonding in chitosan is responsible for the film and fiber-forming properties of the polymer. According to Chen et al. (17), the degree of deacetylation of chitosan, which will determine the number of intermolecular hydrogen bonds, was found to affect the rigidity of the polymer film. For chitosan hydrogels, the extent of dissociation of the hydrogen bonding may affect the swelling kinetics of the gels. At low pH, the hydrogen bonding dissociates due to the protonation of the amine groups leading to faster swelling.

Because chitosan has favorable biological properties such as biodegradability (18) and biocompatibility (19,20), it has attracted a lot of attention in the pharmaceutical and medical fields. Chitosan has low oral toxicity with an  $LD_{50}$  in rats of 16 g/kg (20,21). Toxicity of chitosan might depend on different factors such as degree of deacetylation, molecular weight, purity, and route of administration. Further studies of toxicity need to be carried out for particular application of the polymer.

The pharmaceutical requirements of chitosan are as follows: particle size  $< 30 \mu\text{m}$ , density between 1.35 and 1.40 g/cc, pH 6.5–7.5, insoluble in water, and partially soluble

**Table 10.1** Chemical Properties of Chitosan

Cationic polyamine
High charge density at pH $< 6.5$
Adheres to negatively charged surfaces
Forms gels with polyanions
Low to high molecular weight range
High to low viscosity
Chelates certain transition metals
Reactive amino/hydroxyl groups

in acids (11). The chemical and biological properties of chitosan are summarized in Tables 1 and 2.

### E. Chitosan as a Biomaterial

A biomaterial is defined as a material that is capable of establishing an interaction with the surrounding biological environment without stimulating an adverse response by the host (23,24). Chitosan has a broad range of biological activities and thus has many applications. It could be used in wound healing by giving comfortable and painless wound surface protection. For burns, chitosan can be used for the development of an artificial skin that is devoid of postoperative scar formation. Chitosan could also be applied as a topical treatment for certain infections like athlete's foot infections. In purulent diseases, chitosan can accelerate the granulated tissue formation. Acting as a drug delivery system, chitosan is also used for tumor-selective drug delivery. Since chitosan acts as a chemotactic for polymorphonuclear leukocytes it is promising for treating mastitis. N-Acyl chitosan membranes and fibers are commonly used for artificial kidney. Since chitosan is highly permeable to oxygen, contact lenses made from chitosan could be worn for a long period of time. N-Octanoyl and N-hexanoyl derivatives of chitosan have blood coagulant and antithrombogenic effect. Chitosan acts as a hypocholesterolemic agent since it binds bile acids. The biopolymer has also found utility in agricultural, food, and cosmetic industries (7,25).

## II. CHITOSAN AS A BIOADHESIVE

### A. Definition of Bioadhesion

Bioadhesion is defined as the ability of a synthetic or biological material to adhere to a biological tissue for an extended period of time (26).

### B. Importance of Bioadhesion

Bioadhesive polymers have attracted a lot of attention as they can increase the residence time and also can improve the localization of controlled release formulations at the mucosal sites of administration. Bioadhesive formulations have been used for administration of drugs to the gastrointestinal tract and buccal, nasal, ocular, and vaginal routes (27–29). Examples of bioadhesive polymers include cellulose derivatives, alginates, natural gums (30–32), polyacrylates (33), hyaluronic acid (34), scleroglucan (35), and pregelatinized and modified starches (36,37).

### C. Chitosan as a Bioadhesive

In the cationic form, the D-glucosamine residue of chitosan could interact with the N-acetylneuraminic acid (sialic acid) residues of mucin by electrostatic interactions (32,38). The bioadhesive properties of chitosan may allow a prolonged interaction of the delivered drug with the membrane epithelia facilitating more efficient absorption. Increased absorption of drugs at mucosal sites by chitosan could be due to prolonged interaction with the membrane epithelia, inhibition of degrading enzymes, or opening of the tight junctions between cells to facilitate transport.

Table 3 illustrates the role of chitosan in increasing the absorption of drugs at mucosal sites.

#### 1. Bioadhesive and Rheological Properties

Ferrari et al. (39) studied the rheological and bioadhesive properties of three viscosity grades of chitosan: high, medium, and low. They found that the temperature and the pH of the hydration medium could influence the rheological properties of the three grades of chitosan. The polymer solutions and polymer–mucin mixtures prepared at the same concentrations were subjected to mucoadhesive testing with a tensile stress tester. All of the grades of chitosan were found to strongly interact with mucin and can be excellent candidates for use in bioadhesive formulations. Table 4 illustrates the maximum force of detachment and the work of adhesion of polymer solutions and the polymer–mucin mixtures. For the high grade chitosan, the force of detachment was 1038.8 mN for polymer alone and 1420 mN for the polymer–mucin mixture. The low grade chitosan, on the other hand, had a force of detachment of 667.6 mN for polymer alone and 1345.9 mN for the polymer–mucin mixture.

#### 2. Bioadhesive Bilayered Devices as Buccal Drug Delivery Systems

Bioadhesive bilayered devices were developed by Lopez et al. (40). Chitosan was used as the adhesive material,

**Table 10.3** Chitosan as a Bioadhesive

Model compound	Function of chitosan	Reference
Nifedipine and propranolol	Mucoadhesive	40

<sup>14</sup> C mannitol	Absorption enhancer	56

<sup>a</sup> Not described.

while ethylcellulose was used as an impermeable backing material. Adhesive capacity was estimated by measuring the maximum detachment force using a tensile tester. Bovine sublingual mucosa was used as the biological substrate. The detachment force of buccal bilayered devices based on chitosan was 0.5 N/cm<sup>2</sup>, while for the buccal bilayered devices based on chitosan crosslinked with polycarbophil, the detachment force was 0.85 N/cm<sup>2</sup>. Cross-linking of chitosan with polycarbophil allowed further swelling and hence enhanced adhesion. To evaluate these new devices as buccal drug delivery systems, a lipophilic drug, nifedipine, and a hydrophilic drug, propranolol hydrochloride, were entrapped. Almost 100% of propranolol was released within 4 h, while only 30% of nifedipine was released within 6 h. Propranolol release was faster than nifedipine because of the higher solubility of the drug in the release medium.

### 3. Poly(Vinyl Alcohol) Gel Spheres Containing Chitosan

Sugimoto et al. (41) formulated poly(vinyl alcohol) gel spheres that contained chitosan. When administered orally, the bioavailability of ampicillin, a poorly absorbable drug, was significantly improved. The bioavailability was further increased by the addition of chitosan. Seventy percent of the ampicillin oral solution was unabsorbed and entered the large intestine. The absorption of ampicillin from chitosan-containing gel spheres occurred for a longer period of time than from gel spheres without chitosan. The residence time of the gel spheres in the small intestine was increased by chitosan addition and the period of absorption of ampicillin was increased. Table 5 illustrates the pharmacokinetic parameters of ampicillin after oral administration of poly(vinyl alcohol) gel spheres and

**Table 10.4** Force of Detachment and Work of Adhesion of the Three Viscosity Grades of Chitosan Hydrated in 0.1 M HCl

Chitosan grade	Force of detachment (mN)		Work of adhesion ( $\mu$ joule)	
	Polymer alone	Polymer + mucin	Polymer alone	Polymer + mucin
Low	667.6	1345.9	71.4	182.5
Medium	784.8	1154.9	85.8	170.2
High	1038.8	1420.0	101.3	166.6

Chitosan–poly(vinyl alcohol) gel spheres	10.63	4.79	4.28	0.485

Note: The dose of ampicillin was 50 mg/kg.

<sup>a</sup> AUC is the area under the plasma concentration–time curve of the drug for the different formulations.

<sup>b</sup> MRT is the mean release time of the drug for the different formulations.

<sup>c</sup> MAT is the mean absorption time of the drug for the different formulations.

Source: Adapted from Ref. 41.

chitosan–poly(vinyl alcohol) gel spheres in rats. The bioavailability of ampicillin in solution medium is only 31.6%; however, the bioavailability of the drug was increased up to 48.5% using chitosan–poly(vinyl alcohol) gel spheres.

#### 4. Acyclovir-Loaded Chitosan Microspheres

Since acyclovir is a relatively hydrophilic antiviral drug, its permeability through the ophthalmic epithelium is very low. A drug delivery system that can prolong the release of acyclovir and increases the residence time at the site of absorption will enhance the bioavailability of the drug in the eye. Acyclovir-loaded chitosan microspheres with a diameter of  $\leq 20 \mu\text{m}$  were prepared (42). Following administration into the rabbit eye, the area under the aqueous humor concentration–time curve from 0 to 240 min of the drug-loaded chitosan microspheres was  $172 \mu\text{g} \cdot \text{min}/\text{mL}$ . However, for the control suspension formulation, the area under the aqueous humor concentration–time curve from 0 to 240 min was only  $39.3 \mu\text{g} \cdot \text{min}/\text{mL}$ . The total dose of acyclovir was 0.26 mg for both the microsphere formulation and the suspension. The maximum drug concentration in the aqueous humor was reached after 240 min from the drug-loaded chitosan microspheres. However, for suspension formulation, the drug was not detected after 120 min. Chitosan microspheres were able to prolong the residence time and increase bioavailability of acyclovir.

#### 5. Bioadhesion of Hydrated Chitosans

Freshly excised bovine corneas were treated with tritiated [<sup>3</sup>H] chitosan in solution. A two-cubic factorial design was used to find out the effect of parameters like pH, ionic strength, residence time, and chitosan molecular weight on the adsorption of chitosan on the corneal surface. All of the parameters were significant for the adsorption. Also, the interaction between these parameters was observed. In the in vivo study, liposomes and chitosan-coated lipo-

somes, containing <sup>125</sup>I-labeled bovine serum albumin (BSA), were instilled into the eyes of anesthetized Wistar rats. Liposomes were produced using egg L- $\alpha$ -phosphatidylcholine and egg L- $\alpha$ -phosphatidyl-DL-glycerol in a ratio of 10:1. Free <sup>125</sup>I-BSA (7  $\mu\text{L}$  approximating 300–600 nCi) or BSA loaded in liposomes or chitosan liposomes was applied to each eye. The eyelids and eyes were excised, and then the eyes were washed with 1 mL 1% Triton X-100 to remove excess <sup>125</sup>I-BSA on the surface. The retention of radioactivity in the eyes at 10, 30, and 90 min was measured. Table 6 shows the total recovery of free <sup>125</sup>I-BSA, or liposome and chitosan-coated liposome-entrapped <sup>125</sup>I-BSA instilled into the eyes of anesthetized rats. Both coated and noncoated liposomes had significantly higher retention of <sup>125</sup>I-BSA than from solution. The retention of chitosan-coated liposomes, however, was not significantly

**Table 10.6** Total Percentage Recovery of Free Albumin, Albumin Loaded in Liposome and Chitosan-Coated Liposome Instilled into the Eyes of Anesthetized Rats

Time (min)	Formulation	Average percentage in the eye
0	Free BSA	42.2
10	Free BSA	6.8
	Liposomes	17.3
	Chitosan-coated liposomes	23.9
30	Free BSA	8.1
	Liposomes	23.7
	Chitosan-coated liposomes	20.2
90	Free BSA	5.4
	Liposomes	10.3
	Chitosan-coated liposomes	11.0

Note: Bovine serum albumin was labeled with iodine-125 and administered at a dose of 7  $\mu\text{L}$ , approximating 300–600 nCi.

Source: Adapted from Ref. 43.

different from noncoated liposomes (43). After 90 min, the percent retention in the eye of BSA in solution was 5.4%, while for liposomes and chitosan-coated liposomes the adhesive percentage was around 11%.

## 6. Chitosan-Coated Liposomes

Takeuchi et al. (44) developed polymer-coated liposomes as a novel drug carrier system for the oral administration of insulin. The polymers were chitosan, poly(vinyl alcohol) having a long alkyl chain, and poly(acrylic acid) that had cholesteryl groups. Isolated rat intestine was used for the *in vitro* evaluation of the bioadhesiveness of the polymer-coated liposomes. The number of liposome particles was measured with a Coulter counter after administering the liposome suspension in the isolated rat intestine. The adhesive percentage was calculated by dividing the difference between the number of liposomes before and after contacting with the intestine by the number of liposomes in suspension multiplied by 100. The particle counting method was adopted after confirming a linear relationship between the number of chitosan and the lipid concentration. Table 7 illustrates the adhesive percentage of liposomes coated with various polymers to the rat intestine. The polymer-coated liposomes showed higher adhesive percentage than the noncoated liposomes. The bioadhesive polymer layer on the surface of the liposomes resulted in the attachment of these liposomes to the intestinal mucosa. Chitosan-coated liposomes had the highest adhesive percentage among all of the polymer-coated liposomes tested. For *in vivo* study, rats were used for the drug absorption. For all the formulations administered orally, 24 IU was used as a dose of insulin. Insulin solution, at an equivalent dose, was used as a reference, and the blood glucose level without administering any formulation was kept as control. After the oral administration of chitosan-coated liposomes loaded with insulin, the reduction in the basal blood glu-

cose level was more than that caused by noncoated liposomes or insulin solution for at least 12 h. For instance, a 10% reduction in the basal blood glucose level occurred following the administration of noncoated liposomes or insulin solution after 8 h. However, the reduction in the basal glucose level increased to 33% after the administration of chitosan-coated liposomes in the same time period.

## 7. Chitosan–Ethylenediaminetetraacetic Acid Conjugate

Schnurch et al. (45) have developed a chitosan-based bioadhesive system in which leucine enkephalin was protected from luminal degradation, particularly by aminopeptidase N, one of the most abundant membrane-bound peptidases. Ethylenediaminetetraacetic acid (EDTA), a chelating agent that can complex with divalent metal ions, was conjugated with chitosan. The conjugate was able to bind with zinc, a cofactor for aminopeptidase N activity. The hydrolysis of L-leucine-p-nitroanilide by aminopeptidase N was completely inhibited in the presence of the chitosan–EDTA conjugate. Schnurch et al. (46) showed that the detachment force of chitosan–EDTA conjugates with a D-glucosamine subunit of chitosan to EDTA at a molar ratio of 1:20 was 43.7 mN with mucin, while for unmodified chitosan the detachment force was only 33.1 mN. Also, it was noticed that chitosan–EDTA conjugates do not precipitate once they form complexes with low concentrations of bivalent cations.

Chitosan–EDTA conjugates were found to inhibit the enzymes carboxypeptidase A and aminopeptidase N. After 13 min, the substrate hippuryl-L-phenylalanine was completely hydrolyzed by carboxypeptidase A in the presence of 0.125% chitosan. However, in the presence of the chitosan–EDTA conjugate with a molar ratio of 1:20, 60% inhibition of the enzyme was observed. *para*-Nitroaniline is produced from the hydrolysis of L-leucine-p-nitroanilide by aminopeptidase N. In the presence of 1% chitosan, the concentration of p-nitroaniline after 120 min was almost 170  $\mu$ M. This concentration was reduced to 60  $\mu$ M in the presence of chitosan–EDTA conjugate. Chitosan–EDTA conjugate, therefore, was able to partially inhibit the proteolytic enzyme without compromising the bioadhesive property.

## 8. Chitosan–EDTA Linked with Bowman–Birk Inhibitor

In a separate study, Schnurch et al. (47) examined the bioadhesive polymer that can protect peptide drugs from degradation by the most abundant enzymes in the small intestine. The Bowman–Birk inhibitor (BBI), a protein of a

**Table 10.7** Adhesive Percentage of Liposomes Coated with Various Polymers to the Rat Intestine

Liposomes formulation	Adhesive percentage
Noncoated liposomes	3
Chitosan-coated liposomes	45
Poly(acrylic acid) with a cholesteryl group	12
Poly(vinyl alcohol) having a long alkyl chain	22

*Notes:* The polymers were dissolved in phosphate buffer solution (pH 7.4) at a concentration of 0.75% (w/v). Adhesive percentage was determined as discussed in the text.

*Source:* Adapted from Ref. 44.

molecular weight of 8000 daltons derived from soybean, inhibits serine proteases such as trypsin and chymotrypsin. The bioadhesive polymer chitosan–EDTA that was found to inhibit carboxypeptidase A and aminopeptidase N (45) was covalently linked to the BBI. Using native porcine mucosa, tensiometer studies showed that the bioadhesion of polymer–inhibitor conjugates was less than that of unmodified chitosan–EDTA. The loss in bioadhesion was proportional to the inhibitor concentration. The average adhesive strength of unmodified chitosan–EDTA was 54.4 mN, while for the comparably most adhesive polymer–inhibitor conjugate was 21.0 mN. Hydrolysis of the substrate N- $\alpha$ -benzoylarginine ethyl ester to N- $\alpha$ -benzoylarginine by trypsin was determined at 1-min intervals for 9 min at pH 6.8 and 20°C. After 9 min, using 0.055% of chitosan–EDTA conjugate, 10% of the enzyme activity was inhibited. Using the same concentration of chitosan–EDTA–BBI conjugate (5:1 ratio), 70% of the enzyme activity was inhibited. Hydrolysis of the substrate hippuryl-L-phenylalanine to L-phenylalanine and hippurate by chymotrypsin was also inhibited by chitosan–EDTA–BBI conjugate. Although this novel drug carrier matrix can protect peptides from the enzymatic attack in the intestine after oral administration, there was a compromise in the bioadhesion property of chitosan.

#### 9. Chitosan as an Absorption Enhancer of Buserelin

Luessen et al. (48) showed that the intestinal absorption of buserelin, a synthetic nonapeptide with a molecular weight of 1240 daltons, was enhanced by chitosan in rats. Since chitosan did not inhibit the proteolytic enzyme activity, it was assumed that opening of the intercellular junctions by chitosan could lead to the enhancement of peptide absorption across the mucosa. Table 8 lists the pharmaco-

kinetic parameters after intraduodenal administration of buserelin at a total dose of 500  $\mu$ g. The bioavailability of buserelin was higher when delivered with chitosan polymer than that of the crosslinked polyacrylate. While the absolute bioavailability of buserelin was 0.6% using freeze-dried sodium salt of crosslinked poly(acrylic acid), the bioavailability increased to 5.1% for chitosan formulation when the same dose of buserelin was administered. The authors concluded that the enhancement of buserelin bioavailability was probably by opening of the intercellular junctions. The enzyme inhibitory activity was thought not to be as important as the opening of tight junctions, thus enhancing the permeability.

#### 10. Chitosan Glutamate as an Absorption Enhancer of 9-Desglycinamide, 8-L-Arginine Vasopressin

Borchard et al. (49) used well-characterized colon carcinoma (Caco-2) cell culture system as an in vitro model for the intestinal epithelium. Chitosan glutamate influenced the structure of the epithelial tight junctions, thus enhancing the peptide uptake through the paracellular route. Transepithelial electrical resistance (TEER) is an indicator of the permeability of ionic molecules across the cell monolayer. Chitosan glutamate decreased TEER indicating that the polymer was able to affect the permeability of epithelial cell monolayers in vitro.

Using chitosan glutamate having a concentration of 1% (w/v), almost 1.2% of the total dose of 9-desglycinamide, 8-L-arginine vasopressin, a peptide containing eight amino acids, was transported in vitro across the Caco-2 cell monolayers within 4 h. While for the control only 0.2% of the total dose of 9-desglycinamide, 8-L-arginine vasopressin dissolved in the culture medium was transported in the same time period (50).

**Table 10.8** Pharmacokinetic Parameters After Intraduodenal Administration of Buserelin

Polymer	T <sub>max</sub> (min)	C <sub>max</sub> (ng/mL)	Absolute bioavailability (%)
Buserelin in buffer medium <sup>a</sup>	60–90	6.7	0.1
C934P gel (0.5%) <sup>b</sup>	40–90	112.1	1.9
FNaC934P gel (0.5%) <sup>c</sup>	40–60	45.8	0.6
Chitosan–hydrochloride gel (1.5%)	40–90	364.0	5.1

Note: The dose of buserelin administered was 500  $\mu$ g per rat.

<sup>a</sup> Buserelin in a buffer solution (pH 6.7) was used as control.

<sup>b</sup> C934P is the crosslinked form of poly(acrylic acid) available as Carbopol® 934P.

<sup>c</sup> FNaC934P is the freeze-dried sodium salt of crosslinked poly(acrylic acid).

### 11. Chitosan as an Absorption Enhancer of Insulin

It is believed that the structural reorganization of tight junction-associated proteins could happen as a result of the interaction of chitosans with the cell membrane. This leads to the enhanced transport through the paracellular pathway (51). Illum et al. (52) showed that chitosan can enhance the absorption of insulin, a polypeptide composed of 51 amino acids and having a molecular weight of 6000 daltons, from the nasal cavity in sheep. The area under the plasma insulin concentration–time curve was 1346 mIU/L following the nasal administration of 2 IU/kg sodium human insulin solution in sheep. The area under the plasma insulin concentration–time curve increased to 9809 mIU/L after the nasal administration of 2 IU/kg sodium human insulin solution with 0.5% (w/v) chitosan solution. The histological studies were conducted using light microscopy. Using the epithelium of the nostril of rat that was not treated with chitosan formulation as a control, the nasal epithelium of the other nostril was more disordered than the control after exposure to chitosan formulation. Normal permeability properties of the nasal membrane were regained after 60 min. Thus, chitosan acted as an absorption enhancer on the nasal membrane in a reversible fashion. Eventually, this chitosan delivery system enhanced the nasal uptake of insulin without using penetration-enhancing agents that could be damaging to the nasal mucosa. Further studies are necessary to investigate how chitosan affects the integrity of the nasal epithelial cells. In addition, opening the tight junction for 60 min might lead to certain complications such as the passage of foreign particles through the nasal mucosa that could be dangerous, especially if these particles reach other areas of the body.

### 12. Chitosan as an Absorption Enhancer of Morphine-6-Glucuronide

Although chitosan could affect the integrity of the tight junction between cells, it also can delay the mucociliary clearance. The mucociliary transport rates were depressed longer by increasing the molecular weight of chitosan (53). Chitosan, an absorption enhancer, was administered nasally in combination with morphine-6-glucuronide, a morphine metabolite that has a molecular weight of 461.5. Table 9 shows the pharmacokinetic parameters for morphine-6-glucuronide after intravenous and nasal administration to sheep. Following nasal administration, the maximum plasma concentration was obtained after 13 min. Relative to intravenous injection, the bioavailability of morphine-6-glucuronide after nasal administration in sheep was 31.4%. Nasal administration of morphine-6-glucuronide combined with chitosan could be a good route of administration for this analgesic compound for pain relief that necessitates a

**Table 10.9** Pharmacokinetic Parameters of Morphine-6-Glucuronide After Intravenous and Nasal Administration to Sheep

Pharmacokinetic parameter	Intravenous	Nasal
C <sub>max</sub> (ng/mL)	50	132
T <sub>max</sub> (min)	3	13.2
AUC (ng · min/mL <sup>1</sup> · kg <sup>1</sup> )	2,928	9,314
Bioavailability (%)	100	31.4

*Note:* The doses of morphine-6-glucuronide administered intravenously and nasally were 0.015 mg/kg and 0.15 mg/kg, respectively, in 0.9% (w/v) sodium chloride solution.

*Source:* Adapted from Ref. 54.

rapid onset of action. Unfortunately, in this study the authors have failed to show a comparative bioavailability associated with the nasal administration of morphine-6-glucuronide in saline solution without chitosan (54).

### 13. N-Trimethyl Chitosan as an Absorption Enhancer

Chitosan salts, such as chitosan hydrochloride or glutamate, can enhance the absorption of large hydrophilic compounds through the mucosal surfaces. Chitosan salts, however, will only be soluble at pH <6.5. To enhance the solubility at neutral pH, N-trimethyl chitosan chloride was synthesized (55). Reduction in the TEER of Caco-2 cells by 25% was observed when chitosan derivative was applied at 0.25% (w/v) concentration. Using the same polymer concentration, the transport rate of [<sup>14</sup>C]-mannitol was increased by 11-fold. Confocal laser scanning microscopy study showed that N-trimethyl chitosan chloride was able to open the tight junctions of the intestinal epithelial cells increasing the transport of hydrophilic compounds through the paracellular transport pathway. The authors, however, did not examine the bioadhesive properties of N-trimethyl chitosan for comparison with unmodified chitosan (56).

## III. pH-SENSITIVE CHITOSAN HYDROGELS

### A. Definition of Hydrogels

Hydrogels are defined as three-dimensional crosslinked polymeric material that can absorb significant amounts of water (57). Implants (58), contact lenses (59), and controlled-release drug delivery systems (60) are examples of different biomedical applications where hydrogels have been used. Changes in the environmental factors such as temperature, pH, light, and electrical field might cause a

phase transition of certain hydrogels. These hydrogels are important as physiologically responsive drug delivery devices (61,62).

## B. Interpenetrating Polymer Networks

Interpenetrating polymer networks (IPNs) are blends of polymers in a network configuration. They are intimate mixtures of two or more different crosslinked polymer networks without covalent bonding between the polymers. Thus, each polymer is crosslinked only with other molecules of the same polymer to provide the physical and chemical combination of two or more structurally dissimilar polymers. In this way, the properties of the polymers such as processing, flexibility, tensile and impact strength, and chemical and flammability resistance could be modified to meet specific needs (63). Semi-IPN is defined as a graft copolymer in which one of the polymers is crosslinked, while the other is linear, so different morphologies and properties are developed (64).

## C. pH-Sensitive Chitosan Hydrogels

In acidic environment, the primary amine group of the D-glucosamine residue is protonated making chitosan positively charged. Like charges on the polymer chains lead to electrostatic repulsion and swelling in the network, probably due to the osmotic effect of bound counterions. In the neutral or alkaline environment, the decrease in cationic charge density leads to the collapse of the hydrogel network. The pH-sensitive swelling system would be useful for localized drug delivery in a specific region of the gastrointestinal tract (65).

Table 10 illustrates the different types of semi-IPNs of chitosan that have been evaluated.

### 1. pH-sensitive Semi-IPN by Crosslinking Chitosan with Glutaraldehyde

Chitosan–poly(propylene glycol) blends were crosslinked with glutaraldehyde by Schiff's base reaction mechanism

to form novel pH-sensitive semi-IPNs (66). In the presence of the polyether, infrared analysis showed that the semi-IPN was formed by crosslinking the amine groups of chitosan with the aldehyde groups of glutaraldehyde. Also, there was hydrogen bonding between amino hydrogen and oxygen from polyether. The semi-IPN response to pH changes was reversible. At pH 1, the ionization of the amino groups occurred leading to dissociation of the hydrogen bonding in the network. At pH 13, however, the association of the hydrogen bonding occurred because of the increase in the unionized fraction of the amino groups.

### 2. Chitosan–Poly(Propylene Glycol) Semi-IPN

The pH-sensitive swelling behavior of chitosan–poly(propylene glycol) semi-IPN was examined by Yao et al. (67). The swelling kinetics experiments were conducted by placing the preweighted initially dry samples of semi-IPN gel in the buffer solution and the weight of the swollen samples was measured as a function of time. The degree of swelling at predetermined intervals was measured by dividing the difference between the weight of the swollen gel and the dry gel by the weight of the swollen gel multiplied by 100. At pH 3.19 the swelling was maximal having a swelling ratio of 10% after 50 min, while at pH 13.0 the swelling was minimal having a swelling ratio of 0.2%. Infrared analysis confirmed that when the hydrogels were transferred from an acidic medium to an alkaline medium, the  $\text{NH}_3^+ \rightarrow \text{NH}_2$  transition was reversible.

### 3. Chitosan–Poly(Ethylene Glycol Diacrylate) Semi-IPN

Semi-IPN hydrogels composed of  $\beta$ -chitosan and poly(ethylene glycol diacrylate) macromer (PEGM) were synthesized by adding 10 wt% PEGM aqueous solution into 2 wt%  $\beta$ -chitosan solution that was prepared by dissolving  $\beta$ -chitosan in acetic acid aqueous solution. Hydrogel films were prepared by casting the PEGM– $\beta$ -chitosan solution. The hydrogels were formed by 2,2-dimethoxy-2-phenyla-

**Table 10.10** pH-Sensitive Swelling Hydrogels

Type of semi-IPN	Drug	Reference
Crosslinked glutaraldehyde chitosan semi-IPN	ND <sup>a</sup>	66
Chitosan–poly(propylene glycol) semi-IPN	Chlorhexidine acetate	67
Chitosan–poly(ethylene glycol diacrylate) semi-IPN	ND <sup>a</sup>	68
Chitosan–poly(ethylene oxide) semi-IPN	Riboflavin	69
Freeze-dried chitosan–poly(ethylene oxide) semi-IPN	Amoxicillin and metronidazole	71

<sup>a</sup> Not described.

cetophenone, a nontoxic photoinitiator, using ultraviolet radiation. High equilibrium water content in the range of 77–83% was observed for the photocrosslinked hydrogels and was mainly attributed to the free water content rather than the bound water, hydrogen bonded with components of the semi-IPN hydrogels. The crystallinity, thermal properties, and mechanical properties of semi-IPN hydrogels were examined as well. The crystallinity of chitosan–PEGM photocrosslinked hydrogels was reduced. Cross-linked PEGM segment in the semi-IPNs showed higher glass transition temperature than that of poly(ethylene glycol) itself. The number of crosslinkable acrylate end groups that contribute to the lower glass transition temperature decreased by increasing the  $\beta$ -chitosan content in the semi-IPNs. Since hydrogels in the wet state are more rubbery, the tensile strength values of semi-IPNs in the wet state were much lower than those in the dry state (68).

#### 4. Chitosan-Poly(Ethylene Oxide) Semi-IPN

By crosslinking blends of chitosan and poly(ethylene oxide) (PEO) with an average molecular weight of 1,000,000 daltons with glyoxal, a pH-sensitive semi-IPN hydrogel system was prepared (69). The swelling of chitosan hydrogels was not significant in simulated gastric fluid (SGF) of pH 1.2 or simulated intestinal fluid (SIF) of pH 7.0. However, after 6 h in SGF, the swelling of chitosan–PEO semi-IPNs was about six times higher than that of chitosan hydrogels. The increase in the internal osmotic pressure of the network with the addition of high molecular weight PEO could explain the higher swelling ratio. In other words, at higher osmotic pressure, hydronium ions were able to diffuse into the network at a faster rate leading to a higher charge density. Also, the crystallinity of chitosan matrix might be decreased as a result of the intermolecular association between chitosan and PEO in the semi-IPN. In addition, the presence of PEO in the network may also facilitate the absorption of aqueous medium.

The swelling ratio of the hydrogel increased by increasing the molecular weight and the amount of incorporated PEO. High molecular weight PEO was important for the initial swelling of the hydrogels. Thus, PEO having molecular weight of 1,000,000 daltons was chosen to prepare chitosan–PEO semi-IPN. The swelling ratio of chitosan–PEO semi-IPN in SGF was ten times higher than that in SIF. After 6 h, almost 50% of riboflavin was released from chitosan–PEO semi-IPN in SGF. However, only 30% of the drug was released from chitosan–PEO semi-IPN in the intestinal fluid after 6 h. The drug release from chitosan hydrogels was significantly lower than from chitosan–PEO semi-IPN. Only 30.2 and 6.6% of riboflavin was re-

leased from chitosan hydrogels after 6 h in SGF and SIF, respectively (70).

#### 5. Freeze-Dried Chitosan–Poly(Ethylene Oxide) Semi-IPN

For stomach-specific antibiotic delivery, freeze-dried chitosan and chitosan–PEO semi-IPN hydrogels containing PEO of molecular weight 1,000,000 daltons were prepared for faster swelling and drug release (71). Because of the rapid influx of simulated gastric fluid (pH 1.2) into the porous matrix by capillary action, the swelling of freeze-dried hydrogels was faster than for air-dried hydrogels. The swelling and drug release properties of the freeze-dried chitosan–PEO semi-IPN were affected by the porosity of the matrix, the ionization of glucosamine residues in acidic medium, and the presence of high molecular weight PEO. After 2 h in SGF, the freeze-dried chitosan–PEO semi-IPN released about 65 and 59% of the entrapped amoxicillin and metronidazole, respectively.

### IV. CHITOSAN FOR GENE DELIVERY

The course of many hereditary diseases could be reversed by gene delivery. In addition, many acquired diseases such as multigenetic disorders and those diseases caused by viral genes could be treated by genetic therapy (72–75). Gene delivery systems include viral vectors, cationic liposomes, polycation complexes, and microencapsulated systems (76–82).

#### A. Advantages and Disadvantages of Viral Vectors

Viral vectors are advantageous for gene delivery because they have high efficiency and a wide range of cell targets. However, when used *in vivo* they might exert potential immune responses and oncogenic effects. In addition, it is sometimes difficult to reproducibly prepare viral vectors in large batches (83).

#### B. Nonviral Delivery Systems

To overcome the limitations of viral vectors, nonviral delivery systems are considered for gene therapy. Nonviral delivery systems have certain advantages like ease of preparation, cell/tissue targeting, low immune response, unrestricted plasmid size, and large-scale reproducible production (83).

### C. Chitosan as a Gene Delivery Vehicle

Chitosan could be used as a carrier of DNA in gene delivery systems. It is biocompatible, biodegradable, and has an average amino group density of 0.837 per monosaccharide D-glucosamine unit. This amino group density depends on the degree of deacetylation. The cationically charged chitosan will form polyelectrolyte complexes with the negatively charged plasmid DNA. Chitosan could be modified by coupling with specific ligands, such as lactose, so the chitosan–DNA complex could be targeted to cells that express a galactose-binding membrane lectin. Chitosan–DNA complexes could be protected from DNase to improve the bioavailability of the plasmid DNA delivered into the body for gene therapy.

Table 11 summarizes the different types of chitosan or modified chitosan that have been used for gene delivery.

#### 1. Chitosan as a Delivery System for Plasmids

Negatively charged plasmid DNA will form polyelectrolyte complexes with chitosan, a polycation. Chitosan was first described as a delivery vehicle for plasmids by Mumper et al. (84). They showed that the molecular weight of chitosan ranging from 2000 to 540,000 daltons had significant influence on the particle size of chitosan-condensed DNA particles. As the molecular weight decreased, a more monodisperse particle size distribution was obtained.

#### 2. Self-Aggregates–Plasmid Complexes

Lee et al. (82) showed that self-aggregates, which were stable in aqueous media, were formed when chitosan was modified with deoxycholic acid. The hydrophobically modified chitosan self-aggregates were relatively small with a mean diameter of 160 nm and a unimodal size distribution. After mixing with plasmid of cytomegalo virus encoding chloramphenicol acetyltransferase (pCMV-CAT), the self-aggregates formed charge complexes and were

used for in vitro transfection of genes into mammalian cells. The self-aggregates–plasmid complex formation was confirmed by gel electrophoresis. The transfection efficiency of self-aggregates–plasmid complexes in kidney-derived cells (COS-1) was measured by assaying chloramphenicol acetyltransferase activity. Chloramphenicol and the products of its enzymatic hydrolysis were analyzed by thin layer chromatography and autoradiography. The transfection efficiency of chitosan self-aggregates–plasmid complexes was slightly lower than that of the commercial cationic liposome transfecting agent Lipofectamine® but higher than the transfection efficiency of the plasmid in phosphate buffer solution (pH 7.2). Using Lipofectamine, 1-acetate, 3-acetate, and 1,3-acetate metabolites were formed, while with chitosan self-aggregates–plasmid complexes only 1-acetate and 3-acetate metabolites were formed.

#### 3. Complex Coacervation of DNA with Chitosan

A nanosphere delivery system based on the complex coacervation of DNA with chitosan was developed by Leong et al. (83). The advantages of this gene delivery system are (1) the ability of conjugating these nanosphere with ligands that might help in targeting purposes or stimulating receptor-mediated endocytosis, (2) that DNA degradation could be reduced in the endosomal and lysosomal compartments by incorporating lysosomolytic agents, (3) the coencapsulation of bioactive agents or multiple plasmids, (4) the protection of the DNA from serum nuclease degradation, and (5) the stability of the nanosphere formulation after lyophilization. In addition, since polymers can reduce the degradation of plasmid by DNase, the DNA bioavailability could be improved. Plasmid–chitosan nanoparticles with a diameter of 200–300 nm were prepared using a complex coacervation method. Chitosan solution (0.02% w/v) in acetate buffer was vortexed with equal volume of DNA solution (100 µg/mL in 50 mM of sodium sulfate solution) at 55°C. Human embryonic kidney cells (HEK

**Table 10.11** Chitosan as a Gene Delivery System

Carrier type	Reference
Chitosan	84,87,88
Deoxycholic acid–modified chitosan	82
Complex coacervation of DNA with chitosan	83,85
Chitosan and depolymerized chitosan oligomers	86
Modified chitosan microspheres with transferrin and PEG	89
Lactosylated chitosan	90
N,N,N-trimethyl chitosan–galactose conjugate	91

293) were transfected *in vitro* using these nanoparticles. The transfection efficiency was evaluated with luciferase activity and green fluorescence protein. The transfection efficiency of the chitosan nanospheres was compared to that of Lipofectamine reagent. The percentage of cells transfected with the nanospheres having 5  $\mu\text{g}$  of DNA was 80% of that transfected with 1  $\mu\text{g}$  of standard Lipofectamine (85).

#### 4. Chitosan and Depolymerized Chitosan Oligomers

MacLaughlin et al. (86) showed that plasmid DNA containing cytomegalo virus promoter sequence and a luciferase reporter gene could be delivered *in vivo* by chitosan and depolymerized chitosan oligomers to express a luciferase gene in the intestinal tract. The morphology and size of plasmid–chitosan complexes were characterized by transmission electron microscopy. The transfection of kidney-derived cells (COS-1) with complexes was assayed by measuring the relative luciferase unit per milligram of protein. The expression level of chitosan complexes (chitosan molecular weight 102,000 daltons) was 250-fold less than that of the plasmid–Lipofectamine, a positive control. By incorporating an endosomolytic peptide GM227.3 (Genemedicine, Inc., The Woodlands, TX), the transfection was increased four times as compared with the complex without the peptide. A plasmid consisting of cytomegalo virus promoter sequence and a chloramphenicol acetyltransferase reporter gene was complexed with chitosan and administered in the upper small intestine or in the colon of female New Zealand rabbits. At 72 h postinstillation, the rabbits were sacrificed and tissues were collected for chloramphenicol acetyltransferase expression. The average chloramphenicol acetyltransferase expression after plasmid–chitosan–GM227.3 complex administration was 7.06 pg/mg in the mesenteric lymph nodes. However, for the control (plasmid in 10% lactose), there was no detectable chloramphenicol acetyltransferase activity in the mesenteric lymph nodes.

#### 5. Biodistribution of Chitosan-Complexed DNA

The bioadhesion of intravenously injected chitosan and the ability to complex and prevent DNA degradation was investigated by Richardson et al. (87,88). The molecular weight of highly purified chitosans varied from <5000 to >10,000 daltons. For the low molecular weight  $^{125}\text{I}$ -labelled chitosan (<5000), 26.5% of the dose was in the liver, 32.2% in the blood pool, and 19.1% in the urine after 1 h of administration. In contrast, 82.7% of the high molecular weight chitosan (>10,000) was in the liver and only 2.6% in the blood pool after the same time period. The

hemolytic potential of chitosans in terms of percent hemoglobin released was evaluated spectrophotometrically at 550 nm. For all of the chitosans, less than 10% of hemolysis was observed even after 5 h of incubation. Agarose gel electrophoresis showed that all chitosans complexed with DNA. DNA degradation was assayed spectrophotometrically at 260 nm and the degradation by DNase II was reduced *in vitro* when condensed with chitosan.

#### 6. Modified Chitosan Nanospheres

Chitosan nanospheres containing 2  $\mu\text{g}$  of plasmid DNA encoding luciferase gene and containing respiratory syncytial virus promoter sequence were modified with transferrin and poly(ethylene glycol) (PEG) (89). The size range of these microspheres was between 200 and 700 nm as determined by differential interference microscopy and photon correlation spectroscopy. The transfection of HEK 293 cells was measured by assaying the luciferase activity in permeabilized cell extracts. The transfection efficiency of chitosan–DNA nanospheres was not significantly higher than that of the Lipofectamine control. After lyophilization, the PEG-treated nanospheres were also capable of transfecting cells and the luciferase expression was  $7 \times 10^7$  light units/min  $\cdot$  mg protein. The transfection efficacy of the PEG-treated nanospheres was maintained for 1 month. The higher transfection of lyophilized PEG-treated nanospheres could be due to the fact that PEG might stabilize the nanospheres against aggregation.

#### 7. Lactosylated Chitosan for Cell Targeting

One of the promising uses of chitosan for targeted gene delivery was described by Erbacher et al. (90). The authors developed a lactose conjugate of chitosan and condensed DNA to form stable complexes with a size of about 100 nm. The complex formation was confirmed by transmission electron microscopy. Interestingly, after the chemical modification by lactose, chitosan could be targeted to certain cells like hepatocytes since they have galactose-binding membrane lectins. The authors conducted several transfection experiments mediated by chitosan and lactosylated chitosans. Uterocervical carcinoma cells (HeLa) were transfected with luciferase gene with cytomegalo virus promoter sequence plasmid complexed with chitosan. The gene expression was measured by luciferase assay and expressed as relative luciferase unit (RLU) per milligram of protein in cell lysates. Chitosan–DNA complexes with the number of chitosan nitrogen per DNA phosphate ratio (N/P) of 3 gave the highest transfection efficiency of  $3 \times 10^7$  RLU/mg protein after 72 h post-transfection. To selectively deliver a gene, lactosylated chitosans were used as vectors for targeted delivery to cells expressing a galac-

tose-specific membrane lectin [normal mouse liver cells (BNL CL2) or human hepatoma cells (Hep G2)]. These cells were poorly transfected by lactosylated chitosan with the luciferase activities below  $10^5$  RLU/mg of protein. The low transfection efficacy could be explained by the fact that the lactosylated chitosan complexes do not have as many cationic amino groups. Lack of cationic charge on chitosan may decrease DNA complexation or charge-mediated interactions with the cell surface.

#### 8. Quaternary Chitosan with Galactose Residues

Murata et al. (91) synthesized N,N,N-trimethyl chitosan-galactose conjugate, a quaternary chitosan with recognizable galactose residues. This conjugate was targeted to human hepatoma cells (HepG2) which express galactose binding membrane lectin receptors on the surface. After interacting with the plasmid, a formation of a neutral polyelectrolyte complex was confirmed by gel electrophoresis. After incubating the human hepatoma cells in a culture medium, the expression of  $\beta$ -galactosidase activity by the polycation-luciferase with simian virus promoter sequence plasmid complex was measured using a microplate reader at 420 nm. An absorbance value of 0.1, reflecting low  $\beta$ -galactosidase activity, was obtained by the conjugate. A similar  $\beta$ -galactosidase activity was observed for diethylaminoethyl dextran-complexed plasmid, used as a control.

### V. CHITOSAN AS A VACCINE CARRIER AND MUCOSAL ADJUVANT

#### A. Vaccine Carriers

Many approaches to enhance the absorption of proteins and peptides across the gastrointestinal, urinogenital, and nasal mucosae have been developed. Among these approaches are the use of absorption enhancers and coadministration of enzyme inhibitors. However, the implication of this approach is to alter the membrane permeability, thus allowing foreign particles to go through. For this reason, a better approach is to deliver antigens entrapped in a carrier

system. These carriers could be liposomes, poly(methyl methacrylate), poly(ethylene vinyl acetate), poly(lactide-co-glycolide), albumin, and starch (92).

Chitosan has interesting features that render it as a good vaccine carrier. This compound is mucoadhesive, biocompatible, and can enhance the penetration of proteins and peptides across the nasal, gastrointestinal, and urinogenital mucosae. Chitosan could be associated with proteins and vaccines by electrostatic interactions between the positive amine group of chitosan and the negative acidic groups of proteins. Vaccine carrier systems that are prepared with chitosan could maintain the stability of proteins, allowing them to be released in their active form (93).

The different types of chitosan that have been used as vaccine carriers are shown in Table 12.

#### 1. Chitosan Nanoparticles as a Novel Carrier for Vaccines

Chitosan nanoparticles, prepared by a simple precipitation method with tripolyphosphate, were evaluated as carriers of proteins and vaccines by Calvo et al. (93). Transmission electron microscopy showed that chitosan nanoparticles were uniformly solid and had consistent structure. Proteins and vaccines were associated with chitosan nanoparticles probably by electrostatic interactions between the positive ammonium group of chitosan and the negative acid groups of proteins. Table 13 compares the uptake of bovine serum albumin (BSA), tetanus toxoid, and diphtheria toxoid to chitosan nanoparticles prepared at pH 5. The proteins were incorporated into the chitosan solution after they were dissolved in tripolyphosphate solution. Although the uptake of toxoids to the nanoparticles was efficient, BSA uptake was higher than that of toxoids. The isoelectric point (pI) of BSA is 4.8 and the pI of toxoids varies from 4 to 6 as the toxoids are a mixture of proteins. Thus, different ionization of the toxoids, caused by different pI values, will lead to different uptake by nanoparticles. However, the pH value of 5 is very close to the pI of BSA. Also the positively charged amino group of chitosan was cross-linked with the negative groups of tripolyphosphate, so positively charged amino groups of chitosan are not avail-

**Table 10.12** Chitosan as a Vaccine Carrier

Carrier type	Antigens	Reference
Chitosan-ethylene oxide-propylene oxide block copolymer (Pluronic® F68)	Bovine serum albumin and tetanus and diphtheria toxoids	93
Glutaraldehyde crosslinked chitosan microspheres	Bovine serum albumin, diphtheria toxoid	94

**Table 10.13** Entrapment Efficiency of Bovine Serum Albumin and Tetanus and Diphtheria Toxoids into Chitosan Nanoparticles

Protein	Molecular weight (daltons)	Protein/chitosan (%)	Isoelectric point	Entrapment efficiency (%)
BSA	69,000	12	4.5–4.8	100.0
Tetanus toxoid	150,000	6	4.4–5.9	53.30
		12		56.73
Diphtheria toxoid	62,000	6	4.1–6.0	55.10

Source: Adapted from Ref. 93.

able to provide electrostatic interactions. As a result, it could be concluded that other forces such as hydrogen bonding and hydrophobic interactions may have led to the high uptake of BSA into the nanoparticles. A prolonged release of the entrapped and active protein was obtained. Nanoparticles with BSA loading of 25% released the entrapped protein without burst effect and at a fairly constant rate. The amount released of BSA was almost 14% after 4 h and about 30% after 8 h. For tetanus toxoid, the release profile was biphasic. After incubating the particles for almost 9 days in an aqueous 5% (w/v) trehalose solution, a slower second phase release profile was achieved. The amount of tetanus toxoid released after 9 days was 16%, and an additional 2% was released for up to 18 days.

## 2. Crosslinked Chitosan Microspheres as Carriers of Macromolecular Drugs

Some biological macromolecules are sensitive to pH, organic solvents, surfactants, and temperature. Loading them passively into hydrophilic matrices would preserve the biological activity of the protein molecules. For this reason, bovine serum albumin and diphtheria toxoid were loaded by passive absorption from aqueous solutions into performed glutaraldehyde crosslinked chitosan microspheres (300–600  $\mu\text{m}$ ) (94). The drug release into phosphate buffer (pH 7.4) was modulated after coating the bovine serum albumin-loaded particles with paraffin oil or with a poly(L-lactic acid). Although there was an initial burst of drug seen at day 1 from poly(L-lactic acid)-coated particles, the release rate increased as a function of time for nearly 2 months. Diphtheria toxoid-loaded chitosan microspheres were injected intramuscularly in Wistar rats and showed a constant antibody titer for up to a 5-month period. Tissue compatibility was confirmed by histological studies after intramuscular injection of placebo chitosan microspheres (150–300  $\mu\text{m}$  diameter) into rats. The cross-

linked chitosan microspheres were retained in the rat muscle for up to 6 months without any degradation.

## B. Chitosan as a Mucosal Adjuvant

Parenteral route is the most common method for the administration of vaccines. Since this route is invasive, administration of vaccines into mucosal surfaces such as the nasal, urinogenital, pulmonary, and peroral mucosae has been investigated (50,95–97). However, these routes have limitations because of the chemical and physical instability of vaccines, the high metabolic activity, and the low permeability of the mucosal barrier (98). These limitations can be overcome by using enzyme inhibitors, absorption enhancers, and colloidal carriers (99,100).

Adjuvants are substances that can enhance the immunogen effectiveness by enhancing the immune response. Sometimes antigens on their own may produce a weak specific immune response and hence are ineffective as vaccines. By adding adjuvants, the immune response can be elevated to an effective level. The production of viral vaccines in large quantities is very difficult and expensive. Growing and expanding the viral particles and the extracting and purifying of the effective antigens require sophisticated equipment, highly trained personnel, and prepared biochemicals. Thus, using adjuvants to elevate the immune response to an effective level would enhance the action of small doses of vaccine. Different adjuvants had been investigated for the immunogenicity enhancement of vaccines. The adjuvants include cholera toxin (101,102), poly(L-lactide-co-glycolide) microspheres (103–105), liposomes (106), pluronics surfactants (107), lipopolysaccharides, and aluminum salts (108).

Chitosan can affect the permeability of the epithelial membrane by opening the tight junctions between the cells leading to enhancement of absorption. Chitosan can act as an enzyme inhibitor and a good mucoadhesive. All the

**Table 10.14** Chitosan as a Mucosal Adjuvant

Immune response enhancement	Reference
Mucosal and systemic immune response	108
Mucosal immune response	109

previous properties make chitosan a good candidate as a mucosal adjuvant to enhance the immune response by increasing the residence time of vaccine available at the mucosal site for specific immunity.

Table 14 summarizes the various examples of chitosan used in enhancing immune response.

### 1. Enhancement of the Immune Response

When antigens were administered nasally in rats, the immune response was enhanced by chitosan. Both serum and mucosal immune responses after intranasal immunization of mice with filamentous haemagglutinin (FHA) and pertussis toxin (rPT) doses of 2  $\mu\text{g}$  combined with chitosan were higher than those of the solution of FHA and rPT administered intranasally. This could be explained by higher retention time of the antigen at the absorption site in the chitosan formulation. Two doses (2  $\mu\text{g}/\text{mL}$ ) of FHA combined with chitosan were also administered in mice nasally. While the mucosal response was 100 times higher than that produced after the nasal administration of FHA by itself, the systemic response was 60 times higher. The results show that chitosan can serve to enhance both mucosal and systemic immunity after mucosal administration of vaccine (108).

### 2. Mucosal Vaccination with Chitosan

The immune response to an antigen that is delivered through the mucosa could be enhanced by chitosan, as shown by Makin et al. (109). After nasal administration of purified surface antigen (PSA) of influenza B virus combined with chitosan to mice, the serum antibody response was similar to that produced after the subcutaneous immunization of PSA combined with aluminum hydroxide adjuvant. While the subcutaneous administration of the antigen did not cause any mucosal response, the nasal administration of PSA–chitosan formulation did. The results clearly showed that chitosan could enhance mucosal immunogenic response probably by increasing the residence time of the immunogen at the site of absorption or by increasing the fraction of dose absorbed across the membrane. The combined effect was to enhance the exposure of the antigen to the immune cells of the mucosal epithelia (108).

## VI. MISCELLANEOUS APPLICATIONS OF CHITOSAN

### A. Chitosan Microspheres for Controlled Release of Drugs

Microspheres in drug formulation offer many advantages such as controlled drug release, large surface area, protection against unpleasant tastes, and separation of incompatible drugs. Since microspheres have uniform distribution over absorption sites in the gastrointestinal tract, higher absorption and less irritation could be obtained (110,111).

Table 15 summarizes the various examples of chitosan microspheres that have been used for drug delivery. Different methods had been used to prepare chitosan microspheres, such as crosslinking with glutaraldehyde (112), interfacial acylation (113), precipitation (114), spray-drying technique (115), ionotropic gelation (116), solvent evaporation (117), and capillary extrusion (118).

#### 1. Crosslinked Chitosan Microspheres

An aqueous acetic acid dispersion of chitosan containing progesterone was crosslinked—using glutaraldehyde—in a dispersion of liquid paraffin and petroleum ether (112). The resulting crosslinked chitosan microspheres were characterized by being smooth, spherical, and in the size range of 45–300  $\mu\text{m}$ . The crosslinking density of the microspheres was an important factor affecting the extent of drug release. Microspheres prepared by using 4 mL of glutaraldehyde-saturated toluene were considered weakly crosslinked, while those prepared by adding 1 mL of aqueous glutaraldehyde were highly crosslinked. Seventy percent of the incorporated steroid was released in 40 days from the weakly crosslinked microspheres, whereas only 35% of the drug was released from the highly crosslinked spheres. After intramuscular injection of the microsphere formulation in rabbits, the plasma level of progesterone of 1 to 2  $\text{ng}/\text{mL}$  was maintained for up to 5 months. The authors have failed to examine the biodegradation of microspheres after intramuscular administration.

#### 2. Interfacial Acylation

To minimize stomach irritation, chitosan microspheres containing oxytetracycline were prepared by interfacial acylation method by Mi et al. (113). These microspheres had particle diameters between 420 and 590  $\mu\text{m}$  and were used for intramuscular injection for controlled drug release property. In the simulated stomach medium, the oxytetracycline release was significantly reduced in the microsphere formulation. Using chitosan having a molecular

**Table 10.15** Chitosan Microspheres for Controlled Release of Drugs

Microsphere preparation method	Drug	Reference
Crosslinked microspheres by glutaraldehyde	Progesterone	112
Spray-hardening and interfacial acylation	Oxytetracycline	113
Precipitation process	Prednisolone sodium phosphate	114
Spray-drying technique	Diclofenac sodium	115
Ionic gelation	Bovine serum albumin	116
Solvent evaporation	Diclofenac sodium, bovine serum albumin	117
Capillary extrusion	Diclofenac sodium	118

weight of 2,000,000 daltons, it took almost 9 h to release 50% of the drug. The release of the drug was prolonged in the stomach as acetylation of the amino group of D-glucosamine will reduce the charge density of the polymer leading to lower swelling of the microspheres.

### 3. Precipitation Technique

Using sodium sulfate as a precipitant, chitosan microspheres were prepared by Berthold et al. (114). Photon correlation spectroscopy and centrifugal sedimentation were used to measure the particle size, found to be between 1.5 and 2.5  $\mu\text{m}$ . Side-by-side diffusion cells having a dialysis membrane in between made of cellulose acetate with a molecular weight cut-off of 12,000–14,000 daltons was used to measure the release of prednisolone sodium phosphate from the microsphere formulation. The drug/polymer ratio was a significant factor that affected the release of the drug from the microspheres. As the chitosan/drug ratio increased, the release rate decreased. For instance, 23% of prednisolone sodium phosphate was released after 6 h from microspheres having a chitosan/drug weight ratio of 1:1. However, when the chitosan/drug weight ratio increased to 7:1, the percentage of the drug released after the same period was only 13%.

### 4. Spray-Drying Technique

Using spray-drying technique, diclofenac sodium was loaded into chitosan microspheres. The drug-loaded microspheres were further microencapsulated with Eudragit L-100 and Eudragit S-100 using an oil-in-oil solvent evaporation method to form a multireservoir system (115). Eudragit L-100 and Eudragit S-100 are anionic copolymers of methacrylic acid and methyl methacrylate, used for enteric coating, with ratio of the free carboxyl groups to the ester groups of approximately 1:1 in Eudragit L-100 and about 1:2 in Eudragit S-100. By coating the chitosan micro-

spheres with Eudragit, perfect pH-dependent release profiles were obtained. Although no release was detected at acidic pH, a continuous release for about 8–12 h was observed at the pH of Eudragit solubility. Eudragit L-100 is soluble at pH above 6, while Eudragit S-100 is soluble at pH above 7. The dissolution of chitosan gel cores, the dissolution of the Eudragit coating, and the swelling of the chitosan microspheres were factors that affected the release of diclofenac sodium. Controlled drug release was also achieved by the ionic interaction between the carboxyl groups of Eudragit and the amine groups of chitosan. Coating of chitosan microspheres with anionic polymers, such as Eudragit, could be useful for delivering drugs to specific regions of the gastrointestinal tract.

### 5. Ionic Gelation

Ionic gelation is a simple technique that involves the mixing of an aqueous phase of chitosan and a diblock copolymer of ethylene oxide and propylene oxide with an aqueous phase of sodium tripolyphosphate (116). The size of these microspheres was between 200 and 1000 nm. The particle size increased by increasing the concentration and molecular weight of the diblock copolymer of ethylene oxide and propylene oxide. Up to 80% of bovine serum albumin was entrapped within these microspheres. About 25% of BSA was released after 2 days, and after 6 days the percentage release of BSA increased up to 82%. Almost all of the entrapped drug was released in one week.

### 6. Solvent Evaporation

Chitosan microspheres, prepared by methylene chloride solvent evaporation technique, were entrapped in a hydrophobic polymer made of cellulose acetate butyrate and ethyl cellulose (117). The loading of diclofenac sodium was almost 100% in these microspheres. The loading of the drug was not affected by the amount of chitosan or the

molecular weight of the polymer. One hundred percent of the drug was released after 8 h in a controlled release form from the chitosan microspheres coated with ethyl cellulose, and about 85% was released from chitosan microspheres coated with cellulose acetate butyrate in the same period of time. Since this method of microsphere preparation does not require a crosslinking agent, it could be an alternative method of chitosan microsphere preparation.

## 7. Capillary Extrusion

Diclofenac sodium was loaded into chitosan microspheres that were prepared by capillary extrusion (118). The microspheres were characterized by having a narrow size distribution with a particle of diameter 760  $\mu\text{m}$ . Four different formulations were evaluated for oral administration. The formulations were (1) drug powder, (2) empty chitosan microspheres, (3) sustained-release pellets, and (4) optimum diclofenac sodium-containing chitosan microspheres. In vitro release study was carried out in simulated intestinal medium at a pH of 6.8 and 37°C. A slow release of diclofenac sodium from the optimum microsphere formulation was observed. Nearly 45% of the drug was released from the microspheres after 6 h. To evaluate the efficacy of the product in treatment of ulceration, rabbits were given a dose of 5 mg/kg body weight of the free drug or in the microspheres form once a day by gastric tubing for 21 days. After sacrificing the rabbits, the mucosa of the stomach was examined under a low power (20 $\times$ ) dissecting microscope. The degree of ulceration was determined qualitatively by using a scale of 0 to 4 (4 being highly ulcerative). The ulcerogenic index (UI) was calculated from the degree of ulceration and the percentage of the rabbits that had ulcer in the study. No difference in gastric lesions and ulcerogenic index was observed between the optimum formulation and the commercial product of diclofenac sodium. The microsphere formulation had a lower level of ulcerogenic index (UI 0.25) than the plain drug (UI 1.5), which suggests that chitosan could protect the gastric mucosa from ulceration by nonsteroidal antiinflammatory drugs.

### B. Implantable Sustained Release Forms of Chitosan

Surgical implants devices in the body tissues could provide sustained release of a drug at the site of action (119). One of the most promising materials that could be used for implantable devices is a polymer that can degrade at the site of delivery. Biodegradable polymeric devices could be useful as a second surgery to remove the implant after drug release is avoided. The biodegradable polymer should also

have good mechanical properties, not form harmful degradation products, have capability to be fabricated into devices with different geometry, and be sterilizable (120). Chitosan and chitosan derivatives have been used to develop implantable sustained release dosage forms.

Table 16 shows the different examples of chitosan being used for implantable sustained release systems and the drugs that have been incorporated.

#### 1. Implantable Chitosan Using Uracil as a Model Drug

Chitosan with a degree of deacetylation of  $\geq 85\%$  and hydroxypropyl chitosan were used to prepare an implantable sustained release form of uracil (121). For in vitro studies, lysozyme was used to ensure the enzymatic degradation of chitosan and hydroxypropyl chitosan. The enzymatic degradation was confirmed by gel filtration chromatography. For in vivo studies, 100 mg spherical polymer with an approximate diameter of 5 mm was implanted subcutaneously in the backs of Wistar rats. After 1 month, the weight of chitosan and hydroxypropyl chitosan samples were reduced to 69 and 50% of the original weight, respectively. Extrusion-in-air method was used to design film- and stick-type implantable dosage forms of chitosan containing uracil. After the implantation of 50 mg stick-type dosage form containing 5 mg of uracil into the back of a Wistar rat, controlled release of the drug was achieved for almost 3 days. Following subcutaneous injection of uracil, the peak drug concentration was 3.282  $\mu\text{g}/\text{mL}$  after 1 h. No uracil was found after 24 h, and the area under the plasma concentration–time curve was only 9  $\mu\text{g} \cdot \text{h}/\text{mL}$ . After subcutaneous implantation of the chitosan-based device, however, the peak concentration of uracil was 0.422  $\mu\text{g}/\text{mL}$  after 3 h, and the concentration was sustained at 0.024  $\mu\text{g}/\text{mL}$  for up to 3 days. The area under the plasma concentration–time curve was also 9  $\mu\text{g} \cdot \text{h}/\text{mL}$ . Both methods of administration had the same area under the plasma concentration–time curve, meaning that the release of the drug was prolonged without changing the overall bioavailability. The results of this study showed that a chitosan-based implantable delivery system could be used for sustained release of the anticancer drug. The devices were able to release the drug for up to 3 days in vivo.

#### 2. Local Implantation of Chitosan Microspheres Containing Bisphosphonates

Suberoylbisphosphonate, an agent that is used clinically to inhibit bone resorption in the treatment of hypercalcemia, which may lead to calcification of bioprosthetic heart valve tissue, was loaded into chitosan microspheres (122). The in vitro release rate of the drug in TRIS buffer (pH 7.4)

**Table 10.16** Implantable Sustained Release Forms of Chitosan

Carrier type	Drug	Reference
Film- and stick-type implantable dosage form	Uracil	121
Chitosan microspheres prepared from water-in-oil emulsion	Pamidronate, suberoylbisphosphonate	122
N,O-Carboxymethyl chitosan	Human coagulation factor IX	123
Glutaraldehyde crosslinked microspheres	Mitoxantrone	125
N-Succinyl-chitosan-mitomycin C conjugate	Mitomycin C	126

was retarded in the chitosan microspheres. Almost 100% of the drug was released in 24 h from the microsphere formulation. Chitosan films were used to grow endothelial cells to prove biocompatibility. The results showed that the cells were viable on the polymer surface. After implanting suberoylbisphosphonate microspheres (500  $\mu\text{m}$  diameter) containing 10% (w/w) of the drug subdermally in rats, the bioprosthetic heart valve tissue calcification was inhibited. Sixty-eight percent reduction in calcium concentration of the valve was achieved in 35 days.

### 3. Chitosan as a Delivery System for Coagulation Proteins

An aqueous formulation of human coagulation factor IX was developed for hemophilia treatment. As compared to intravenous dose, the bioavailability of 16% of human coagulation factor IX was achieved after bolus subcutaneous injection in rabbits. When osmotic pumps were implanted subcutaneously in rabbits, human coagulation factor IX reached a plasma plateau that is equivalent to 2.5% of the normal human levels. A chitosan derivative, N,O-carboxymethyl chitosan, was used to prepare hydrogels containing human coagulation factor IX. Using the same dose (8000 units/kg body weight) of intravenous or subcutaneous bolus injections as controls, higher levels of human coagulation factor IX were maintained in mice plasma following subcutaneous injection of the hydrogels. After 72 h, the concentration of human coagulation factor IX in mouse plasma was 0.1 units/mL from the hydrogel, while from the intravenous or subcutaneous bolus injection, the concentration was only 0.05 units/mL (123).

### 4. Crosslinked Chitosan Microspheres

Jameela et al. (124) prepared glutaraldehyde crosslinked chitosan microspheres. Chitosan microspheres, without the drug, were implanted in the skeletal muscle of rats. The

tolerability of the microspheres in muscle tissue was confirmed by histological analysis. There was a moderate cellular response with a few macrophages encircling the beads. All of the loaded mitoxantrone was released into phosphate buffer (pH 7.4) in 1 day from the weakly crosslinked spheres that were made with 2 mL of glutaraldehyde-saturated toluene followed by 0.2 g of additional glutaraldehyde. However, only 25% of the drug was released after 36 days from the highly crosslinked spheres prepared with 10 mL of glutaraldehyde-saturated toluene followed by 0.2 g of additional glutaraldehyde. For 3 months, the microspheres remained intact in the skeletal muscle of rats without any degradation.

Mitoxantrone-loaded chitosan microspheres were injected intraperitoneally in mice with Ehrlich ascites carcinoma. The mean survival time of mice treated with mitoxantrone-loaded chitosan microspheres containing 2 mg of the drug was 50 days. Mice receiving 2 mg of the drug in solution, however, had a mean survival time of only 2.1 days. Thus, mitoxantrone-loaded chitosan microspheres could enhance the therapeutic efficacy of anticancer drugs like mitoxantrone (125).

### 5. N-Succinyl-Chitosan-Mitomycin C as an Implant

Water-soluble carbodiimide was used as a coupling agent between N-succinyl-chitosan and mitomycin C (126). A total weight of 20 mg of the drug was incorporated in the conjugate N-succinyl-chitosan-mitomycin C as a tablet form. After implantation subcutaneously into the back of a male Wistar rat, mitomycin C was released gradually for almost 1 week. For tumor inhibition study, 0.1 mL of the ascitic fluid containing  $1 \times 10^7$  Sarcoma cells was injected subcutaneously into the axillary tissue of 6-week-old mice. To investigate the antitumor effect, the tumor size was measured with calipers at appropriate times. The percent-

age growth ratio was calculated by dividing the volume of the tumor after 19 days of drug administration over the volume of the tumor after 7 days following inoculation. After intratumoral administration of 5 mg/kg of mitomycin C in the mice, the percentage of tumor growth ratio was 30.5%. However, the percentage of tumor growth ratio was reduced to 17.5% after the administration of the conjugate N-succinyl-chitosan-mitomycin C containing 15 mg equivalent mitomycin C/kg by the same route. The conjugate was more effective than free mitomycin C in reducing the tumor growth, but at a much higher dose.

### C. Chitosan for Colon-Specific Drug Delivery

Following oral administration, peptide and protein drugs suffer from poor intestinal absorption due to susceptibility of these drugs to the proteolytic enzymes in the gastrointestinal tract and poor membrane permeability. The absorption of peptide and protein drugs could be enhanced in the colon because of the low activity of proteolytic enzymes there and the long residence time. In addition, it is more effective to treat colonic diseases such as ulcerative colitis, colorectal cancer, and Crohn's disease with direct delivery of drugs to the affected area (127).

Many pH-sensitive or bacterial degradable polymers have been used for colon-specific drug delivery. These polymers include chitosan (127), methacrylic acid or hydroxyethyl methacrylate (128), azoaromatic polymers (129), methacrylated inulin (130), and cellulose derivatives such as ethyl cellulose (131), hydroxypropyl methylcellulose acetate succinates, cellulose acetate phthalate (132), and cellulose acetate butyrate (133).

Chitosan was used in oral drug formulations to provide

sustained release of drugs. Recently it was found that chitosan is degraded by the microflora that are available in the colon. As a result, this compound could be promising for colon-specific drug delivery (127).

#### 1. Improvement of Insulin Absorption Using Chitosan

Hydroxypropyl methylcellulose phthalate, an enteric-coating material, was used to coat chitosan capsules loaded with insulin (127). After 2 h following oral administration, the capsules were eliminated from the stomach. After 2 to 6 h, the capsules moved into the small intestine and were in the large intestine after 6 to 12 h. For in vitro release medium, cecal content from rats was suspended in two volumes of bicarbonate buffer and the pH was adjusted to 7.0. The release of 5(6)-carboxyfluorescein loaded in chitosan capsules, a model water-soluble compound, was increased in the rat cecal content suspension as compared to simulated gastric juice (pH 1.2) and simulated intestinal juice (pH 6.8). While all of the drug was released after 12 h in the cecal suspension, only 20% was released in the simulated intestinal juice after 6 h, and none was released in the simulated gastric juice after 2 h. Degradation of chitosan capsules in cecal contents facilitated the release of 5(6)-carboxyfluorescein. Using male Wistar rats, insulin-containing chitosan capsules were administered orally with a total dose of 20 IU into the stomach with a polyethylene tubing. The hypoglycemic effect started 6 h after the administration, when the capsules were in the colon and lasted for 24 h. The peak plasma insulin concentration of 326  $\mu$ unit/mL was noticed after 7 h of administration. To find out the insulin bioavailability, insulin solution (0.1 IU

**Table 10.17** Chitosan as a Pharmaceutical Excipient in Tablet

Drug	Chitosan DD <sup>a</sup> %	Tests conducted	Reference

<sup>b</sup> ND = not determined.

Source: Adapted from Ref. 143.

was injected intravenously by bolus injection and the area under the plasma concentration–time curve was normalized according to the dose. The bioavailability of insulin from the chitosan formulation was 5.73% as compared to the intravenous one.

#### D. Chitosan as a Pharmaceutical Excipient in Tablet

Table 17 provides the various examples of chitosan when used in the preparation of tablet dosage forms.

##### 1. Angle of Repose Reduction of a Powder Mixture

Angle of repose is defined as the base angle of the cone formed when a powdered or granular material falls freely on a flat surface from an orifice. By adding chitosan to other conventional tablet excipients such as mannitol, lactose, or starch, the angle of repose was decreased. Thus, the fluidity of the powder from the hopper into the die cavity in the tablet machine would be increased. The angle of repose decreased from 65° to 39° in the presence of 80% (w/w) chitosan. In the presence of microcrystalline cellulose, on the other hand, the angle of repose was reduced to 45° at the same concentration (134,135).

##### 2. Chitosan as a Binder in Wet Granulation

When chitosan was used as a binder in wet granulation, the binding efficiency was less than that of hydroxypropyl methylcellulose, but more than that of methylcellulose or sodium carboxymethyl cellulose (136). The binding efficiency was evaluated based on the properties of tablet hardness, friability, and disintegration time. Thus, by dividing the hardness by the friability value, the hardness/friability ratio was obtained. The binder efficiency parameter was obtained by dividing the hardness/friability ratio by the disintegration time. Table 18 compares the binder

**Table 10.18** Binding Efficiency Parameter of Chlorpheniramine Maleate

Polymer	Binding efficiency parameter (kg/s)
Chitosan	0.116
Hydroxypropyl methylcellulose	0.215
Methylcellulose	0.101
Sodium carboxymethyl cellulose	0.037

Disintegrants	Disintegration time (min)
Chitosan	0.6
Corn starch	2.65
Microcrystalline cellulose	7.05

*Note:* Tablets were compressed at 600 pounds force using the various disintegrating agents.

*Source:* Adapted from Ref. 137.

efficiency parameter of chlorpheniramine maleate using 2% (w/v) granulating fluid of different polymers. The binding efficiency of chitosan was found to be 0.116 kg/s, and that of sodium carboxymethyl cellulose was 0.037 kg/s.

##### 3. Chitosan as a Disintegrant

When chitosan was used in tablets at a concentration above 5% (w/w), its disintegration efficiency was higher than starch and microcrystalline cellulose. Table 19 lists the disintegration times of paracetamol tablets compressed at two forces using different disintegrants (137). The disintegration time of chitosan tablet compressed at 600 pounds force was 0.6 min. The disintegration time of 7.05 min, however, was obtained from tablets made with microcrystalline cellulose.

## VII. CONCLUSION

Chitosan is an abundant natural polymer, obtained by alkaline N-deacetylation of chitin. The physical and chemical properties of chitosan, such as inter- and intramolecular hydrogen bonding and the cationic charge in acidic medium, makes this polymer attractive for the development of conventional and novel pharmaceutical products. As a bioadhesive polymer, chitosan has been found to increase residence time of dosage forms at mucosal sites, inhibit enzymes, and increase the permeability of protein and peptide drugs across mucosal membranes. Chitosan networks can serve as pH-sensitive swelling system for region-specific drug delivery in the gastrointestinal tract. Chitosan–DNA complexes have been shown to facilitate transfection and inhibit degradation of DNA by DNase. A number of investigators have also shown that chitosan could be used as a mucosal vaccine carrier and may have adjuvant effect. The future of chitosan as a pharmaceutical aid looks very bright as a number of derivatives have been synthesized that will lead to more useful applications.

## Immobilization of Active Biopolymers from Cold Plasma–Functionalized Surfaces for the Creation of Molecular Recognition and Molecular Manufacturing Systems

Ferencz Denes and Sorin Manolache

*University of Wisconsin, Madison, Wisconsin*

### I. INTRODUCTION

Biomaterials can be broadly defined as specially designed inorganic materials (e.g., ceramics, metals) and organic polymers (e.g., natural or synthetic polymers or their surface-modified versions) whose surfaces are in direct contact with biological components such as blood, tissue fluid, proteins, cells, etc. The interaction of these substrates with biological components, including covalent coupling, and adsorption of these materials on polymer surfaces depend greatly on their surface properties, including surface energy, surface functionality, composition, and surface morphology.

Depending on the intensity of the interaction (chemical bonding or adsorption), biomaterials are involved in different applications. Biomaterials for *in vivo* applications should not adsorb any proteins and should not induce any activation of complementary systems. Similarly material surfaces involved in food processing industry should have antifouling characteristics in order to avoid biofilm formation. On the contrary, biosensor applications require functionalized surfaces (e.g., polymer surfaces), which should selectively interact (e.g., covalently link) with specific molecules, cells, etc. Significant biological effects can also be induced by strongly adsorbed or covalently attached specific biomolecules (e.g., albumin) on polymer surfaces.

Biosensors combine the selective interaction between the immobilized biological molecules and entities, such as DNA, enzymes, and antibodies as well as certain molecules (biological or nonbiological), cells, bacteria, etc., with detection systems based on electrical or optical signals. The transducer of the detection system recognizes the molecular interaction between the target molecules and the detector biomolecules and converts the electrical, electrochemical, optical, thermal, or mass changes of the nascent surface layers generated as a result of the interaction into electrical or optical signals.

The first step in the preparation of molecular recognition systems is the surface functionalization of specific substrates. The resulting active layers should anchor, in a next step, covalently or by physical adsorption, biomolecules with highly selective activity.

Molecular recognition between biological macromolecules, small molecules, and macromolecules and specific surfaces plays a crucial role both in the understanding of various biological systems and in the design of artificial, intelligent surfaces (molecular manufacturing systems) with tremendous practical potential. As soon as a primitive molecular assembler, which is able to self-replicate by atomic precision positional control is constructed, migration pathways will allow the generation of increasingly sophisticated assemblers.

In order to understand the molecular basis of the interaction, controlled immobilization of biomolecules must be performed by taking into account the chemical and physical (crystallinity, morphology) structure of the substrates, the nature of the bonding between the biologically active molecules and substrates, the surface density of immobilized molecules, and the distance between the anchored biomolecules and the substrate. By understanding and controlling of surface functionalization and the consequent anchoring reaction mechanisms, tailored and very specific reaction pathways (molecular recognition) can be developed.

The nature of surface topographies of "host substrates" plays a significant role both in the efficiency and selectivity of the immobilization processes. Biologically active molecules like enzymes and nucleotides usually favor a single, initial conformation to "catalyze" reactions. However, recently it has been found that over time an enzyme can adopt more than one functional conformation with different catalytic efficiencies (1). The bonds responsible for the existence of secondary, tertiary, and quaternary structures are based on noncovalent-type ionic, hydrogen, and van der Waals interactions. The high number of these relatively labile individual bonds involved in the interactions assure the stability of the bimolecular structures. However, the labile nature of individual linkages restricts significantly their handling parameters. Mild pH and temperature conditions are usually required.

Conformational changes of biomolecules as a result of replica interactions (presence of amorphous or crystalline surfaces) and multiple bonding between the surface of the substrate and the biomolecules can alter significantly the efficiencies of catalytic activities. As a consequence, the activities of immobilized biomolecules usually are modest (e.g., immobilized enzymes) in comparison to the free molecules. However, controlled substrate–molecule interactions might open up a novel route for generating optimal substrate surfaces for the immobilization of biomolecules. Molecularly imprinted polymer surfaces and the corresponding technologies are already a rapidly emerging area in which synthetic polymer surfaces are generated in the presence of the "print molecules."

The preparation of oligonucleotides for clinical trials will require kilogram to ton amounts of specific oligonucleotide derivatives, while the preparation of oligonucleotide libraries requires nanoscale beads that have high loading characteristics and optimal accessibility of their surfaces to biomacromolecules. Conventional rigid-lattice supports have their limitations due to the nonspecific inside/outside loading. Controlled pore glass (CPG) or macroporous polystyrene exhibit, for instance, nucleoside loading of 0.8–0.9  $\mu\text{mol}/\text{m}^2$  regardless of porosity or size

dimensions. Swellable resins show at the same time diffusion-retarded kinetics in the diverse reactions of the elongation cycle. Hence, the yields from oligonucleotide chain extension mechanisms do not exceed 97%, which would be required for application purposes. A solution to this problem would be the preparation of surface-functionalized, nonporous, inert, inorganic and organic polymeric beads. These support systems would allow oligonucleotide extension yield of 99%, and solutionlike kinetics could be achieved, while having oligonucleotide capacities of 100–200  $\mu\text{mol}/\text{g}$  in comparison to 50–70  $\mu\text{mol}/\text{g}$  of the currently used systems. Thus, polymer supports of the core shell type may lead to a 3- to 4-fold increase in the output of therapeutic oligonucleotides per batch (2,3).

Polymer-bound oligonucleotides will find their applications in hybridization-based diagnostics and in the discovery of new therapeutics based on molecular recognition. Prenatal diagnostics of genetic aberrations, identification of virus-borne diseases, detection of mutations of regulatory proteins controlling carcinogenesis, and novel hybridization-based identification techniques oriented to forensic or archeology fields are only some of potential applications.

Molecular recognition will also play an essential role in areas other than medicine, pharmaceuticals, and biotechnology. Development of ultrasensitive chemical sensors and absorbent surfaces is crucial for creating environmentally safe processes. Monitoring the quality of water is one of the major demands in this area. Bimolecular-based chemical sensors and filters for toxic chemicals and microorganisms (e.g., *Escherichia coli*) will play a significant role in future technologies.

Current accurate tests for DNA sequences are based on fluorescent signals. Analytical set-ups for quantitative evaluations usually are time consuming and expensive. Recently it has been demonstrated that hybridization (when a single DNA strand "bumps" into a complementary partner, it will hybridize) can be detected by changes in an electrochemical signal through a redox or conducting molecule, which behaves differently in the presence of a DNA hybrid than in the presence of a single strand (4). The advantage of using electrical signals (current or voltage) instead of fluorescence for detecting hybridization would be the rapidity of the assay and the possibility of using large area arrayed DNA-immobilized surfaces for the development of automated hybridization monitoring procedures. The electrochemical approach *ab initio* involves surfaces, e.g., DNA immobilized on solid electrodes. In many systems under investigation electroactive groups that mediate electron transfer (e.g., ferrocene complexes) are attached to molecules that preferentially bind double-stranded

DNA. Recently DNA-functionalized conducting polymers like polypyrrole, polythiophene, etc., have been employed as well.

Polyanilines have received increased attention due to their ease of synthesis and doping and stability in the doped state; their processability; and their great versatility. For example, polyanilines can be tuned to conductivities in the range from insulators to conductors, and there is a large variation in the chemical nature of the dopants that can be employed. Controlled thickness, ultrathin polyaniline films and self-assembled polyion-containing (e.g., protein-containing) polyaniline layers can conveniently be prepared. These polymeric structures are very promising candidates for mediating electric signal-based detection of hybridization mechanisms.

Most of the natural and synthetic polymeric substrates can easily be functionalized through polymer-analog reactions. Main chain and side group homogeneous reactions are the most common approaches in this field. The use of polymers as “carriers” or “supports” for chemical reagents, catalysts, or substrates represents a relatively new significant rapidly developing area. In this case the polymer is in the form of an insoluble inert substrate that may be a solvent-swollen crosslinked gel or a surface-active solid. This approach eases the separation of reagents or catalysts (e.g., enzymes) from the reaction products, permitting consequently the automation of the complex chemistry. However, the specific structure of the repeating units of the macromolecules often limit considerably the variety of polymer-analog reactions. These reactions are even more difficult to develop under heterogeneous environments. Natural and even some synthetic polymeric substrates can also undergo undesired chemical modifications and sometimes biodegradation during the polymer-supported organic reactions. Inert polymeric substrates, e.g., polyethylene (PE), polypropylene (PP), poly(ethylene terephthalate) (PET), polytetrafluoroethylene (PTFE) and inorganic supports (e.g., glass, silica), however, cannot be functionalized efficiently by using conventional wet chemistry approaches.

## II. CONVENTIONAL FUNCTIONALIZATION AND COATING FOR BIOTECH APPLICATIONS

The immobilized affinity ligand technology (5,6) has grown rapidly in recent years. Starting as a purification method, it has now become a technique also for scavenging reagents to remove unwanted contaminants (7–11), for modification and catalysis to effect specific transforma-

tions (12–21), and for separation tools to develop sensitive and highly accurate analytical techniques (5,8,22).

The affinity ligand technique is based on the combination of a ligand with a matrix (a solid insoluble substance). The ligand usually is a well-known structure (e.g., oligonucleotide (7), biotin (9), enzyme (5,12–21), bacteria (10), fungi (11), etc.) and is firmly attached to the surface of the support by physical forces (23–25), covalent bonds (most used method), or autocoupling (26). The matrix can be any material to which a biospecific ligand may covalently be attached. Each component of the molecular assembly influences the partner molecules, and the entire combination matrix must function as a unique system in an environment. A “matrix effect” or an “activation effect” occurs when a change in the matrix material or activation chemistry will result in a radically different behavior of the same ligand from that seen on a reference support.

### A. Natural and Synthetic Supports

The preferable functional group for conventional functionalization reactions is the primary hydroxyl group (5). It is amenable to various activation procedures, but does not contribute to nonspecific binding of nontarget molecules. Agarose, which has a natural abundance of primary and secondary OH groups, represents an ideal surface for functionalization: the secondary hydroxyls preserve the hydrophilic nature of the matrix even after the primary hydroxyls are consumed in activation or crosslinking process. The abundance of primary amine or carboxylic acid functionalities on supports like polyethyleneimine or carboxymethyl cellulose (15) improve the functionalization possibilities. However, the resulting support may exhibit nonspecific ion exchange effects.

#### 1. Natural Supports

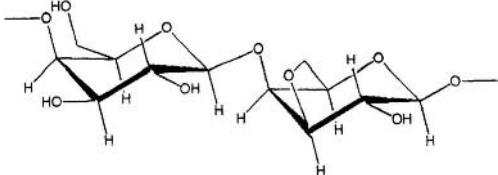

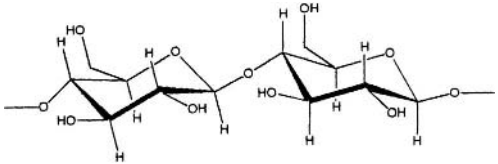

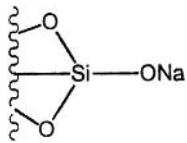

Natural polysaccharide matrices (7,12,13,24,25) such as agarose and cellulose or naturally occurring materials such as silica, alumina, and glass (6,9,14,23) must be processed before they can be exploited as affinity supports. Table 1 summarizes the chemical structure and the required engineering of natural materials in order to convert them into the desired affinity ligand supports.

#### 2. Synthetic Supports

The synthetic supports (5,10,16–21) typically have superior physical and chemical durability in comparison to the natural matrices. Most synthetic polymer supports can withstand higher-pressure environments without structural collapse and can work under high-pressure gradient and

**Table 11.1** Natural Supports and the Required Engineering for Their Modification

Support	Primary structure	Engineering	Observations
Agarose		<p>Alternating residues of <math>\beta</math>-D-galactose and 3-anhydrogalactose</p> <p>Crosslinking (30–50% loss of hydroxyl groups)</p> <p>Crosslinked agarose stability: 110–120°C and pH 3–14</p> <p>Working pH 4–9</p> <p>Tolerates a wide range of water-miscible solvents such as alcohols, dioxane, tetrahydrofuran, dimethylformamide, dimethylsulfoxide, pyridine, etc.</p>	<p>Contains primary and secondary alcohol groups</p> <p>Secondary and tertiary structure can be described as single fibers spun into a yarn of multiple fibers</p> <p>Remarkable fabric with large accessible pores</p> <p>Beads can be dissolved by heating or by strong denaturants such as guanidine hydrochloride</p>
Cellulose		<p>Linear polymer of 1,4-<math>\beta</math>-D-glucose</p> <p>Easy derivatization (substitution)</p> <p>Stability: 115°C at pH 7</p> <p>Working pH 3–10</p> <p>Can withstand a wide range of solvents, denaturing, and mild oxidation conditions</p>	<p>Contains primary and secondary alcohol groups</p> <p>Simple secondary and tertiary structure</p> <p>Tangled wad of string</p> <p>Low level of effective porosity or extended surface area</p>
Silica and controlled pore glass	 <p>Macromolecular anorganic structures</p>	<p>Glass with covalent coating such as glycerol</p> <p>Dissolved in deionized water</p> <p>Working buffers should be neutral or acids (pH lower than 8) and with at least 0.05 M salt</p> <p>Can withstand enormous pressure, any organic solvent, or temperature in excess of 300°C</p>	<p>Contain silanol groups</p> <p>Porous glass, silica, alumina, and zeolites relatively rigid</p>

flow rate conditions. Various-geometry (spheres, tubes, sticks, plates, etc.) porous or nonporous polymeric materials have already been successfully involved in the immobilization and affinity ligand techniques. Commercially available synthetic supports for affinity chromatography applications are presented in Table 2.

## B. Functionalization

Functionalization is a process of chemical modification of the matrix (support) in order to form a covalent bond with the ligand. The chemistry of the process must be compati-

ble with both the support and the ligand. It is required that the activation of the matrix and the coupling of the ligand should not add any nonspecific characteristics to the system. The major objectives of the functionalization processes are to create a stable binding of ligand to the support without changing the porosity or the surface topography of the substrate, and without generating nonspecific effects, and to be rapid, efficient, and user friendly.

The functionalization process should be specific for the active groups present both in matrix and ligand. Table 3 summarizes the most used classical chemical derivatization techniques for commercial available affinity supports.

**Table 11.2** Synthetic Support and the Required Engineering for Their Modification

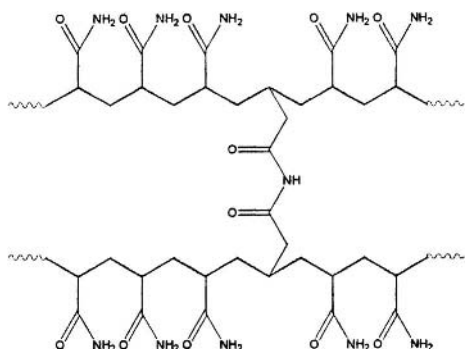

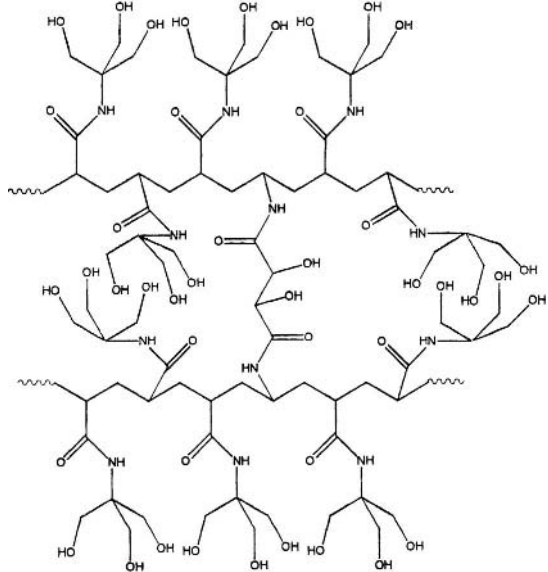

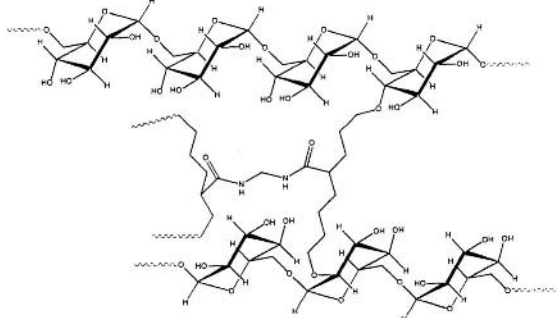

Support	Primary structure	Engineering	Observations
<i>Acrylamide derivatives</i>			
Polyacrylamide		<p>Copolymer of acrylamide and N,N'-methylene-bis(acrylamide) (crosslinking agent)</p> <p>Poor mechanical stability</p> <p>Low working flow rates</p> <p>Dimensional changes when working with various solvents (shrink or swell)</p>	<p>Resistance to microbial attack</p> <p>pH stability: 2–10</p> <p>Excellent chemical stability</p> <p>Low nonspecific binding characteristics</p>
Trisacryl		<p>Copolymer of trihydroxylic derivative of acrylamide and N,N'-diallyltartra-diamide (crosslinking agent)</p> <p>Good mechanical properties</p> <p>Can withstand a wide range of solvents</p>	<p>Resistance to microbial attack</p> <p>pH stability: 2–11; more basic pH can slowly hydrolyze it</p> <p>Excellent chemical stability</p> <p>Stability: -20 to 120°C</p>
Sephacryl		<p>Copolymer of allyl dextran and N,N'-methylene-bis(acrylamide) (crosslinking agent)</p> <p>Increased mechanical properties</p> <p>Can withstand a wide range of organic solvents without shrinking or swelling</p>	<p>Resistance to microbial attack</p> <p>Stable to 0.5 N NaOH solution</p> <p>Excellent chemical stability</p> <p>Stable in autoclave conditions</p>
Ultrogel	Complex mixtures of polyacrylamide and agarose polymers knitted together	<p>Matrices resulting from a blend of agarose and polyacrylamide</p> <p>Denaturants or detergents can affect and destroy the integrity of macromolecular structure</p> <p>Some organic solvents may damage the gel</p>	<p>Working pH range: 3–10</p> <p>Working temperature range: 2 to 36°C</p>

Table 11.2 Continued

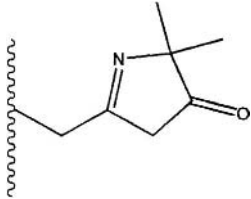

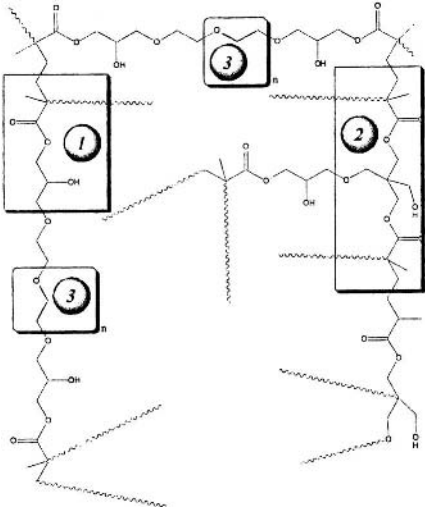

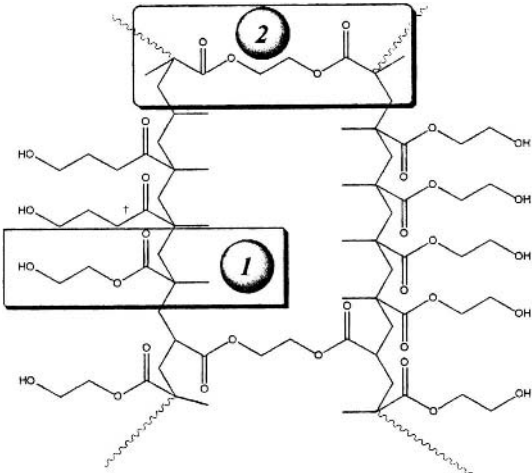

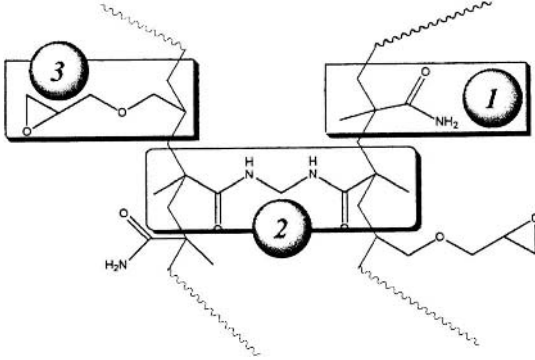

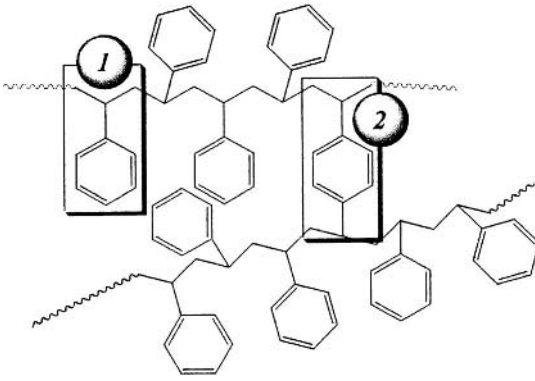

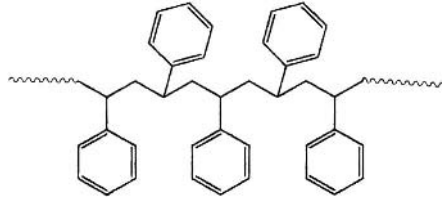

Support	Primary structure	Engineering	Observations
Azlactone		Copolymer of vinylidene methyl azlactone and N,N'-methylene-bis(acrylamide) (crosslinking agent) Slightly hydrophobic; for some proteins a lyotropic agent is required Allows high pressure and high flow rate operation	Stability, pH range: 1–14 Working pH range: 4–9 Proteins and small ligands are coupled in high yields and short times Maintains high coupling capacity even at elevated flows
<i>Methacrylate derivatives</i>			
TSK-gel toyo-pearl HW		Copolymer of glycidyl methacrylate (1), pentaerythritol dimethacrylate (2), and polyethylene glycol (3) Surface mildly hydrophilic Hydrophobic properties under certain conditions Good mechanical stability	Stability, pH range: 2–12 Do not support microbial growth Stable in detergents, organic solvents, or concentrated denaturants solutions Originally designed for GPC
HEMA		Copolymer of 2-hydroxyethyl methacrylate (1) and ethylene dimethacrylate (2) (crosslinking agent) Micropore and macropores structures Can withstand pressures exceeding 1,000 psi (4,400 psi for some products) and very high flow rates	Stability, pH range: 2–13 Can be washed with 2 N NaOH or 2 N HCl for short period of time Thermal stability: 170°C Very resistant to detergents, organic solvents, or concentrated buffers solutions Contains numerous tertiary $\alpha$ -carbonyl esters of pivalic acid (most stable and least hydrolyzable ester known)

Table 11.2 Continued

Support	Primary structure	Engineering	Observations
Eupergit		<p>Copolymer of methacrylamide (1), N,N'-methylene-bis(methacrylamide) (2), and allyl glycidyl ether (3) or glycidyl methacrylate</p> <p>Can withstand pressures up to 4,000 psi</p>	<p>Very good chemical and physical stability</p> <p>Porous or nonporous varieties</p>
Polystyrene derivatives			
Poros		<p>Copolymer of styrene (1) and divinylbenzene (2) (crosslinking agent)</p> <p>Maximum operational pressure: 3,000 psi</p> <p>Large pores passing through particles that allow high flow rates</p>	<p>Resistant to extreme pH: 1–14</p> <p>Robust chemical and physical structures</p>
Polystyrene balls, plates, and devices		<p>Nonporous particles with different geometries</p> <p>Surface etched to increase area for affinity interactions</p> <p>Polymer surface blocked by adsorption with a nonrelevant substance to prevent nonspecific hydrophobic interactions (e.g., bovine albumin)</p>	<p>Not suitable for chromatographic applications</p> <p>Can easily be mixed or separate from solvents</p> <p>Good optical properties in visible range for light absorption diagnostic using enzyme-linked assay</p>

### III. DEPOSITION OF ANTIFOULING LAYERS

The growth of living organisms and the attachment of biologically active molecules on solid surfaces exposed to aqueous media present one of the most important problems to be considered for food industry and medicine. Bacterial adherence to various solid surfaces is a naturally occurring process. Many bacterial species live and proliferate under “attached” conditions or embedded in polymeric matrices, called biofilms, generated by their own metabolism. Adherence of bacteria on various substrates and the subsequent biofilm formation can lead to the enzymatic degradation of the host materials or to the development of biofilm-related infections. It is recognized that adhesion of microorganisms to surfaces represents the initiating step in the development of biofilms and, as a consequence, of many infectious diseases. Biofilm environ-

ments protect microorganisms, through the embedding phenomenon, against substrate-origin defense mechanisms and antibiotics, enhancing in this way the survival of microorganisms and making extremely difficult treatments against biofilm-origin infections.

When a typical material is placed in a biological fluid or in a microorganism-containing liquid environment, proteins are adsorbed rapidly and usually nonspecifically on its surface. It is suggested that this physicochemical protein adsorption process is mediated by entropic phenomena associated with the presence of a highly ordered water mono-

layer on protein molecule surfaces and electrostatic and van der Waals long- and short-range interactions. The adsorbed protein molecules act as ligands and the cell surface proteins and proteoglycans produced by the cells as the receptor counterparts in the molecular recognition mechanism.

Adherence of microorganisms to polymer or metal surfaces and subsequent colonization of the exposed surfaces are the major initial steps in the pathogenesis of foreign body infections. Two approaches have been developed for avoiding polymer surface-mediated infections (9): devel-

opment of polymers with antiadhesive characteristics and development of polymers with antimicrobial properties. A large number of polymers were tested for antiadhesive properties. It has been found that bacterial strains usually exhibited a high adhesion to polymers with a high surface energy and having rough surface topographies, and that ionic groups are also involved in the adhesion mechanism. Most bacteria exhibit in an aqueous environment a negative surface charge; accordingly, it has been shown that negatively charged polymer surfaces can reduce bacterial adhesion. However, none of the attempts focused on the generation of antiadhesive polymeric surfaces resulted in a total reduction of bacterial attachment. It was also emphasized that the adhesion of bacteria to biomaterials *in vivo* is also mediated by bacterial adhesion. It was demonstrated, for instance, that preadsorption of albumin decreases bacterial adhesion, while fibronectin promotes adherence. By considering polymeric materials which selectively adsorb proteins, potential routes could be developed for the reduction of bacterial adhesion, and thus prevention of foreign body-mediated infections.

It has been shown that coating surfaces with noncharged hydrophilic polymers resulted in reducing protein and cell adsorption on a variety of surfaces due to the elimination of electrostatic attractive forces and the hydrophobic interactions between the solid surfaces (usually polymeric materials) and proteins in solutions. Most of the research in this area involved poly(ethylene glycol) or its derivatives; however, polysaccharides and nonionic cellulose ethers were also considered.

#### A. Conventional Approaches for Avoiding Protein Adsorption, Bacterial Attachment, and Biofilm Formation

Poly(ethylene oxide) (PEO),  $[-\text{CH}_2-\text{CH}_2-\text{O}-]_n^-$ , [or polyethylene glycol (PEG) (when the molecular weight is less than 10,000 Daltons)] is highly water soluble and has a good structural fit with the water molecules, which explains the presence of a strong hydrogen bonding between the ether oxygen atom of PEG and hydrogen atoms of the water molecules. Its decreased solubility in water at elevated temperatures is also related to the hydrogen bonding; higher temperatures result in decreased hydrogen bonding and in an increase of hydrophobic interactions between the macromolecular chains.

Poly(ethylene oxide)-containing surfaces have been prepared by a number of approaches including physical adsorption and entrapment, covalent grafting, photo-induced grafting, high-energy radiation grafting, and glow discharge-mediated grafting (27–42). It has been shown that only relatively high molecular weight PEO

(>100,000) can be effectively adsorbed on hydrophobic surfaces, and that the adsorption of PEO-containing amphiphatic block copolymers and multiblock copolymers (pluronics) would result in stable adsorbed layers. Homopolymers or copolymers of PEO containing shorter hydrophobic segments can be displaced by other macromolecules that have higher affinity for the specific base polymer surfaces. Entrapment of PEO chains or its copolymers bearing hydrophobic segments is achieved by surface swelling of polymeric supports, which will allow the entanglement of loosened macromolecular chains of the substrate with the hydrophobic segments of the PEO-based copolymer. The process is usually completed by immersing the system into a nonsolvent of the base polymer. The limitations of this approach are related to the toxicity of the solvents and their removal from the surface layers. Covalent grafting of PEO or its copolymers can only be achieved in the cases of functional polymer surfaces (e.g., PET, polyurethane, etc). Poly(ethylene oxide) can only be covalently linked to chemically inert substrates such as PE, PP, and Teflon when their surfaces are prefunctionalized. Photo-induced and high-energy radiation-mediated grafting and grafting/crosslinking processes represent an additional approach to this problem. However, the complex wet chemistry required for the generation of photoactive groups bearing PEG and the often undesired high-energy radiation-induced structural modification of the bulk of polymeric systems are limitations for application purposes.

Literature data indicate that most of approaches for the generation of PEO-rich polymeric surfaces involving physical adsorption or entrapment (including the generation of interpenetrating PEO-containing polymeric networks) and covalent grafting of PEO on a variety of substrate surfaces (PET, polyurethane, PVC, cellulose, functionalized glass, gold, etc.) have resulted in significantly reduced protein, platelet, and bacterial adsorption and in enhanced biocompatibility.

#### B. Silver as an Antimicrobial Molecular Recognition Agent

Another approach to prevent biofilm formation and consequently foreign body infections is to create antimicrobial polymeric materials by loading the substrates with antibiotics, detergents, disinfectants, iodine, or metals (e.g., silver) (27). These composite materials gradually release the antibacterial agents and can in this way prevent colonization. However, most of the organic bacteriostatic compounds incorporated in biomaterials have limited action due to the limited loading, and they only can be used for short-term biofilm prevention.

Silver was considered in many investigations due to its good antimicrobial activity and low toxicity. Silver is one of the most powerful natural disinfectants known. Research indicates that resistant strains do not appear in connection with the use of colloidal silver. Other metals also have germicidal effects, such as copper and mercury. However, most of these metals are toxic to mammalian cells. Bacteria have a strong ability to adapt to various substances. Antibiotics, for instance, destroy bacteria which are susceptible to them; however, they can become resistant by mutation.

Colloidal silver is a dispersion of tiny silver particles in water. The ultimate colloidal silver suspension would be at the molecular level. It has been suggested that the smaller the silver particles, the more effective the colloid is.

Silver occurs under several oxidation states. The most common are elemental silver ( $\text{Ag}^0$ ) and the monovalent silver ion ( $\text{Ag}^+$ ). However, higher oxidation states of silver are also known ( $\text{Ag}^{2+}$ ,  $\text{Ag}^{3+}$ ). It has been proposed that silver could be prepared in a molecular crystal form (an oxide lattice where one pair of silver ions in the molecule is trivalent and another pair of silver ions is monovalent) (43,44). This tetrasilver tetroxide is suggested to have biocidal properties through an electron release mechanism. The exact antimicrobial action of silver is not completely understood. Several possible mechanisms have been proposed which involve the interaction of silver with biological macromolecules, such as enzymes, DNA, etc. (45–49).

The deposition of silver or silver oxide on polymer (plastic) surfaces is rather difficult. Conventional silver coatings involve the preparation of silver-containing polymer solution (e.g., silicon, latex) that can be applied in the next step to polymer surfaces. However, most of the silver is buried into the bulk of the coating, and accordingly the resulting low silver surface area reduces significantly the efficiency of the molecular interaction. Sputtering and ion beam-assisted deposition of silver on plastic surfaces have also been evaluated. These processes are energy intensive and most of the silver is lost through undesired reactor wall deposition processes, and it can be applied only on substrates of high thermal stability.

These conventional approaches focused on the generation of antifouling layers on various substrate surfaces, including deposition of PEO and PEO-based copolymers. Incorporation of antimicrobial substances into common or modified polymeric structures and deposition of thin silver layers have the following limitations for their application:

Physical adsorption of PEO or PEO-based copolymers on polymeric surfaces usually results in the forma-

tion of labile films and even in less stable layers in the cases of low surface energy polymeric materials (e.g., PP, PE, Teflon).

PEO structures cannot be deposited on metal surfaces and exploited in water environments due to their high water solubility, while less-soluble PEO-based structures require complex procedures for their synthesis and deposition.

Conventional grafting processes developed for the covalent anchorage of PEO type structures on hydrophobic polymeric substrate surfaces require complex wet chemistry processes and often the presence of toxic solvents. The removal the trace solvent amounts or other chemicals (toxic materials incorporated into the surface layers of the substrates as a result of swelling processes) from the structure of surface layers of the base polymers is sometimes very difficult.

Photochemical grafting mechanisms have low efficiencies and the high-energy radiation processes usually alter the bulk characteristics of the materials.

Polymeric materials are not conductive electrically; consequently, thin silver layers cannot be deposited using conventional electrochemical techniques. Silver does not have stable, volatile organometallic compounds except a low-vapor pressure complex derivative: perfluoro-1-methyl propenyl silver (50), and as a result plasma-enhanced chemical vapor deposition (PECVD) is also less attractive. The sputtering approach is also excluded for polymeric materials; their surface structures would be damaged by the energetic (high temperature) metal particles. Sputtering is also usually limited to low surface area coatings.

#### IV. SURFACE FUNCTIONALIZATION OF BIOMATERIALS USING A COLD PLASMA APPROACH

Literature data accumulated in the last two decades indicate that active species of cold plasma environments can induce significant chemical reactions in the surface layers of various substrates including organic or inorganic materials. It has been demonstrated that surface characteristics like surface energy, surface roughness, and optical and electrical properties can conveniently be tailored under plasma conditions. Due to the fairly high energy levels of the plasma particles, even surface characteristics of materials as inert as quartz or Teflon can be altered by selecting the proper discharge environments (51–57).

### A. Cold Plasma State

The plasma state, the fourth state of matter, is associated with the high energy content of the matter, and it can be broadly defined as a collection of an equal number of oppositely charged gas phase carriers with a net zero electrical charge. It is estimated that more than 95% of the known universe exists in the plasma state. All active celestial bodies are plasmas, and the interstellar space is also considered as rarefied plasma. Lightning, the Northern lights, and the ionosphere surrounding our planet are plasma states as well.

Manmade plasmas can be created by increasing the energy content of matter regardless of the nature of the energy source. Mechanical, chemical, thermal, radiant, and electrical energies can be employed for the creation of plasma state. Plasmas are losing energy toward the walls which confine them, and in order to sustain the discharge, energy must be supplied into the system continuously. The easiest way to supply energy into the plasma on a continuous manner is by using electrical energy. This explains why electrical discharges are the most common manmade plasma states.

Depending on the nature of the electric or electromagnetic fields that generate the plasma, DC, low- and high-frequency AC, and microwave glow discharges can be defined.

Close to totally ionized gases are termed as hot plasmas (near-equilibrium discharges). In these cases, the temperature of both the charged species of atomic or molecular origin and the electrons is extremely high.

Cold plasmas (glow discharges, silent discharges, and nonequilibrium discharges) are produced in matter with much lower energy contents. The degree of ionization is small ( $10^{-1}$  to  $5 \times 10^{-3}\%$ ), and the atomic and molecular charged and neutral species have low energies, while the electrons have relatively high energies. These electrical discharges are nonequilibrium plasmas and, owing to the low energy levels of the species composing the plasma, they alone are suitable for modifying organic matter. Electrical energy–initiated cold plasma states arise when the accidentally free electrons (e.g., created by cosmic rays) of a low pressure gaseous environment are accelerated by electric or electromagnetic fields to kinetic energy levels at which ionization, excitation, and molecular fragmentation processes are generated. These energies are usually expressed in energy or temperature units ( $1 \text{ eV} = 11,600\text{K}$ ) based on the kinetic theory. The mass of electrons being much smaller than those of molecular or atomic species, their velocities and consequently their kinetic energies will be much higher in comparison to ions or free radicals.

Characteristic 3- to 4-eV electron energies of glow discharges would be equivalent to 34,800–46,400K. However, owing to the low heat capacity of electrons these energies will not raise significantly the temperatures of the surfaces which confine the plasma. These systems are characterized by the simultaneous presence of photons, electrons, ions of either polarity, neutral atoms and gas molecules and their corresponding excited species, and molecular fragments (mono and multiple free radicals). They can be considered as quasineutral gases exhibiting a collective behavior (local concentration of charges can influence, for instance, the motion of particles through long-range Coulomb effects) (58–61).

Depending on the nature of the electric or electromagnetic fields that generate the plasma, DC, low- and high-frequency AC (e.g., radiofrequency plasmas), and microwave glow discharges can be defined.

### B. Plasma Chemistry

The electron energy distribution of nonequilibrium (low pressure) plasmas can be often described by a Druvesteyn approximation (Fig. 1) when the temperature of the electrons is considered much higher than that of the ions and when it is assumed that the only energy losses are by elastic collisions (the electric field strength in the plasma is sufficiently low to neglect inelastic collisions). However, at higher degrees of ionization the influence of electron density on the energy distribution can be significant (60,61). It can be observed that a small number of electrons have relatively high energies (5–15 eV), while the bulk of the electrons belong to the low energy electron range (0.5–5 eV). Since the ionization potentials of the atoms of com-

**Figure 11.1** Druvesteyn electron energy distribution of a cold plasma (average electron energy: 3 eV).

mon organic structures belong to the tail region of the electron energy distribution (e.g.,  $C^+ = 11.26$  eV;  $H^+ = 13.6$  eV;  $O^+ = 13.6$  eV;  $N^+ = 14.53$  eV, etc.), the low degrees of ionization of cold plasmas appear obvious.

However, it is important to note that the energy range of most of the electrons (2–8 eV) is intense enough to dissociate almost all chemical bonds involved in organic structures (62) and to create free radical species capable of reorganizing into macromolecular structures. As a consequence, all volatile organic compounds and organic derivatives containing main group elements can be fragmented and/or converted into high molecular weight compounds, even if they do not have the functionalities peculiar for common monomers (63,64). The plasma-generated macromolecular networks do not retain the structural characteristics of the starting materials, they are not based on repeating units. Consequently, the term plasma polymers which is often used is inappropriate for describing these structures. Higher energies are required only for the dissociation of unsaturated linkages and the formation of free radicals from a small number of atoms ( $CH_2$ ,  $SiCl_2$ , etc.). Thus, it can be understood why plasma-generated macromolecular structures are usually characterized by unsaturation and branched and crosslinked architecture.

Besides the recombination mechanisms developed on the surfaces which limit the plasma, the active species of the discharge interact and continuously tailor the artificially exposed (reactor walls, various substrates, etc.) and self-generated (e.g., plasma-synthesized macromolecular structures) surface layers. The competition between the recombination–deposition processes and interaction of plasma species with the nascent macromolecular structures (etching) will control the intensities and the predominance of ablation, surface functionalization, or macromolecular film formation reactions.

Macromolecular plasma chemistry has developed in the last two decades in the following directions: plasma-enhanced synthesis (deposition and/or grafting) of thin layer macromolecular structures; conventional graft-polymerization reactions from plasma-activated substrate surfaces; surface functionalization of polymeric materials; and etching of inorganic or polymeric substrate surfaces.

### C. Plasma Reactors

The most commonly used plasma reactors for the synthesis of macromolecular structures and surface modification of various substrates are radiofrequency (RF) installations (62,65). These discharges can be excited and sustained even by using insulated electrodes located inside or outside the reaction chamber. This is an important feature relative

to DC plasmas because in the case of RF discharges dielectric material depositions on the electrodes during the plasma process will not significantly influence the regime of the discharge. Radiofrequency plasmas can also be sustained under lower pressure conditions and have higher ionization efficiencies than DC discharges. The energies of sample-bombarding ions of RF plasmas can conveniently be controlled by adjustable negative bias, while in the case of DC plasmas this possibility is limited by the breakdown voltage.

The main advantages of plasma chemistry versus conventional wet chemistry approaches in the areas of coating and modification (e.g., functionalization, ablation) of surfaces are

- The energies of the active species of plasmas are comparable with the bond energies involved in all organic compounds and organic compounds containing main group elements, and as a result all volatile derivatives can be converted from their plasma-generated molecular fragments into thin layer macromolecular film depositions. This practically assures unlimited possibilities for the development of structure- and functionality-controlled coatings.

- The controlled interaction of plasma state with surfaces allows the tailoring of surface characteristics (chemical functionalities) and morphologies of even the most inert substrates (e.g., Teflon, silica, etc.).

- Cold plasma treatments are dry chemistry technologies. The reaction mechanisms are mediated by the interaction of gas phase active species of the discharge with solid surfaces (metal, inorganic, and organic macromolecular compounds).

- Plasma chemistry technologies usually require moderate vacuum environments (100–10,000 mTorr) and the active species of the discharge alter only the very top layers of the substrates (deposition/etching). As a consequence, these processes require very low quantities of starting materials.

- Plasma chemistry technologies are cost effective and environmentally friendly.

## V. PLASMA TECHNOLOGIES FOR THE PREVENTION OF PROTEIN ADSORPTION, BACTERIAL ATTACHMENT, AND BIOFILM FORMATION

The cold plasma state can be used to create new surface functionalities, morphologies, and chemistries that will re-

**Table 11.4** Cold Plasma-Enhanced Modification of Surfaces for the Control of Protein and Cell Adhesion

Objective	Experimental conditions	Results Ref.	
Covalent immobilization of PEO on allylamine (AA) and allyl alcohol (AAI) plasma-treated PET	13.56 MHz RF reactor with external moving (controlled speed of capacitor plates in same direction with vapor flow) copper plate electrodes	Successful cyanuric chloride-mediated immobilization of PEO from AA and AA plasma-coated PET surfaces. AA-treated PET surfaces exhibit higher PEO attachment than AAI-modified PET substrates.	70
Evaluation of <i>S. epidermis</i> adhesion to hydrophilic films deposited on PS from hydroxyethyl-methacrylate (HEMA) plasma and the effects of surface energetic parameters on the bacteria-synthetic surface interaction	Stainless steel, capacitively coupled, parallel plate reactor (RF power: 40–100 W; base pressure: 15 Pa; gap between electrodes; 10 cm), with samples located on the water-cooled ground electrode	The <i>S. epidermis</i> adhesion on PS discs coated with HEMA plasma films was significantly higher than on PS. The number of bacteria adhered to plasma-coated and oxygen plasma-treated PS was comparable. It is suggested that a significantly higher Lewis base characteristic associated with the plasma-modified substrates is responsible for this phenomenon.	71
Study of cell adhesion on ammonia, dimethyl acetamid, methanol, and methyl methacrylate RF plasma-coated fluoroethylenepropylene copolymer substrates evaluating the putative role of serum fibronectin (Fn) and vitronectin (Vn) in the initial attachment of human vein endothelia (HUEV) and human dermal fibroblast (HDF) to surfaces coated under oxygen- and nitrogen-containing vapor conditions	RF (125–375 kHz and 13.56 MHz) reactor; specially designed vapor flow system for the controlled introduction of vapors directly into discharge zone (4–15 sscm); tape type substrate; reversible, speed-controlled transport mechanism for the tape (0.05–0.4 m/min)	Surfaces resulting from oxygen-containing vapors do not bind sufficient Fn from fetal bovine serum (FBS) to support cell attachment, and the initial adhesion of HUEV cells has a high dependence upon FBS-origin Vn. Surfaces based on nitrogen-containing gases/vapors more effectively bind FBS-origin Fn, resulting in a higher dependence of cell attachment upon serum Fn. It was concluded that cell adhesion to the nitrogen-based substrates is dependent upon either Vn or Fn, but not exclusively to one of them.	72
Evaluation of the platelet-adhesion activity of fibrinogen adsorbed on tetrachloroethylene (TCE) and tetrafluoroethylene (TFE) plasma-treated PET surfaces	Tubular Pyrex glass reactor; degassed monomers; substrates initially treated with Ar plasma (2.5 W; 3 cm <sup>3</sup> /min; 0.1 mmHg; 3.3 mm/s)	Fibrinogen adsorbs strongly on both TFE- and TCE-treated PET. It is suggested that this tenacious binding behavior is related to the conformational rearrangement of fibrinogen, which results in a molecular state, that prevents its recognition and binding by platelet receptors.	73
Investigation of the adsorption and subsequent detergent elutability of fibrinogen and albumin on virgin and tetrafluoroethylene and perfluoropropane (PFP) plasma-treated polymer (PET) surfaces, evaluating their relative adsorption-related thromboresistance	13.56-MHz, 300-W RF capacitively coupled tubular glass reactor provided with external movable (1–4 mm/s electrodes (Ar etched substrates; TFE: 15 sscm; 200 μmHg; 30 W; 3.3 mm/s; and 3 sscm, 200 μmHg; 2.5 W; 3.3 mm/s; PFP: 3 sscm; 200 μmHg; 2.5 W; 1 mm/s)	The adsorption of fibrinogen and albumin to plasma-treated PET are comparable to their adsorption to PTFE and PET; however, their elutability with SDS is much lower in comparison to PTFE and PET.	74
Study of deposition of ultrathin poly(2-hydroxyethylmethacrylate (PHEMA) by simultaneous condensation and RF plasma exposure of HEMA vapors, comparing interaction of plasma and conventional PHEMA surfaces with <sup>125</sup> I-radiolabelled fibrinogen	Capacitively coupled, external electrode, tubular glass, RF plasma reactor provided with a liquid nitrogen cooling system of the substrate holder (0.2 Torr; 20 W; Ar plasma-activated substrate: PE; deposition time: 5 min for cooled and 15 min for noncooled substrates.	Plasma HEMA films deposited at low temperatures were similar in nature and interacted similarly with fibrinogen in comparison to conventional PHEMA structures.	75

Table 11.4 Continued

Objective	Experimental conditions	Results Ref.	
Study of nitrogen and oxygen plasma-mediated modification of PTFE for enhancement of adhesion of endothelial cells and serum fibronectin	Plasmafab 505 (Electrotech, Bristol, UK) plasma reactor (20 Pa for N <sub>2</sub> ; 9 Pa for O <sub>2</sub> plasmas; 250 W)	Oxygen and nitrogen plasma-treated PTFE have improved wettability and human endothelial cell adhesion (from serum-containing culture medium) comparable to tissue culture PS. The amounts of serum proteins including fibronectin adsorbed to plasma-modified substrates are larger than those adsorbed on virgin PTFE	76
Study of the platelet activation and adhesion to ethylene oxide (EO) and N-vinyl-2-pyrrolidone (VP) plasma-coated dimethyldichlorosilane (DDS)-treated glass substrates	13.56-MHz inductively coupled, Pyrex glass RF plasma reactor [Ar plasma pretreatment; EO plasma: 15–100 mTorr; 20–80 W; EO flow: 0.8–8.6 mL/min (STP); treatment time: 5–30 min; VP plasma: 30 mTorr; 0.1 mL/min (STP); 30 W].	Hydrophilic EO- and VP-based plasma-created macromolecular layers do not prevent platelet adhesion and activation. The film thickness does not influence significantly these parameters. Based on adhesion data resulting from Pluronic structures, it is suggested that steric repulsion might be involved in the protein and platelet repelling mechanisms	77
Evaluation of protein adsorption, cell attachment, and biocompatibility of 2-methacroyloxyethyl phosphorylcholine-grafted silicon rubber surfaces (pMPC-SR), prepared by plasma-induced reaction mechanisms	Ar plasma-treated and oxygen-exposed SR membranes sealed in glass ampoules containing degassed MPC/ethanol solution and heated for a predetermined time at 75°C	Protein adsorption of high MPC concentration pMPC-SR surfaces was reduced in comparison to SR. Epithelial cell attachment and growth onto the grafted samples were suppressed. Platelet adhesion data indicate good biocompatibility.	78
Evaluation of fibrinogen adsorption and host tissue responses to hydrophilic and hydrophobic plasma-functionalized PET substrates	RF pulsed allyl alcohol, allylamine, perfluorohexenes (PH), and hexamethyldisiloxane (HMDSO) plasma environments (0.1 ms on, 3 ms off; 200 W)	Surface functionalities do significantly influence both the adsorption and denaturation of adsorbed fibrinogen, and these surfaces provoke different degrees of acute inflammatory responses. It is suggested that surface-induced conformational changes of adsorbed fibrinogen may be critical to the recognition of biomaterial implants by phagocytes.	79
Analysis of the influence of free energy of polymers (PET, PE, PTFE, PDMS, and fluorocarbon-copolymer-coated PET) on resistance of adsorbed albumin to sodium dodecyl sulfate (SDS) elution for untreated and TFE, ethylene, and HMDSO RF plasma-exposed surfaces	Tubular Pyrex glass, capacitively coupled reactor with external, stationary or movable electrodes (2.5 W; 3 cm <sup>3</sup> /min; 0.1 Torr; 3.3 mm/s) and presence or absence of Ar plasma precleaning	TFE-treated polymers retain a larger fraction of the adsorbed albumin than ethylene- and HMDSO-modified surfaces. It is suggested that the albumin retention is closely related to their surface free energy, and that the tight binding of albumin to the fluorocarbon polymers may be related to the strong hydrophobic interactions.	80

Table 11.4 Continued

Objective	Experimental conditions	Results Ref.	
Preparation of fouling-resistant PE, PTFE, TCPS, and glass surfaces by plasma deposition of macromolecular layers from tetraethylene glycol dimethyl ether (TEGDME)	Capacitively coupled, external electrode, RF tubular, heated glass reactor (Ar plasma; 40W; 0.175 mmHg; 5 min)	Adsorption of <sup>125</sup> I-labelled fibrinogen, albumin, and IgG from buffer and plasma on plasma-treated polymer surfaces was very low in comparison to unmodified substrata. Coated glass substrates adsorbed more protein than plasma-treated PE and PTFE. Short-term nonadhesiveness of platelet and endothelial cells to plasma-treated substrates was also observed.	81
Evaluation of five different gram-positive and gram-negative bacteria and the different strains' adhesion to plasma-treated Vicryl sutures	13.56-MHz RF tubular, capacitively coupled, external electrode plasma reactor (plasma vapors: dimethylaminoethylmethacrylate (DMAEMA) and acrylic acid (AAc); 10 W; 5 min; 0.5 Torr; monomer flow: 30 mL/min)	Hydrophobic bacteria attached more to hydrophobic (unmodified) Vicryl sutures. Both plasma treatments generated significant decrease in bacterial attachment. The effect of AAc plasma was more pronounced.	82
Study of adhesion of <i>S. epidermis</i> to plasma-deposited HEMA macromolecular layers deposited on PS substrates	Capacitively coupled, parallel plate reactor (gap between the electrodes: 10 cm); water cooled electrodes (HEMA plasma: 40–100 W; 15 Pa; monomer temperature: 75°C; monomer flow: 10 cc(STP)/min; oxygen plasma: 20 cc(STP)/min; 80 W; 20 Pa)	Bacteria adhered more to the plasma-deposited or plasma-treated surfaces than to PS. Experimental conditions did not have a significant influence on the adhesion efficiencies. It is suggested that electron donor–electron acceptor interactions control the adhesion mechanism.	83
XPS and SSIMS characterization of glass surfaces modified by plasma-modified oligo(glyme) films	13.56-MHz RF tubular, capacitively coupled (external copper electrodes), glass reactor (20–80 W, base pressure: 14–18 mT; oligo-glyme flow: 50 sccm; deposition time: 20 min)	The surfaces of oligo(glyme)-origin deposited layers appear to be populated with methyl-terminated oligo(ethylene oxide) chain ends. At higher RF power values, the oxygen-based functionalities are lost; the deposited layers have an unsaturated hydrocarbon type character.	84
Evaluation of controlled release of antibiotic (Ciprofloxacin) of triethylene glycol dimethyl ether (triglyme) and poly(butyl methacrylate) (pBMA) plasma-modified polyurethane membranes (PEU) to prevent bacterial ( <i>Pseudomonas aeruginosa</i> ) adhesion and biofilm formation	Glow discharge deposition of triglyme- and pBMA-origin layers (“monomer” temperature: 60°C)	The rate of initial bacterial cell adhesion to triglyme-coated PEU was 0.77% and to the pBMA-coated PEU releasing ciprofloxacin was 6% of the observed adhesion rates for the control PEU.	85

sult in a different interaction of discharge-exposed surfaces with biomacromolecules and cells in comparison to the nonmodified materials. Literature data indicate that a large variety of plasma reactors, precursor plasma gases/vapors (selected for the creation of specific surface functionalities and surface layers), and experimental parameters has been employed to control protein and cell adsorption and consequently biofilm formation and foreign body-mediated infections (66–69).

#### A. Plasma-Enhanced Modification of Polymeric Substrates

Owing to this “multidirectional approach” the comparison and evaluation of experimental data and theoretical considerations is very difficult and often the results are apparently inconsistent. Accordingly, a tabular comparison of experimental parameter space, objectives, and findings appears more adequate (Table 4).

**Figure 11.2** Survey ESCA diagram of polyethylene, formaldehyde plasma-treated polyethylene, and silver-coated polyethylene.

**Figure 11.3** High resolution  $C1s$  ESCA diagrams of untreated polyethylene (U), formaldehyde plasma-treated polyethylene (P), and silver-coated polyethylene (Ag).

### B. Silver Deposition on Polymers

Plasma-enhanced deposition of thin silver layers on polymer (dielectric) substrate surfaces and the production of large quantities of high-concentration (200–400 ppm) colloidal silver solutions under dense medium plasma (DMP) conditions have also been accomplished (86–88). Thin silver layers were deposited on formaldehyde plasma-functionalized PE surfaces by involving ex situ, second-stage Tollen's reaction in the absence of plasma, where diamminsilver (I) ions are reduced by the discharge-generated aldehyde functionalities to metallic silver according to the following reaction:

The implantation of aldehyde functionalities was achieved using paraformaldehyde (PF)-origin formaldehyde-RF plasma environments. Formaldehyde is only available commercially in water solution, and other aldehydes (aldehyde group precursors) are usually less volatile and would also generate under plasma conditions undesired hydrocarbon-type fragments. Paraformaldehyde is a solid phase material that decomposes at relatively elevated temperatures into formaldehyde. Accordingly, a temperature-controlled "formaldehyde feeder" was designed and employed. Aldehyde functionalities were implanted onto PE surfaces under the following experimental conditions: stainless steel, cylindrical, parallel-plate, capacitively coupled reactor; frequency of the driving field: 40 kHz; base pressure: 50 mTorr; formaldehyde pressure in the absence of plasma: 200 mTorr; formaldehyde pressure in the presence of discharge: 400 mTorr; RF power dissipated to the

**Figure 11.5** SEM images of untreated (left) and silver-coated (right) polyethylene. Magnification:  $\times 24,000$  (top);  $\times 125,000$  (bottom).

electrodes: 250 W; reaction time: 10 min; temperature of the PF container:  $170^{\circ}\text{C}$ . Survey (Fig. 2) and high resolution *C1s* (Fig. 3), *O1s*, and *Ag3d* ESCA data indicate the presence of silver on the surface of PE films and the formation of  $-\text{COOH}$  functionalities as a result of the Tollen's reaction. Visual observation (metallized surface appearance), AFM (Fig. 4), SEM, and energy dispersive x-ray spectroscopy (Fig. 5) substantiate the presence of silver particles of the plasma/Tollen's modification of PE.

### C. DMP Plasma Generation of Colloidal Silver

Water-based colloidal silver nanoparticles were prepared in a redesigned version of DMP reactor. The DMP, a new plasma tool, developed at the Center for Plasma Aided Manufacturing (C-PAM), University of Wisconsin—Madison, allows the initiation and sustaining of discharges in coexisting liquid/vapor medium at atmospheric pressure and may offer a significantly higher efficiency for the processing of liquid phase materials in comparison to common plasma technologies.

The reactor (Fig. 6) is composed of a cylindrical glass chamber (7), provided with two stainless steel upper and bottom caps (9,17), and a cooling jacket (4). The rotating, cylindrical, stainless steel, upper electrode (19) is equipped with a quartz jacket for avoiding the penetration of the reaction media to the electrode-sustaining central shaft and bearings. The upper electrode has a cylindrically shaped, cross-section disc end, which is terminated in an interchangeable ceramic pin array (8) and holder (23). The lower electrode is hollow, has also an interchangeable conical cross-section end piece, and in addition is provided with channels (25) for the recirculation of the reaction media. Both the spirally located pin array and the interchangeable metallic part of the lower electrode can be made of different metals required by the specific plasma treatment. In this case, for the synthesis of colloidal silver solutions, both the spirally located pin array and the interchangeable metallic part of the lower electrode are made of pure silver. The distance between the pin array and the lower electrode can be varied by a micrometric (thimble) screw system. The reactor is vacuum tight (copper gasket sealings to

**Figure 11.6** Redesigned version of dense medium plasma reactor. 1—DC power supply; 2—gases evacuation; 3, 26—coolant exit and inlet; 4, 7—glass cylinders; 5—electrical contact; 6—coolant; 8—ceramic pin array; 9, 17—caps; 10—nonrotating electrode; 11—ground; 12—gas inlet; 13—motor; 14—digital controller; 15, 18—magnetic coupling system; 16—liquid inlet; 19—rotating electrode; 20—sealed volume; 21—quartz isolator; 22—recirculating pump; 23—pins; 24—electrical discharges; 25—recirculated flux; 27—valve.

avoid the escape of the components of the reaction medium into the environment), and the rotation of the upper electrode is assured through magnetic coupling system (15, 18). The reactor can be operated in a batch-type or continuous flow mode, depending on the specific application. The rotation of the upper electrode is digitally controlled in the range of 0–5000 rpm. The plasma (multitude of spark discharges) can be initiated and sustained using adjustable and commercially available DC or AC power supplies. Although the actual mechanism for electron emission and energy transport through the liquid is not well characterized at this time, the rotation of the electrode, and the spirally arranged pin array system (which acts as a high current density field emission arc source) will generate under DC

or AC voltage conditions many microdischarges covering the whole area of the electrode surfaces.

Rotating the electrode serves several important purposes. The action spatially homogenizes the multiple microarcs, activating a larger effective volume of fluid. Spinning the electrode also simultaneously pumps fresh liquid and vapors into the discharge zone, and it thins the boundary layer between the emission tips and the bulk liquid.

Reactive or inert gases can also be introduced into the reaction media during the plasma process through the hollow, lower electrode. The simultaneous presence of a gas environment contributes also to the homogenization of the reaction system and enhances the microarc formation process owing to the lowered density of the media.

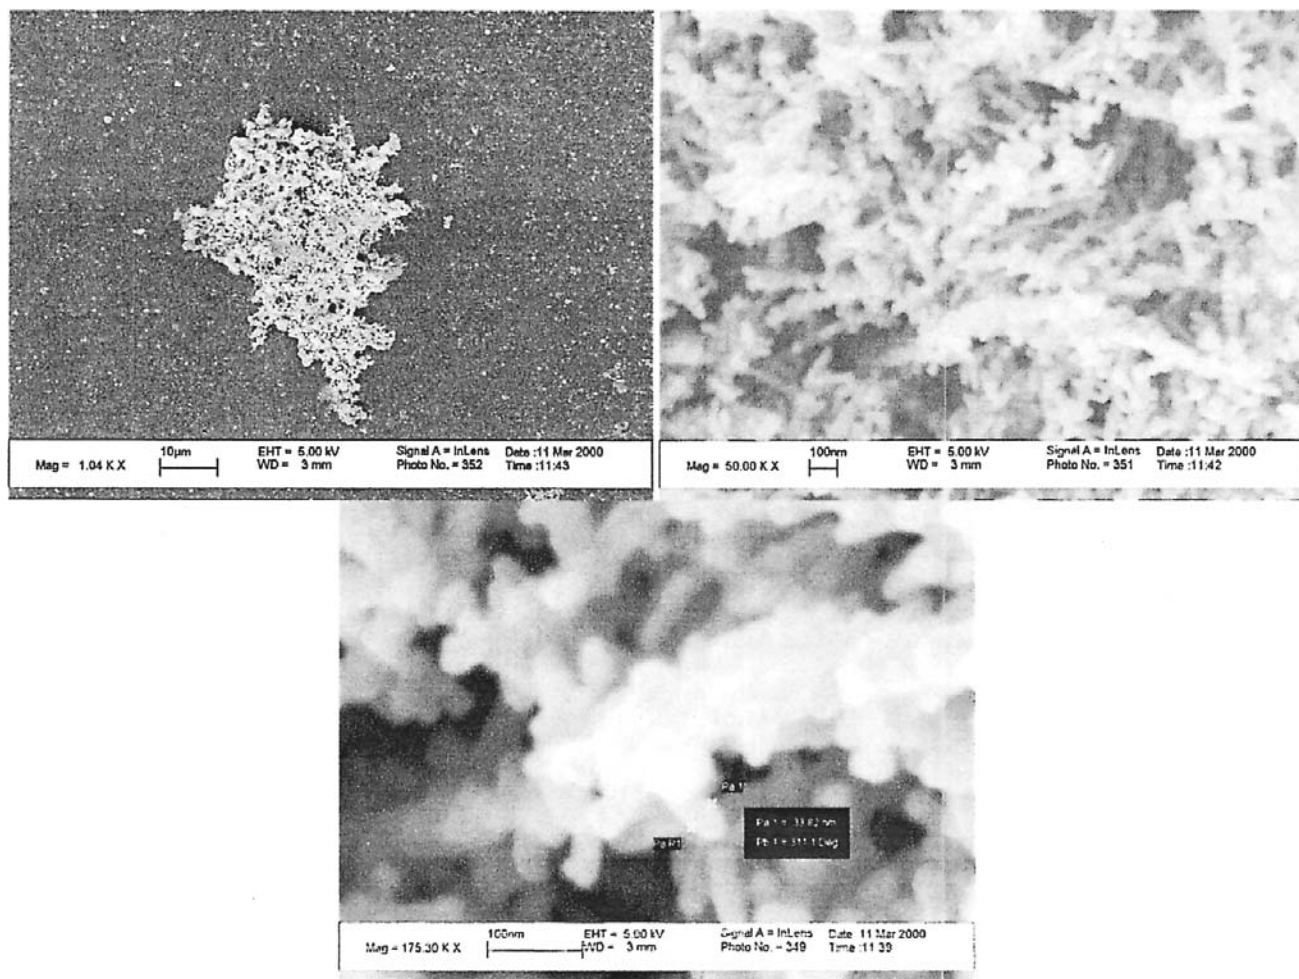

The DMP reactor shows an attractive potential for the creation of an efficient way for the synthesis of nanoparticle systems: the rapid spinning of the pin array electrode, and consequently the microarc system, essentially converts a surface process to a volume process. The individual arclets, under spin, sweep out a circular volume of plasma while simultaneously pumping fresh fluid into the reaction zone, thus thinning the diffusive boundary layer and enhancing mobility of free radicals into the bulk. Accordingly, all plasma-initiated and -sustained processes will be more efficient and will have a volume character.

Typical colloidal silver solutions were prepared under the following experimental conditions: initial liquid media: 200 mL pure water; angular speed of the upper electrode: 1000 rpm; DC voltage: 200 V; DC current during the process: 1.0–1.5 A; flow rate of Ar (bubbled through the liquid medium): 20 sccm; reaction time: 1 min; temperature of the reaction medium: 8°C; modus operandi: batch-type. SEM images of nanoparticle silver clusters formed by the evaporation of 100  $\mu$ L colloidal silver solution (200 mL initial water; 20-s reaction time) show the nano-scale nature of the DMP-plasma generated silver particles (Fig. 7). It was demonstrated that the colloidal silver solutions have very strong bactericid characteristics (Table 5). Extremely short plasma treatment times are enough to kill high concentrations of bacterial populations. The following can be concluded:

Cold plasma reaction mechanisms allow the deposition of macromolecular layers, which, depending on the starting components and the selected plasma parameters, can enhance or diminish the adsorption of proteins and cells on various substrate surfaces.

For each application the specific plasma gases and reaction conditions should be carefully selected.

Systematic investigations targeting the deposition of antifouling layers should be developed for the specific PEG precursor material (influence of experimental

parameters on the molecular fragmentation and surface mediated recombination reaction mechanisms).

## VI. PLASMA-MEDIATED IMMOBILIZATION OF ACTIVE BIOMOLECULES

The advantages of using enzymes in chemical synthesis are related to their very high specificity (regio- and stereospecificity) and versatility, to their mild reaction conditions (close to room temperature and to pH neutral media), and to their high reaction rates (89–91). However, due to the poor recovery yields and reusability of free enzymes, much attention has been paid to the development of efficient enzyme immobilization processes.

Immobilized enzymes are defined as enzymes physically confined in a certain region of a substrate with retention of their catalytic activities. The immobilization process includes the localization of enzymes chemically or physically on various insoluble (usually water-insoluble) organic or inorganic polymer matrices. This research area is currently generating increased interest among biochemists, biophysicists, chemists, and physicists due to its interdisciplinary nature. Two main reasons attracted the attention of scientists in this field: first, it was obvious that the results of these investigations can lead to potential for using immobilized enzymes as stable and renewable industrial catalysts, and second these investigations might help to understand the influence of heterogeneous environments on enzyme-catalyzed reactions. Most biologically active in

vivo species, such as enzymes and antibodies, function in heterogeneous media. These environments are difficult to reproduce *in vitro* for applicative purposes. Immobilized enzyme systems are useful for experimental and theoretical research purposes for understanding the mechanisms of *in vivo* biocatalyzed reactions, and can offer solutions for use in batch-type reactions where there is a poor adaptability to various technological designs and recovery of the enzymes is difficult. Most of the intracellular enzymes are working under such environments and do not meet the Michaelis–Menten dilute solution conditions.

The molecular recognition ability and activity of enzymes (polypeptide molecules) are based on their complex three-dimensional structures containing sterically exposed, specific functionalities. The polypeptide chains are folded into one or several discrete units (domains) which represent the basic functional and three-dimensional structural entities. The cores of domains are composed of a combination of motifs which are combinations of secondary structure elements with a specific geometric arrangement. The molecular structure–driven chain-folding mechanisms generate three-dimensional enzyme structures with protein molecules orienting their hydrophobic side chains toward the interior exposing a hydrophilic surface. The —C(R)—CO—NH— based main chain is also organized into a secondary structure to neutralize its polar components through hydrogen bonds. These structural characteristics are extremely important, and they make the enzyme molecules very sensitive to the morphological and functional characteristics of the potential immobilizing substrates. High surface concentrations of enzyme-anchoring functionalities can result, for instance, in excessive enzyme densities or multipoint connections which can “neutralize” the active sites or can alter the three-dimensional morphologies of the enzyme molecules through their mutual interaction and their interaction with the substrate surfaces. These are just a few of the factors that may be responsible for the significantly lower activities of immobilized enzymes in comparison to the activities of free enzyme molecules. Rough substrate surface topographies or stereoregular surfaces (e.g., isotactic or syndiotactic polymers) might also influence, in a positive or negative way, the specific activities. Morphologically ordered surfaces might induce changes of the stereoregular shapes of protein molecules. Recently it has been found that enzymes can adopt more than one functional conformation other than its lowest potential energy state (92). Consequently, one of the potential solutions for achieving enhanced immobilized enzyme activities, comparable to that of the free enzymes, would be to intercalate selected length and densities of spacer molecules between the substrate and the enzyme molecules during the immobilization reaction processes (93–97).

Techniques for immobilizing enzymes can broadly be

divided into two categories: chemical and physical methods. Chemical methods of immobilization involve the formation of at least one covalent bond between one or more enzyme molecules and the polymer matrix. These processes are usually irreversible. Physical methods include adsorption (e.g., electrostatic interaction) and entrapment within microcompartments (e.g., entrapment of enzyme within gel matrices or semipermeable microcapsules, etc.) and are usually based on reversible bond formations.

The classification of enzyme immobilization techniques can also be made according to the binding procedure: carrier binding, crosslinking, and entrapping (98). Carrier binding can be accomplished by physical adsorption, ionic bonding, and covalent bonding, while entrapping can be achieved by microencapsulation and lattice entrapping. According to the carrier binding technique, the amount of the enzyme bound to the carrier and the activity after immobilization depend on the nature of the inorganic or organic carrier. An increase of the densities of the hydrophilic groups on the carrier surfaces and the concentration of the bounded enzymes results in enhanced activity of the immobilized enzyme.

Covalent attachment of enzymes to a solid phase matrix must involve only functional groups of the enzyme that are not essential for catalytic action. This immobilization approach is much more complex and less mild than those based on physical adsorption and ionic binding procedures. As a consequence, covalent binding may alter the conformational structure and the active centers of the enzyme, resulting in diminished activity. However, due to the covalent bonding, the immobilized enzyme will not be released into the surrounding liquid environment even in the case of reactive substrates and under high ionic strength conditions.

Physical adsorption immobilization of enzymes causes little or no conformational change of the enzyme or annihilation of its active centers. However, due to the much weaker forces (van der Waals, hydrogen bonding, etc.) which retain the protein molecules on the carrier surfaces, the enzyme may be released from the carrier surface and diffuse into the surrounding solution.

The ion binding method relies on the attachment of the enzyme molecules by charged functionalities (e.g., ion exchange residues) present on the surfaces of water-insoluble carriers. This approach causes little change in the conformation and the active site of the enzyme, and as a consequence the activity of the immobilized enzyme is usually high. The enzyme-to-carrier linkages are significantly stronger in this case, in comparison to the physically adsorbed enzyme systems, but are less strong than in covalent binding. Dissociation of the enzyme from the carrier surface under high ionic strength solution conditions (specific pH values) is one of the weak points of this approach.

### A. Plasma Functionalization of Natural and Synthetic Supports

Immobilization of active enzymes from 40 kHz and 13.56 continuous wave (CW) and pulsed MHz, capacitively coupled, RF plasma-functionalized natural and synthetic polymer surfaces has been accomplished in the absence and presence of spacer molecular chains intercalated between the polymeric substrates and the immobilized enzyme (99–102). It has been demonstrated that oxygen, hydrazine, and dichlorosilane RF plasma environments are proper for the implantation of carbonyl, primary amine, and halosilane functionalities onto various polymeric substrate surfaces, including poly(ethylene terephthalate),

polypropylene, polyethylene, atactic and isotactic polystyrene (APS, IPS), and cellophane, and that  $\alpha$ -chymotrypsin can conveniently be immobilized under ex situ plasma conditions directly to the substrate surfaces or by involving spacer chain molecules generated under in situ conditions in the absence of the discharge, according to the reaction mechanisms shown in Scheme 1 (99–101).

The activity of the immobilized enzymes was evaluated by monitoring the pH change as a result of the enzyme-induced hydrolysis of acetyl tyrosine ethyl ester. The pH values were recorded using a Virtual instrument (Lab-View) serial connected to a pH meter. The enzyme activity was also tested by reusing thoroughly washed enzyme-immobilized substrates for as many as five cycles.

**Scheme 11.1** (A) Direct immobilization of enzyme from oxygen plasma-functionalized PE (aldehyde and ketone groups). (B) Immobilization of enzyme involving  $\text{SiH}_x\text{Cl}_y$  functionalities, from  $\text{SiH}_2\text{Cl}_2$  RF plasma-functionalized PE. (C) Immobilization of enzyme involving spacer molecules from  $\text{SiH}_2\text{Cl}_2$  RF plasma-functionalized PE.

Scheme 11.1 Continued

The presence of the enzyme on the polymeric substrate surfaces and the covalent nature of the anchorage was demonstrated by x-ray photoelectron spectroscopy, attenuated total reflectance, Fourier transform IR spectroscopy, atomic force microscopy, and laser desorption Fourier transform ion cyclotron resonance mass spectroscopy techniques. It was shown that the tacticity of the polystyrene substrates do not influence the activity of the immobilized  $\alpha$ -chymotrypsin; however, spacer molecules intercalated between the synthetic polymeric substrates and enzyme significantly increase the enzyme activity (Fig. 8) (99,100). It was suggested based on computer-aided conformational modeling of the substrate-spacer system (Fig. 9) that the enhanced enzyme activity might be related to the increased freedom of mobility of  $\alpha$ -chymotrypsin as a result of the intercalation of spacer-chain molecules. The stability of

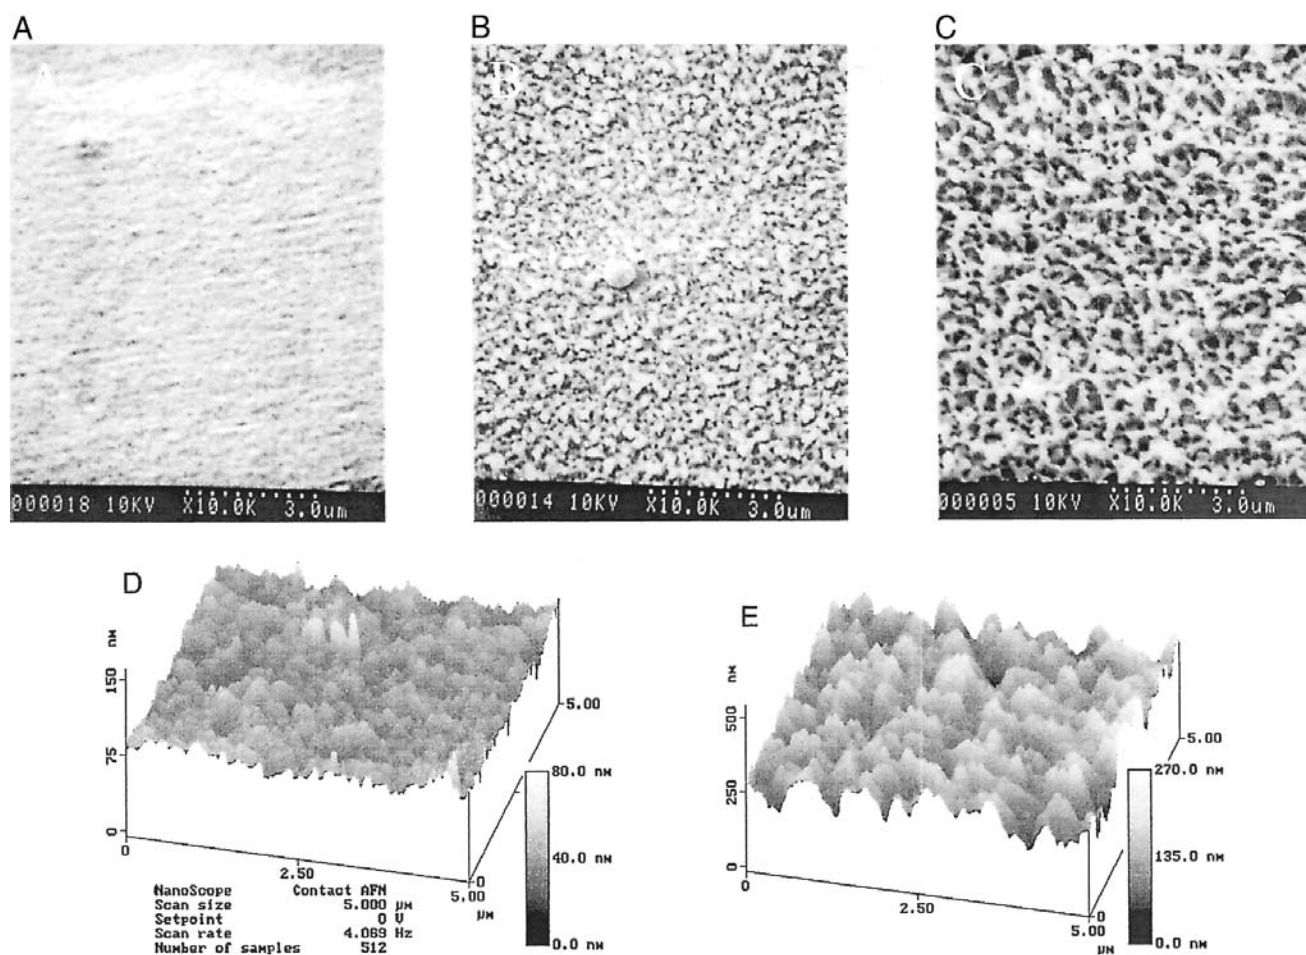

**Figure 11.9** Space-filling models of the conformations of HFGA and HFGA-PD-HFGCl spacers attached onto polyethylene surface.

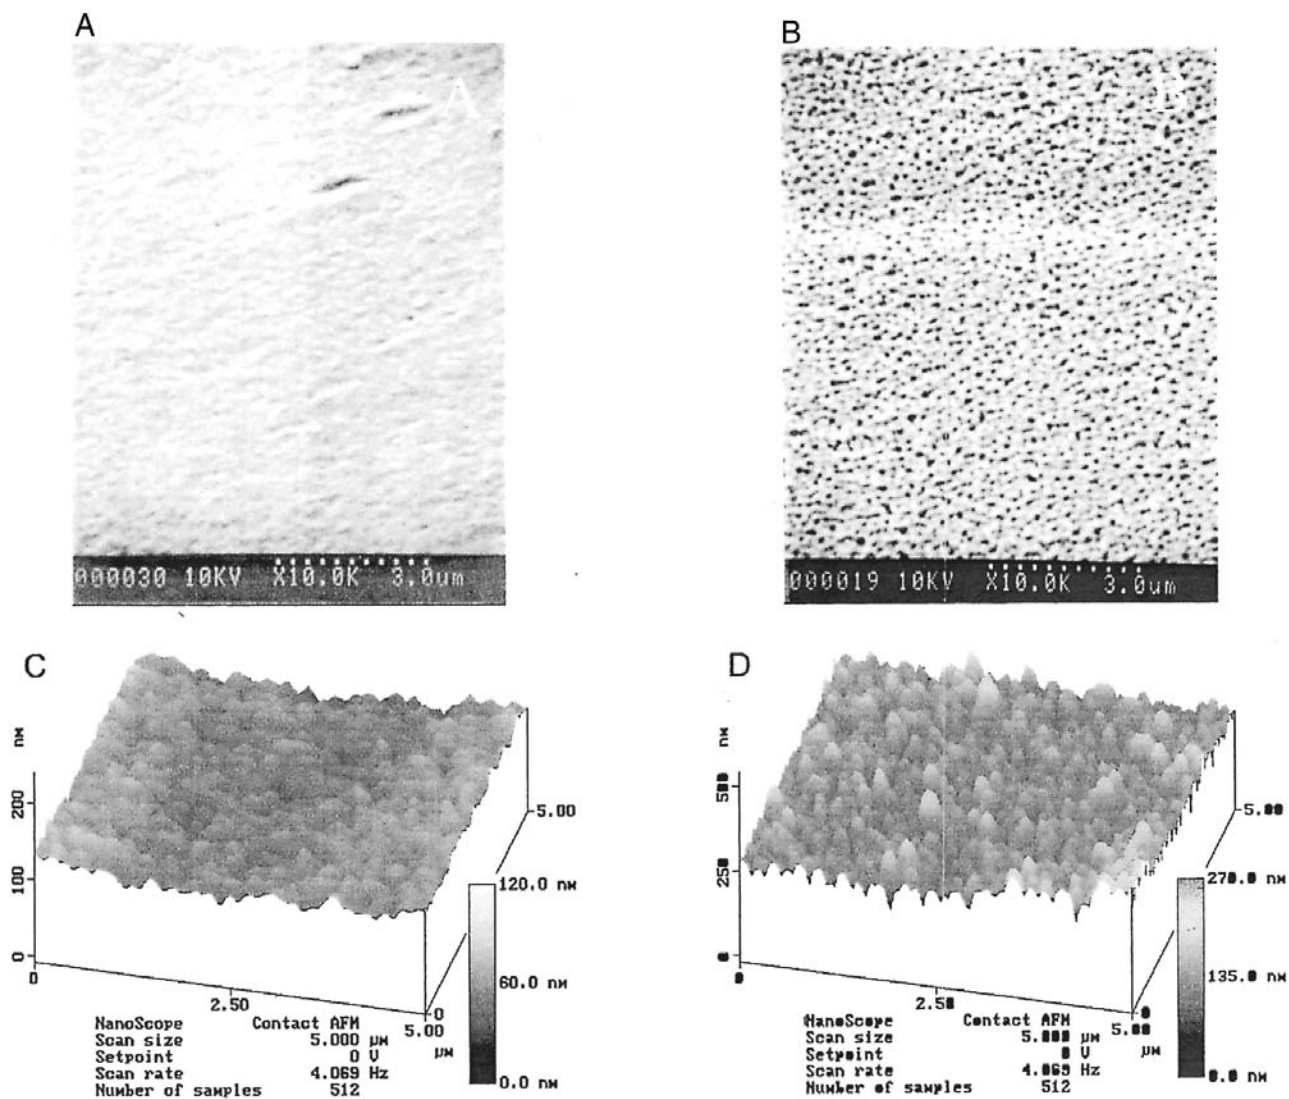

the immobilized enzyme was found to be fairly good in all cases; it retained most of its activity after several washing/assay cycles.

Cellophane (CE), a natural polymeric material which swells in water-based environments, has also been tested as a substrate for the plasma-enhanced immobilization of  $\alpha$ -chymotrypsin (101). Results from 40 kHz and 13.56 MHz CW and pulsed hydrazine plasma treatments of CE revealed that the 40-KHz plasma environments generate significantly rougher cellophane surfaces in comparison to the pulsed 13.56-MHz plasma conditions (Figs. 10 and 11). It also has been shown that the longer the plasma treatment time (e.g., the longer the plasma-on interval of the duty cycle), the higher the surface roughness of the plasma-exposed CE, regardless of the low or high driving frequency conditions. Accordingly, most of the enzyme im-

mobilization reactions were carried out using cellophane substrates exhibiting the lowest surface roughness in order to avoid the influence of the plasma-created cavity structures on the physical retention of the enzyme on the CE surface (Tables 6 and 7). Enzyme assay data indicate that the activities of the immobilized enzyme from CE—CO—(CF<sub>2</sub>)<sub>3</sub>—CO—OH and CE—[CO—CO—NH—(CH<sub>2</sub>)<sub>2</sub>—NH]<sub>n</sub>—CO—CO—Cl (where n = 1, 2, and 4) spacer-chain segments and that of the enzyme directly immobilized to the CE substrate from =C=O groups are comparable with the activity of the free enzyme (Fig. 12). It was also found that the presence of CE in the free enzyme solution reduces significantly the activity of the enzyme, and that the spacer molecular chains intercalated between the substrate and the enzyme do not enhance the activity of the immobilized enzyme in comparison to

**Figure 11.12** Activities of the free enzyme and the enzyme immobilized on cellophane samples expressed as time-dependent pH changes.

the enzyme directly, covalently attached in the absence of spacer molecules. It is suggested that the swollen state of the CE plays a significant role in the deactivation both of the free and immobilized enzyme molecules as a result of the entrapment of the enzyme molecules into the three-dimensional complex CE matrix. The incorporation of enzyme molecules into the swollen environment might result in reduced freedom of mobility and might also alter the supramolecular morphology of the enzyme through the development of multipoint connections (Scheme 2).

Papain has also been immobilized on RF plasma-functionalized polyethylene and glass substrate surfaces in the presence and absence of spacer molecules (Scheme 3) (102).

It has been shown that the activities of the papain, immobilized involving dichlorosilane (DS), propylenediamine (PD), oxallyl chloride (OC), and DS-PD-hexafluoroglutaric anhydride (HFGA)-based one- and multistep spacer chains, are comparable with the activity of the free enzyme, and that the activity of papain anchored directly to the oxygen plasma-functionalized PE substrate surfaces is significantly lower (Fig. 13). However, the papain covalently anchored to the PE surface by involving a longer spacer chain (PE-DS-[PD-OC]<sub>3</sub>-PD-OC) has considerably lower activity (pH after 25 min: 5.7) in comparison to that of two-step spacer chain-linked papain (PE-DS-PD-OC-PD-OC) (pH after 25 min: 4.6) (Fig. 14). Computer-aided conformational modeling of the two- and four-step spacer chains revealed that the most probable conformations for two- and four-step systems render distances between the terminal active sites (-COCl) and the PE substrate surface of 5.3 and 3.1 Å, respectively (Fig. 15). Accordingly, it is suggested that the distance of the immobilized enzyme relative to the surface of the substrate might influence significantly the activity of the enzyme.

The influence of the concentration of N- $\alpha$ -benzoyl L-arginine ethyl ester (BAEE) substrate on the activities of free and immobilized enzyme were also evaluated. It was found that at higher BAEE concentrations (12 mM) the activities of immobilized enzymes are comparable with that of the free enzyme, and that at lower concentration values of BAEE the activity of the directly connected papain to the PE is significantly diminished relative to the free and spacer chain-anchored enzyme molecules. It is suggested that the modification of the conformational shape of papain as a result of the close vicinity to the PE substrate might be responsible for this phenomenon.

The Lineweaver-Burk diagrams plotted for the free papain and for the enzyme anchored directly and by involving spacer chains (Fig. 16; Table 8) indicate that the Michaelis constant,  $K_m$ , of spacer-immobilized papain are

**Scheme 11.2** (A) Immobilization of enzyme involving NH-NH<sub>2</sub> and NH<sub>2</sub> functionalities from N<sub>2</sub>H<sub>4</sub> RF plasma-functionalized PE. (B) Immobilization of enzyme involving spacer molecules from N<sub>2</sub>H<sub>4</sub> RF plasma-functionalized PE.

**Scheme 11.3** Immobilization of papain involving RF plasma-functionalized polyethylene (PE).

higher in comparison to the  $K_m$  values of free and directly anchored enzyme. On the other hand, the maximum reaction velocity ( $V_m$ ) value of spacer chain (one-step)-immobilized papain is comparable to that of the free enzyme, while the  $V_m$  value of the directly connected papain is substantially lower. It is suggested that the activity of the directly anchored papain to the PE was diminished significantly during the close-proximity coupling.

Trypsin (from bovine pancreas type III) was also covalently immobilized onto plasma-functionalized polytetrafluoroethylene substrate surfaces (103). The surface modification of PTFE was carried out in a two-step reaction. Soxhlet, methanol extracted, thin PTFE films (0.01 cm) were first pretreated under argon plasma conditions (bell jar type reactor; gap between the parallel plate electrodes: 8.0 cm; rotating substrate holder located between the elec-

Scheme 11.3 Continued

trodes; 5 kHz; 28 W; 0.04 Torr) followed by the near-UV radiation-mediated graft polymerization reactions of acrylic acid (AAc), sodium salt of styrenesulfonic acid (NaSS), and *N,N*-dimethacrylamide (DMAA). The AAc graft polymer films were further functionalized via covalent immobilization of trypsin. It has been shown that a stratified thin-layer microstructure is generated on the PTFE substrate surfaces and that the graft yields increased with the argon plasma pretreatment time and monomer concentration (Fig. 17) during the graft polymerization reactions. Acrylic acid and NaSS polymers grafted with PTFE substrates coated with thin polyaniline (emeraldine) layers resulted in semiconducting surfaces as a result of charge transfer interactions. The immobilized trypsin retained around 30% of its original activity, and the effective enzyme activity was dependent on the surface concentration of the grafted AAc polymer. The enzyme activities increased initially with increasing AAc graft polymer concentrations, then became saturated at higher AAc polymer concentration values.

### B. Plasma-Assisted Development of Biosensors

The development of reliable and sensitive glucose biosensors will open up novel ways for the continuous *in vivo* monitoring of this clinically relevant compound. It is not

surprising, then, that the immobilization of glucose oxidase (GOD) has become an increasingly active research area in recent years. Approaches for the achievements of efficient immobilization of GOD based on cold plasma techniques offer additional possibilities in this area.

Glucose oxidase was immobilized onto PE substrates functionalized according to a multistep reaction mechanism, involving argon plasma treatment followed by exposure to oxygen (for the generation of hydroperoxid groups) as a first step, and the activities of the immobilized enzymes were compared to that of the free GOD (Scheme 4) (104).

Glucose oxidase was anchored covalently to the modified PE surface in the absence and presence of poly(ethylene oxide) spacer molecules. It was demonstrated that the amount of immobilized GOD depends significantly on the initial GOD concentration in the low concentration range, and it remains constant at higher initial GOD concentration values (Fig. 18). Glucose oxidase immobilized onto polymeric films in the absence and presence of PEO spacer chains obeys the Michaelis kinetics. The Michaelis constant,  $K_m$ , was found to be larger for the immobilized GOD than for the free enzyme, while the  $V_m$  value was smaller for the immobilized enzyme (Table 9). The bioactivity of PEO-modified PAAc-grafted PE (PAAc-PEO-GOD) was also higher than that of PAAc-grafted PE (PAAc-GOD).

**Figure 11.13** pH diagrams of enzyme assay involving free papain, DCS-PD-HFGA spacer-attached, DCS-PD-OC spacer-attached, and directly attached papain to the polyethylene substrate.

Both the thermal and pH stabilities of the immobilized enzymes prepared in the absence of spacer PEO were higher in comparison to the same characteristics of the immobilized enzyme involving spacer molecules.

Glucose oxidase was also immobilized onto RF plasma-modified poly(etherurethane urea) (PEUU), and the activities of the free and immobilized enzymes were evaluated by measuring the amount of hydrogen peroxide produced in the GOD-catalyzed redox reaction developed between the glucose and oxygen using cyclic voltametry and a specially designed sandwich-type thin layer electrochemical cell (105). Approximately 100-nm thick films of plasma-polymerized N-vinyl-2-pyrrolidone (PPNVP) were deposited onto PEUU films by RF glow discharge to PPNVP/PEUU layers. Surface hydroxyl groups were generated by the reduction of carbonyl functionalities present in the PPNVP layers with aqueous sodium borohydride, then the films were activated by cyanotransfer coupling using 1-cyano-4-dimethyl-aminopyridinium tetrafluoroborate. The first and second cycles of a typical cyclic

voltammogram of a GOD-PPNVP/PEUU thin layer cell under air is presented in Fig. 19. It was concluded that the incorporation of GOD, immobilized onto a thin film of RF plasma-modified PEUU into the thin layer chamber allowed for the detection of immobilized enzyme activity at room temperature.

A glucose sensor was fabricated using semiconductor dry technology and plasma-deposited macromolecular layers, originating from ethylenediamine RF discharge (106). The sensor was prepared by the successive deposition of an intermediate adhesive dexadimethyldisiloxane (HMDSO) and a functional (amino group-bearing) ethylenediamine plasma layer on glass substrates, followed by patterned platinum sputtering. The plasma-enhanced depositions were carried out in a Pyrex glass, tubular reactor provided with an external inductive copper coil under the following experimental conditions: frequency of the driving field: 10 MHz; base pressure:  $7 \times 10^{-3}$  Pa; RF power: 40 W; pressure of the plasma vapors: 4.6 Pa; deposition time: 1 min. Immobilization of GOD was achieved by applying 2.5%

**Figure 11.14** pH diagrams of enzyme assay involving two- and four-step spacer-attached papain onto the polyethylene substrate surfaces.

**Figure 11.15** Influence of spacer chain length on the activity of the immobilized enzyme (lowest pH after 25 min, highest enzymatic activity). Molecular design for 2 and 4 units of alternating 1,3-propylene diamine and oxalyl chloride spacer chains are computed using Conformer and Chem3D.

aqueous solution of glutaraldehyde to the surface of plasma-deposited ethylenediamine-based film, followed by washing and by the exposure of the functionalized plasma film to a 0.1% GOD solution (phosphate buffer: pH 5.6). The evaluation of the activity of the immobilized enzyme was performed using amperometric technique. It was demonstrated that the biosensor has a short response time (12 s) and is effective for glucose concentration estimation in the range of 0 to 30 mM with a detection limit of 1 mM.

High-performance glucose biosensor was also developed using acetonitrile-RF plasma-deposited, cross-linked, thin macromolecular layers (107). The step-by-step schematic diagram of the biosensor fabrication is presented in Scheme 5.

Hexamethyldisiloxane (HMDSO) and acetonitrile (AN) RF plasma environments (*HMDSO plasma*—Pyrex glass bell jar type reactor; 13.56 MHz; inductive coupling; base pressure:  $10^{-3}$  Pa; RF power: 100 W; flow rate HMDSO: 15 mL/min; HMDSO pressure: 4.6 Pa; deposition time: 1 min; resulting film thickness: 100 nm; *AN plasma*—base pressure:  $10^{-3}$  Pa; RF power: 80 W; flow rate AN: 15 mL/

**Figure 11.16** Lineweaver–Burk plot for (◆) free papain, (▲) direct, and (■) spacer-attached papain onto plasma-treated polyethylene.

min; AN pressure: 2.1 Pa; deposition time: 1 min; resulting film thickness: 118 nm) were employed both for the deposition of an intermediate layer between the glass substrate and the sputtered platinum electrode and for the generation of AN-based reactive surface. A second biosensor was also fabricated by substituting the AN plasma step (AN-based plasma deposition) for a conventional APTES step [functionalization via 3-(aminopropyl)triethoxysilane (APTES) in the absence of plasma], and the performances of the two devices were compared. It is concluded based on steady-state amperometric responses (Fig. 20) that the sensors fabricated using AN plasma films are more reproducible, exhibit lower noise, and have a reduced effect of

interference than the sensors made using conventional immobilization method (e.g., APTES). It is suggested that due to the highly crosslinked network structure of the plasma-deposited AN-based layers and their thin layer character, the amperometric response was significantly reduced.

Amperometric and colorimetric enzyme immunoassay biosensor was developed for the evaluation of concentration of insulin in serum and that of urinary human serum albumin (HAS) using as a molecular recognition element antibodies and enzymes immobilized on water vapor plasma-functionalized microporous, hydrophobic polypropylene films (108–110). The biaxially stretched PP films were partially functionalized in a bell jar type reactor equipped with aluminum, parallel plate electrodes (180 × 180 × 1 mm) with a gap between them of 180 mm. The PP film was sandwiched between two aluminum masks (180 × 180 × 4 mm), provided with 64 holes of 6 mm in diameter, and positioned symmetrically between the electrodes and exposed to the water vapor discharge (base pressure: 10<sup>-3</sup> Torr; driving frequency: 5 kHz; power: 42 W; treatment time: 5 min; pressure in the presence of discharge: 0.5 Torr) in order to generate the water-permeable 6-mm hydrophilic spots on the membrane. The hydrophilic spots were aldehyde groups functionalized by a conven-

Immobilized papain on oxygen plasma-treated PE	4.5	0.00642

tional consecutive octamethylenediamine and glutaraldehyde treatment. The proteins were immobilized by dropping on each functionalized spot of the membrane 20  $\mu$ L of antiserum, diluted 150-fold in 0.15 M phosphate buffered saline (PBS) (pH 7.2) and incubated at 4°C overnight. Then, 20  $\mu$ L of 0.3% (w/v) BSA solution was applied at 25°C for 2 h. After each treatment with protein the film was washed with 0.15 M PBS (pH 7.2). Results from the immunoreactions performed on the antibody-immobilized membrane spots (a competitive reaction between GOD-HAS and HAS), amperometric determination of HAS, and colorimetric evaluation of HAS indicate that the measurable range of this system is between 0.5 to 100 mg/L HAS in urine, which is suitable for the prognosis of diabetic nephritis.

Urea biosensor was also assembled from ammonia plasma-treated PP membrane (111,112). One side of a porous Celgard PP (pore size: 0.04  $\mu$ m; thickness: 25  $\mu$ m) membrane was ammonia plasma treated in a bell jar type reactor (base pressure: 0.1 Torr; ammonia pressure: 0.2–0.9 Torr; driving field frequency: 13.56 MHz; RF power: 20–60 W; ammonia plasma exposure time: 1–6 min), and subsequently ex situ functionalized in the presence of a 3% glutaraldehyde aqueous solution (pH: 7.0; 20 h; 25°C). It is suggested that the ammonia plasma treatment resulted in the generation of nitrogen atom-based functionalities on the PP surface.

A urea sensor was assembled by substituting the gas-permeable membrane of an ammonia electrode for plasma-modified membrane containing the immobilized urease. It was demonstrated that there is a strong interdependence between the external plasma parameters (pressure, RF power, and reaction time) and the activity of the immobilized urease (Figs. 21–23). This might be explained by the retention of different enzyme densities on the PP membrane surfaces. It was shown that the urea sensor has response sensitivities ranging from 19 mV/decade to 30 mV/decade, depending on the plasma parameters employed, and it has a shorter response time in comparison to the corresponding conventional urea electrodes. It was emphasized that deamination of the plasma-modified PP membrane did not occur in aqueous solution, even after 12 days of operation.

Application of extremozymes, enzymes that are capable of surviving under harsh conditions, including low and high pH environments, extreme temperatures and pressure, organic solvent environments, etc., immobilized on ce-

ramic substrate surfaces presents a special interest for bio-reactor applications. Recently glucoamylase was immobilized on  $\gamma$ -aminopropyltriethoxysilane/water vapor corona discharge-modified ceramic membrane surfaces, and the activity of the covalently bound glucoamylase was evaluated (113). The schematic diagram of the corona discharge apparatus is presented in Fig. 24. The surface modification and enzyme immobilization reaction mechanisms are shown in Scheme 6.

The tubular alumina eramic membranes are placed between two rod type (exciting electrode) and coil copper (discharge electrode) electrodes, and the discharge is initiated and sustained in the vapor phase mixture, at atmospheric pressure at 9.5 kHz and 20 kV. It is emphasized that the corona discharge is a less aggressive technique for the fragmentation of gas phase molecules, and consequently a larger part of the structures of the starting components can be retained in the nascent plasma-deposited layers. It was demonstrated that the plasma-enhanced immobilization of glucoamylase is more efficient relative to

the conventional technique, and that the corona-immobilized enzyme is active in a broader pH and temperature range in comparison to the free enzyme (Figs. 25–27). It also has been found that the operational stability of the immobilized enzyme increased with the number of plasma-enhanced surface modification processes.

The toxicity of organophosphorus derivatives (neurotoxins) and their use in agricultural and military applications stimulated the development of accurate detection methods for monitoring the concentrations of these neurotoxins. One of the promising approaches to this subject is to use organophosphorus hydrolase (OPH) for the development of efficient biosensors (114,115). Organophosphorus hydrolase is often used as an alternative to acetylcholinesterase, which requires inhibition-mode sensor operation, long sample incubation time, and a constant source of acetylcholine substrate. Organophosphorus hydrolase hydrolyzes a range of organophosphate esters (e.g., pesticides, parathion, soman, sarin, etc), and as a result protons are generated that can be measured and correlated to the

**Figure 11.18** Effect of the GOD concentration on the amount of GOD immobilized onto ( $\Delta$ ) PAAc-grafted PE and ( $\circ$ ) PEO spacer-modified PAAc-grafted PE at 4°C and 16 h. (From Ref. 104.)

concentrations of the organophosphorus derivatives (OPDs). The hydrolysis of some of the OPDs produce specific chromophoric sites, which allow spectroscopic concentration evaluation of OPDs. Potential efficient plasma-enhanced immobilization routes of OPH can be envisaged for the fabrication of biosensors for the detection and monitoring of the concentration of OPDs.

Immobilization of tailored-structure synthetic, active biopolymers (e.g., synthetic peptides, polysaccharides) might play a significant role in the future for the study and the development of high quality biosensors. Recently it was suggested that “side effects” associated with the immobilization and use of natural biopolymers during preliminary studies could be avoided. For example, immobilized proteins may partly or entirely lose their activities through denaturation mechanisms, extracellular enzymes may rap-

**Figure 11.19** Cyclic voltammogram of a  $GO_x$ -PPNVP/PEUU thin-layer cell in 0.2 M sodium phosphate/5 mM  $\beta$ -D(+)-glucose (pH 5.2) under air. Sweep rate: 1.0 mV/s. (a) First cycle; (b) second cycle. (From Ref. 105.)

idly break down a surface-anchored protein layer, and biological coating may generate safety hazards during in vivo testing. Current measures for diminishing these phenomena can be costly and time consuming; however, tailored-structure active synthetic biopolymers could be used instead (116). Accordingly, peptoid-containing  $[H-(Gly-Nleu-Pro)_9-NH_2; Ac-(Gly-Nleu-Pro)_9-NH_2; H-(Gly-Pro-Nleu)_9-NH_2; H-(Gly-Pro-Nleu)_{10}-Gly-Pro-NH_2, \text{ and } H-(Gly-Nleu-Pro)_{10}-NH_2]$  collagenlike molecules (CLMs) were synthesized and immobilized onto cold plasma-functionalized (coated sur-

**Scheme 11.5** Fabrication of high-performance glucose biosensor.

faces) perfluorinated ethylene-propylene (FEP) surfaces, and the biological performances of the modified surfaces were evaluated. For the generation of aldehyde and amine groups containing macromolecular layers on the FEP substrates, acetaldehyde (A), acrolein (Al), ethylbutyraldehyde (EBA), and n-heptylamine (HA) plasma deposition reactions were performed, respectively. All plasma exposures were carried out in a custom-built, cylindrical, glass plasma reactor provided with a substrate holder, circular grounded electrode, and a U-shaped powered electrode under the following plasma parameter conditions: driving-field frequency: 125 kHz for aldehyde discharges and 200 kHz for HA plasma; base pressure: 0.02 Torr; AA, Al, and EBA pressure: 0.3 Torr; HA pressure: 0.13 Torr; RF power for AA, Al, and EBA: 5 W for 1 min; RF power for HA: 20 W for 20 s. The immobilization of synthetic enzymes from aldehyde group-functionalized surfaces were carried out using a conventional sodium cyanoborohydride chemistry, while the covalent anchorage of the enzymes from amine group-functionalized surfaces was achieved by a two-step process involving polycarboxylic acid derivatives (32-carboxy-terminated PAMAM starburst dendrimer and custom-synthesized carboxymethyldextran)/carbodiimide mechanism.

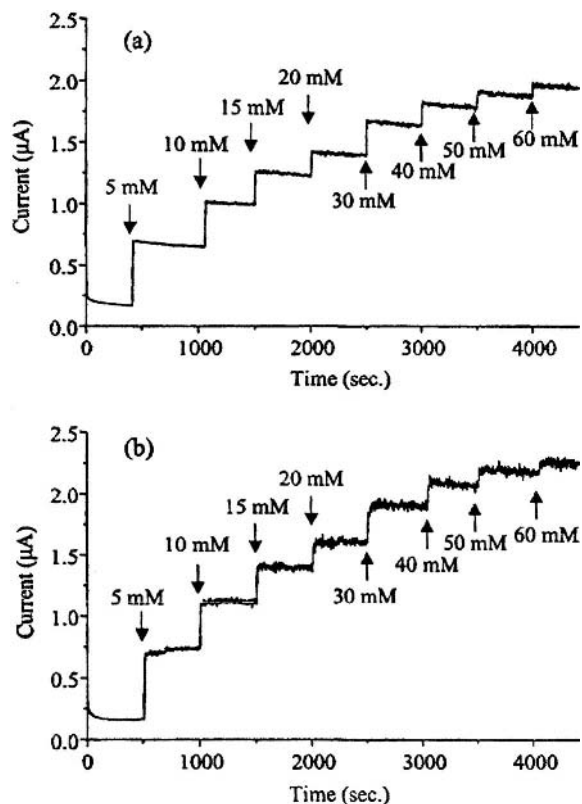

Based on XPS, MALDI-MS, and autoclaving data resulting from the substrates bearing the immobilized enzymes, it was shown that not all the surface-bound CLM

molecules are attached through covalent bonding; some of them are only retained by the physical forces within the triple helical peptide assemblies. Initial cell attachment and growth assays indicate that the biological performance of the CLMs is related to specific amino acid sequences.

It was recently found that the surface protein binding interactions strongly influence the efficiency of protein ionization by MALDI technique (117). Poly(vinylidene fluoride) and poly(ethylene terephthalate) substrate surfaces were modified under pulsed allylamine-RF plasma environments for the generation of primary amine rich functionality surfaces and consecutively exposed to radio-labelled peptide ( $^{125}\text{I}$ -radiolabelled peptides including angiotensin I and porcine insulin) adsorption procedure. The peptide retention processes were carried out in a flow-through cell to avoid denaturation of the peptides at the air-water interface and to avoid formation of Langmuir-Blodgett film formation. The experimental results demonstrated that for the sample preparation method employed ( $\alpha$ -cyano-4-hydroxycinnamic acid in methanol and 10% trifluoroacetic acid in water-based MALDI matrix), increases in the surface peptide binding affinity leads to decreases in the peptide MALDI ion signals. This phenomenon should be considered during MALDI evaluations.

Good antithrombogenicity of blood-contacting devices is a crucial characteristic for the development of advanced biomedical applications. To achieve these requirements, hepa-

rin, a well-known anticoagulant, is often considered for surface coating of these devices. Polyurethanes are frequently used for the fabrication of catheters, artificial hearts, etc., due their remarkable mechanical properties.

Polyetherurethane urea (PU) was functionalized in a three-step process composed of an initial oxygen plasma treatment, followed by graft polymerization of 1-acryloyl-benzotriazole (AB) and a subsequent substitution reaction of AB with sodium hydroxide and ethylene diamine (Scheme 7) (118).

The primary amine and carboxylic groups were further functionalized by coupling with heparin in the presence of carbodiimide. The plasma-modification step of PU was performed in a cylindrical stainless steel reactor equipped with two disc-shaped upper (stressed) and lower (grounded) 12-cm diameter parallel plate electrodes. The peroxide group concentrations on the plasma-exposed PU surfaces were evaluated by using 1,1-diphenyl-2-picrylhydrazyl. It was shown that the amounts of heparin cova-

**Figure 11.21** Effect of plasma exposure time on the extent of polypropylene membrane modification. The modified membrane was immersed in 2 mL of 0.01 M phosphate buffer (initial pH 7.0) containing 100 mM urea, and the extent of modification was analyzed by the rate of pH change. Each bar represents standard deviation from three experimental data points. Plasma treatment conditions were 60 W discharge power, 0.9 Torr ammonia gas pressure. (From Ref. 111.)

lently immobilized on the PU-NH<sub>2</sub> and PU-COOH surfaces were 2.0 and 1.4 μg/cm<sup>2</sup>, respectively, and that the immobilized heparin exhibited high stability in physiological solution.

Various enzymes have been immobilized by the N<sub>2</sub>, NH<sub>3</sub>, or O<sub>2</sub> RF plasma treatment (parallel plate reactor; capacitive coupling) of dry mixtures of enzymes or mix-

tures predeposited from buffer (phosphate, tris, citric buffers) solution onto hydrophilic PE membrane surfaces. The authors claim (119) that various proteins, including glucose oxidase, lactate oxidase, 1-glutamate decarboxylase, 1-lysine decarboxylase and invertase, mutarotase, and glucose oxidase mixtures, can be covalently immobilized on various hydrophobic and hydrophilic polymeric materials, including polyolefins and cellulose acetate (e.g., cuprophane), and that the membranes (enzymes immobilized on polymeric supports) are stable and retain 50% of their activities after storing them at 4°C for 45 days in a glycerol buffer. The plasma exposures of the predeposited proteins/ buffer layers were performed under the following plasma parameter range: substrate temperature: 0–25°C; pressure: 0.1–0.2 Torr, RF power: 50–300 W; driving frequency: 13.56 MHz. The authors do not present any evidence for the covalent coupling of the proteins to the polymeric substrates. This process might only resulted in the surface crosslinking of the solid-phase protein particles with the formation of an insoluble surface layer. This crosslinked protein surface layer (the plasma species interact only with

the 100–150 Å depth of the exposed solid surfaces) might be responsible for the encapsulation of unmodified protein molecules and consequently for the retained enzyme activities.

The use of cold plasma technique for patterning of immobilized biopolymer layers for biosensor applications has recently attracted attention (120–122). It has been shown that plasma-mediated reaction mechanisms can be involved in different stages of the fabrication of biosensors both for accomplishing surface-functionalization reactions and for generating conveniently patterned surfaces for mo-

**Scheme 11.7** Oxygen plasma treatment, graft polymerization, and substitution reaction of polyetherurethane urea.

lecular recognition processes. Protein, antibody, and conducting polymeric layers were successfully patterned by involving various cold plasma techniques and plasma gases including oxygen, water vapor, and others.

Hot plasma technique (plasma spraying) has also been considered for biotech applications. Owing to the high energy levels of the plasma species this approach can only be employed for the processing of inorganic and thermally stable starting materials, such as metals and inorganic oxides. Hydroxyapatite, a calcium phosphate ceramic, titanium and titanium in association with of alkaline phosphate has been extensively used as a bone replacement (123–125). The importance of plasma spray technique and the plasma-sprayed implants for the long-term proliferation of human osteoblastic cells have been emphasized.

### C. Synthesis of Oligonucleotides from Plasma-Functionalized Surfaces

Dichlorosilane (DS) RF plasmas have successfully been used for the functionalization of both inorganic and or-

ganic polymeric substrates. Eight hundred-nm silica beads were exposed to DS 13.56 MHz discharges under RF rotating plasma reactor conditions for the implantation onto the particle surfaces  $SiCl_xH_y$  functionalities and, consecutively, further in situ, derivatized in the presence of various volatile diamines (e.g., hexafluoropropylenediamine). The presence of  $Si-O-$  and  $C-NH_2$  linkages were revealed with survey and high resolution ESCA and differential ATR-FTIR techniques and fluorescence labelling techniques. The surface-functionalized beads were used in the next step for synthesizing oligonucleotides according to the mechanism shown in Scheme 8.

Twenty-six-mer oligonucleotides were synthesized from  $-SiCl_x-NH-(CF_2)_x-NH_2$  plasma-implanted functional spacer chains in the total absence of side reactions. From primary amine functionalized and cytidine coupled [loading  $0.16 \mu\text{mol/g}$ , which is only 1% of the loading of a porous-controlled pore glass (CPG) support] silica bead surfaces, long chain (26 mer) oligonucleotides were synthesized using a Pharmacia Gene Assembler 4 Primers system according to the modified small scale pro-

tolcols. It has been shown that the average coupling yield was as good as that of GPS with a higher than 99% loading (126–128) (Fig. 28). These findings indicate that the surface has a good accessibility and that the support presents significant interest for small scale synthesis of long nucleotides and that the plasma-enhanced technique might open up novel highways for building up oligonucleotide libraries and for creating molecular recognition- and molecular machining-based advanced technologies.

## VII. CONCLUSIONS

Nonequilibrium plasma technologies allow the deposition of tailored-structure, thin macromolecular layers on various substrate surfaces by involving monomers or common organic derivatives as plasma gases. The controlled interaction of plasma state with surfaces permits the pre-designed modification of surface characteristics (implantation of the required chemical functionalities) and morphologies of even the most inert organic and inorganic materials (e.g., Teflon, silica, etc.).

Cold plasma approaches are environmentally friendly dry-chemistry technologies; the reaction pathways are mediated by the interaction of plasma-generated nascent charged and neutral active species with the surfaces, which confine the discharge. The importance of using plasma technologies, relies on the fact that they can take advantage

of most of the technological developments associated with the semiconductor industry (e.g., patterning, etching, deposition, etc.).

Plasma-modified surfaces open up novel highways for the efficient anchoring covalently or by physical forces of active biomolecules on inorganic or organic substrate surfaces, under in situ or ex situ conditions, and in the presence or absence of spacer molecular chains.

These technologies will find their applications in the near future in the preparation of oligonucleotide libraries; the identification of motifs of single-strand nucleic acids to selectively interact with cellular (pathogenic) proteins, glycoproteins, etc.; the basic understanding of structural chemistry and/or biomedical diagnostics; the identification of hybridization processes based on electrical signal by plasma deposition of electrically conducting organic polymeric layers; the development of biopolymer-based molecular recognition sensors (biosensors, biochips) for the instant identification of the presence of specific biomolecules and toxins, for example, and in many other areas.

## Advances in Designed Multivalent Bioconjugates with Dendritic Structure

**Bogdan Comanita**

*Institute for Chemical Process and Environmental Technology, Ottawa, Ontario, Canada*

### I. INTRODUCTION TO DENDRIMERS

Dendrimer chemistry is a burgeoning field of macromolecular science that evolved over the last decade from the status of “aesthetically appealing molecules” to mainstream interdisciplinary research. The results of a key word search on the term “dendrimer\*” carried out in scientific and technical databases serve to illustrate the exponential surge of publications and patents over the last couple of years (Fig. 1).

What sets dendrimers apart in the rich landscape of polymer chemistry and why have research groups all over the world become increasingly interested in these materials?

The progress of the macromolecular chemistry was marked by the discovery of three types of major macromolecular architectures that triggered the development of significant chemical industries (Fig. 2). New polymeric structures were therefore related to novel materials with important economical implications. The dendrimers have indeed a unique structure consisting of constantly branching segments from a central core, and they are expected to prompt the discovery of breakthrough, high value added products. Unlike older milestone discoveries in polymer science that had a crucial impact on the commodities market, the increased cost of the dendrimer synthesis (vide infra) will most likely confine these new molecular

entities to the high technology sector such as pharmaceuticals and medical devices (Fig. 2) (1).

Worldwide producers of dendrimers are Dendritech (United States), DSM (Netherlands), and Perstorp (Sweden). The commercial availability of the polyamidoamine (PAMAM) and polypropylene amine (DAB) dendrimers, as well as the in-depth study of the benzyl ether dendritic structures (2) have provided an important initial impetus to this field (Fig. 3).

The dynamics of the dendrimer chemistry have certainly lived up to the expectations and their applications are now spanning the entire spectrum of macromolecular science.

This chapter focuses on the use of dendrimers in the biomedical field and is intended as a cross-pollination point for professionals who are active at the interface of chemistry and biology. Other excellent reviews focusing on more specialized aspects of dendrimer chemistry are highlighted as an entry point to the literature for the interested reader (3–5).

#### A. The Dendritic Molecular Architecture

The etymology of the word *dendrimer* stems from the Greek words *dendron* and *meros*, meaning tree and part. Other common terminology such as Starburst® (6), Cascade, or Arborol (7) polymers are suggestive for the same

**Figure 12.1** Dynamics of dendrimer chemistry: Series 1: Chemical Abstracts; Series 2: Science Citation Index; Series 3: U.S. patent and trademarks database (number of patents multiplied by a factor of 10).

type of molecular structure consisting of (1) one common core (2) successive layers of concentric branched monomers, and (3) end groups (Fig. 4).

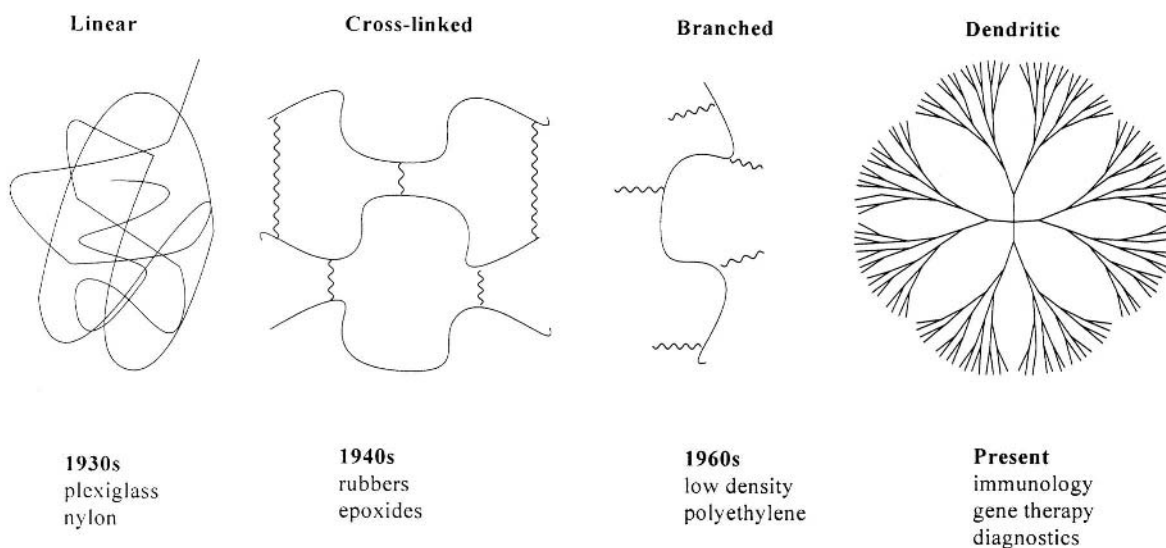

The core can be a single atom or a group of atoms and is defined by a branching functionality, which is given by the number of covalent bonds irradiating outward (e.g., the branching functionality of the core is 3 in Fig. 4). A first “layer” of branched monomeric units surrounds the core to form the first-generation dendrimer. Larger homologs can be built through a sequence of similar iterations leading to an onionlike structure of the molecule, each monomer layer corresponding to a new generation. Due to the branching of the monomer the number of segments in each layer grows exponentially from the core to the periphery

**Figure 12.3** Commercially available dendrimers.

**Figure 12.4** The main components of the dendritic architecture.

**Figure 12.2** New macromolecular architecture is conducive to the discovery of novel materials.

of the dendrimers. Thus, the number of end groups (also known as peripheral, superficial, or terminal groups) will be given by the formula

$$N = f(b - 1)^G \quad (1)$$

where

- N = number of end groups
- f = branching functionality of the core
- b = functionality of the monomer
- G = generation number

The exponential nature of Eq. (1) translates into an accelerated increase of the molecular mass with the generation of the dendrimer. Consequently, it is possible to obtain macromolecules with molecular weight of  $10^4$ – $10^5$  D and extremely low polydispersity by using only several monomer layers.

## B. Theoretical Models and Experimental Characterization of Dendrimers

Many of the potential applications for dendritic materials depend directly on the organization and distribution of the end groups and internal segments throughout the volume of the molecule. In particular, the possibility of reduced density of the core (e.g., in drug delivery systems) and the location and accessibility of terminal end groups (e.g., in neoglycoconjugate synthesis) are crucial parameters for the successful utilization of these molecules in biomedical applications. The microstructure of the dendrimers has been therefore extensively investigated both theoretically and experimentally.

Maciejewski's "dendritic box" (8) hypothesis predicted that increased peripheral steric compression with the generation number would ultimately lead to a high-density outer shell with hollow intramolecular cavities. Theoretical calculations by Hervet and De Gennes (9) used a modified version of Edwards's self-consistent field (10) to confirm this molecular architecture. According to these authors, the inner branches become elongated at higher generations while the end groups lie on the dense surface of the globular construct. This is the dense shell model and is graphically described by the structure shown in Fig. 4.

At the other end of the spectrum Muthukumar and Lescaec generated dendritic structures using an off-lattice kinetic growth algorithm of self-avoiding walks to arrive at a density profile that decreases monotonically from the center to the periphery (11). The end groups are not necessarily positioned on the outer surface. This is the dense core model.

Theoretical Monte Carlo (12) and molecular dynamics (13) simulations also predict extensive back folding of the

dendritic branches. According to these models, the segment density profile within the dendritic space is relatively constant with minimal values at the core and on the surface. The end groups are positioned preferentially throughout the outer shells, while the segments pertaining to the lower generations are located near the core. Similar results are obtained for "flexible dendrimers" by using a self-consistent mean-field model (14).

None of these generic molecular models address the chemical nature of the dendrimers. Consequently, it is not surprising that experimental measurements and computational simulations on chemically defined dendrimers have validated them all. The false dichotomy between these findings can be explained by the peculiarities of each case in point. It is important to realize that either the dense shell or the dense core architecture will be dictated not only by the branching functionality and the connectivity between the atoms, but also by the chemical nature of the layers within the dendrimer and the surrounding environment (pH, ionic strength, etc.).

The dense shell model will be favored when the back-folding of the dendritic arms is prevented. One way to achieve this end is by the use of "stiff" branches generated from acetylene- and phenylene-based monomers (15).

Back-folding can also be prevented by the incompatibility between the nature of the end groups and the core of the dendrimer. For example, the use of hydrophilic oligosaccharides as end groups on a hydrophobic carbosilane dendrimer will most likely lead to a more favorable presentation of the carbohydrate antigen on the surface, while the use of a hydrophilic dendritic core could favor back-folding (Fig. 5).

Recent data using this architectural principle offer strong proof of this concept. Theoretical studies on poly(propylene imine) dendrimers peripherally functionalized with *N*-*t*-BOC-1-phenylalanine confirm increasing interaction between the end groups of higher generation dendrimers (16) and a reduced degree of back-folding in these systems. Similar results were obtained for hydroxyl-terminated carbosilane dendrimers, although in this case hydrogen bond networking on the surface of the dendrimers could not be observed up to the fourth generation (17). These theoretical studies are confirmed by experimental evidence for perfluorinated end groups on polyaryl ether (18,19) and carbosilane dendrimers (20). The dendritic box hypothesis is also supported by experimental proof reporting on the successful inclusion of guest molecules inside the dendritic cavities (21), as well as by another body of evidence (22,23).

On the other hand  $^2\text{H}$  and  $^{13}\text{C}$  NMR<sup>22</sup> provided early experimental support for the back-folding of PAMAM dendrimers. Electron paramagnetic resonance (EPR) (24)

**Figure 12.5** The chemical nature of the dendritic layers and the surrounding environment can favor the dense shell or the dense core models.

and fluorescence spectroscopy (25,26) have also been used to characterize with limited success the molecular dynamics of various dendrimers. More recently, small angle x-ray (SAXS) (27,28) and neutron (SANS) (29) scattering experiments provided crucial evidence that PAMAM, DAB, and Fréchet type (benzyl ether) dendrimers display a rather uniform internal segment density with partial back-folding of the dendritic branches. These experiments clearly establish that neither the dense shell nor the dense core model apply for these dendrimers under the reported experimental conditions.

### C. Synthetic Strategies in Dendrimer Chemistry

“Retrosynthetic” analysis (30) of the generic dendritic structure **1** (refer to Fig. 6) suggest two possible solutions for the synthesis of dendrimers. This is essentially a logical way to deconstruct a target molecule to simpler molecular entities, which in turn undergo the same analysis until simple raw materials are identified. The process follows a direction that is opposite to the actual synthesis and is therefore called retrosynthesis. Disconnection A leads to the generation  $n - 1$  dendrimer **2** and the branched monomer synthon **3**. This rationale can be successively applied until the problem is reduced to the reaction of a core synthetic equivalent **4** with the branched monomer **3**. The process represents the divergent method (31) and is currently applied for the synthesis of the industrially available dendrimers DAB and PAMAM. From a synthetic perspective,

the dendrimers are assembled from the core to the periphery.

Alternatively, along path B, the core synthon **4** can react with the branched “dendron” **5** (A dendron is a dendritic structure with a chemically reactive core—also called focal point—that will react to form a higher generation dendrimer.) to provide the target dendrimer **1**. After further iterative disconnection of dendron **5**, the problem is reduced to the reaction of two monomer synthons **6** and **3**. This is the convergent method (32), whereby the dendrimers are assembled from the periphery to the core.

The recent synthesis of the carbosilane-based dendrimers shown in Fig. 7 (33) can illustrate the advantages and drawbacks of the divergent approach. The core tetravinylsilane is hydrosilylated with methylchlorosilane followed by the reaction of the octachloro intermediate **8** (refer to Fig. 7) with vinylmagnesium bromide to yield the first-generation (8 arm) dendrimer **9**. Reiteration of the same sequence of reactions provides the second-generation (16 arms) compound **10**. Finally, the third-generation (32 arms) dendrimer **11** is obtained by the reaction with a hydrosilane containing the end group in a masked form. Assuming that all 16 hydrosilylation reactions in the final step occur with a 99% yield, one expects an 85% overall yield. The remaining 15% will be side products that are very similar in structure and molecular mass with the target dendrimer and therefore impossible to remove in the work-up. The divergent approach is thus suitable only for the very high yielding reaction sequences, and considerable re-

**Figure 12.6** Retrosynthetic analysis of dendritic structures: FG, FP, and X,Y are respectively interconvertible functional groups.

search effort is required to optimize the system for industrial scale production. Nevertheless, this approach is applied today for the synthesis of the commercially available dendrimers produced by DSM (ASTRAMOL<sup>®</sup>) and Dendritech (PAMAM) (34–38).

In the convergent approach (39), the dendritic construct is synthesized from the periphery to the core, as exemplified in Fig. 8. Protection of the phenolic groups (that will eventually become the end groups of the dendrimer) is followed by activation of the benzyl alcohol **13** (refer to Fig. 8) to the benzyl bromide **14**. This highly reactive intermediate is further developed to generate dendron **16**. The focal point of this dendron is transformed back to a benzyl bromide **17** and the reaction sequence is reiterated to the branched structure **18**. Finally, this reacts with the trifunctional core **19** to obtain the desired dendrimer **20**. Any misfire of the reagents in the last step will result in a side product **21** that has considerably lower molecular weight than **20**. Consequently, purification of the product at the final and intermediate stages becomes possible, and this is the method of choice to produce defect-free dendrimers on a laboratory scale. Unfortunately, steric hindrance often limits the accessibility of higher generation dendrimers due to reduced reactivity of the focal point. Another important drawback of the convergent method is the exposure of the end groups to repeated chemical cycles. This can be a substantial restriction for dendrimers with sensitive end groups such as proteins or polyglycosides.

When radial block dendrimers are desired, the direct reaction of the end groups on a dendrimer with the focal group of a chemically different dendron can be achieved in a process called the double growth synthesis (40–46). This hybrid method also has the advantage of an accelerated growth due to increased overall convergence.

## II. DENDRIMERS AS NANOSCOPIC SCAFFOLDS IN BIOLOGICAL APPLICATIONS

### A. Three-Dimensional Control at the Nanometer Level

#### 1. The $\beta$ Factor, Practical Alternative to the Cooperativity $\alpha$ Factor

The 20th century has witnessed extraordinary scientific and technical achievements that will prefigure our advancement for forthcoming generations. Headline-making news such as the exploration of space and the creation of cyberspace was accompanied by the quieter but equally relevant biological revolution that provided us with spectacular insights in the microcosmos of life.

One of the most intriguing working hypotheses of modern molecular biology is the concept of polyvalent interactions (47). Multiple simultaneous interactions between various ligands and receptors have important functional consequences that could not be accomplished through a

**Figure 12.7** The divergent synthesis.

Figure 12.8 The convergent synthesis.

single or an equivalent number of independent binding events.

In the case of monovalent ligands (Fig. 9) each binding event has approximately the same constant of equilibrium, i.e.,  $K_1, K_2, \dots, K_N$  in the figure are the same, provided that the receptors behave independently. (Often, the binding of the first ligand can trigger important conformational modifications that will accelerate the binding of the subsequent monovalent ligands. The classic example is binding of oxygen to hemoglobin. These are cooperative effects and do not involve polyvalency.) For polyvalent ligands however the overall affinity is given by the product of the individual binding constants  $K_1, K_2, \dots, K_N$ . Thus, a considerably stronger binding can occur between the two multivalent entities.

The cooperative effect has been largely underappreciated in the rational design of new polyvalent drugs and research reagents for biochemistry and biology. However, a recent milestone article by Whitesides et al. (47) summarizes the latest developments in the field and sets the theoretical framework for using polyvalency as a key concept in the design of new biopharmaceutical products.

Starting from basic thermodynamic considerations, the article defines the free energy and equilibrium constant for two entities (cells, molecules, organelles, etc.) interacting

through an N-order polyvalent interaction, that is, through N ligands and N receptors. See Table 1 and Eq. (2) to (5). The thermodynamic equations relating these metrics are the following:

$$\Delta G_{\text{avg}}^{\text{poly}} = \frac{\Delta G_N^{\text{poly}}}{N} \quad (2)$$

$$\Delta G_N^{\text{poly}} = -RT \ln K_N^{\text{poly}} \quad (3)$$

$$K_N^{\text{poly}} = (K_{\text{avg}}^{\text{poly}})^N \quad (4)$$

$$\Delta G^{\text{mono}} = -RT \ln K^{\text{mono}} \quad (5)$$

Positive cooperativity in the traditional sense (48) is defined by the sequence of binding events that display a higher average binding constant  $K_{\text{avg}}^{\text{poly}}$  than the corresponding monovalent binding constant  $K^{\text{mono}}$ . The degree of cooperativity,  $\alpha$ , is a parameter that relates the monovalent free energy  $\Delta G^{\text{mono}}$  to the observed polyvalent free energy  $\Delta G_{\text{avg}}^{\text{poly}}$  through Eq. (6).

$$\Delta G_{\text{avg}}^{\text{poly}} = \alpha \cdot \Delta G^{\text{mono}} \quad (6)$$

A polyvalent interaction is noncooperative (additive) when  $\alpha = 1$ , positive (synergistic) for  $\alpha > 1$ , and negative (interfering) if  $\alpha < 1$ . It is important to realize that polyvalent interaction, even with interfering cooperativity, will

**Figure 12.9** Polyvalent interactions versus monovalent interactions.

ultimately lead to an enhanced overall binding. For example, Lee et al. (49) reported in a classic reference the affinity of the divalent and trivalent galactose ligands which bind to C type lectines on the surface of hepatocytes (Table 2).

Since  $K_{\text{avg}}^{\text{bivalent}} = \sqrt{K_2^{\text{poly}}} < K^{\text{mono}}$  and  $K_{\text{avg}}^{\text{trivalent}} = \sqrt[3]{K_3^{\text{poly}}} < K^{\text{mono}}$ , the divalent and trivalent interactions both have negative cooperativity, and therefore  $\alpha < 1$ . Nevertheless, the binding of the trivalent ligand is still 2857 times stronger than the monovalent galactose ligand. Consequently, the cooperativity parameter  $\alpha$  is not as useful a parameter in the case of the multivalent interactions as it is in the case

of multiple monovalent, independent ligands. Moreover, from a practical point of view, the number of polyvalent interactions  $N$  is usually unknown and no statement about cooperativity  $\alpha$  is even possible. Whitesides et al. propose therefore a new parameter,  $\beta$ , correlating the binding constant of the monovalent ligand,  $K^{\text{mono}}$ , and  $K^{\text{Elisa}}$  determined from a common Elisa type assay [Eq. (7)]:

$$\beta = \frac{K^{\text{Elisa}}}{K^{\text{mono}}} = \frac{K_N^{\text{poly}}}{K^{\text{mono}}} \quad (7)$$

This “enhancement factor”  $\beta$  can better serve the purpose of comparing various polyvalent systems and will emphasize the beneficial effect of polyvalency even for systems with negative cooperativity.

**Table 12.1** Proposed Nomenclature for the Polyvalent Interactions

Symbol	Comments
$\Delta G_N^{\text{poly}}$	Free energy of the polyvalent interaction
$K_N^{\text{poly}}$	Equilibrium constant of the polyvalent interaction
$\Delta G_{\text{avg}}^{\text{poly}}$	Average free energy per each ligand–receptor interaction
$K_{\text{avg}}^{\text{poly}}$	Average equilibrium constant per each ligand–receptor interaction
$\Delta G^{\text{mono}}$	Free energy for the monovalent ligand–receptor interaction
$K^{\text{mono}}$	Equilibrium constant of the monovalent ligand–receptor interaction

## 2. Enthalpy and Entropy in Multivalent Interaction

Another important aspect of multivalent interactions is the correlation between the enthalpic and the entropic components. Thus, in order to maximize the overall binding effect, it is necessary to use multivalent ligands that fit perfectly in the receptor (the well-known lock and key concept). The ideal solution requires a rigid spacer that places the multivalent ligands in a matching, precisely defined topology. Any deviation from this three-dimensional distribution will lead to a strained conformation at the binding site and diminish the favorable enthalpic component of the multivalent interaction. Since the configuration

**Table 12.2** Binding Constant for Multivalent Galactose Ligands

Oligosaccharide	Binding constant ( $M^{-1}$ )
Gal( $\beta$ 1)OMe	$K^{\text{mono}} = 7 \times 10^4$
Gal( $\beta$ 1,4)GlcNAc( $\beta$ 1,2)	$K_2^{\text{poly}} = 3 \times 10^7$
Gal( $\beta$ 1,4)GlcNAc( $\beta$ 1,4)	$K_3^{\text{poly}} = 2 \times 10^8$
Gal( $\beta$ 1,4)GlcNAc( $\beta$ 1,2)Man( $\alpha$ 1,6)	
Gal( $\beta$ 1,4)GlcNAc( $\beta$ 1,2)Man( $\alpha$ 1,3)	
Gal( $\beta$ 1,4)GlcNAc( $\beta$ 1,4)	

of the receptor is usually not known, one way to overcome strain is by using flexible spacers. This allows the ligands to probe the surface of the receptor and achieve interaction at the expense of an entropic price, which explains why flexible linkers often fail to provide a spectacular solution to the problem (50–51).

Although the entropic and the enthalpic effects of the multivalent interactions are difficult to delineate quantitatively, it is obvious that the end groups on the dendritic surface will have quite a different behavior than the functionality attached to the graft or star polymers. It can be speculated that the entropic loss of the dendritic multivalent ligands will be considerably diminished due to their restricted motion on a spherical surface, as opposed to the usual situation whereby the ligands move freely in the three-dimensional space. At the same time, the fine-tuning of the distance between ligands on the dendritic surface can be achieved from a combination of architectural parameters, such as monomer and core functionality, length of the monomer arm, and chemical nature of the constituent atoms. Consequently, it can be concluded that dendrimers can provide a unique compromise between the enthalpic and entropic components of the multivalent interactions warranting systematic future studies.

### 3. Shape and Size Control at the Nanoscopic Level

Shape and size control at the nanoscopic level represents an important desiderate from a technological point of view since it defines a theoretical threshold for miniaturization. The subnanoscopic level circumscribes the interaction within the molecules and is therefore irrelevant for practical applications in the field of life sciences. Typical dimensions for biological compounds range between a few nanometers (e.g., insulin and hemoglobin) to hundreds of nanometers (e.g., histones). It is therefore obvious that having precise control at this scale is of paramount importance for the rational design of the new drugs.

The dendritic structure offers peerless possibilities in the control of the size and shape of new molecular entities. For example, the PAMAM dendrimers increase in diameter by approximately 1 nm per generation (52). Even finer tuning can be achieved with the carbosilane dendrimers shown in Fig. 6, whose diameter can be incrementally increased by one-half of a nanometer from one generation to another (53).

By using dendrimers as building blocks in a molecular Lego<sup>®</sup> chemists have already synthesized macromolecules in various shapes such as spheres, ellipsoids, and rods, as shown schematically in Fig. 9. (See Ref. 54 for a recent review on the dimensions and shapes of dendrimers and dendrimer–polymer hybrids.) The possibility to design clefts and protrusions on these surfaces having a desired chemical functionality in a precise reciprocal position has therefore become accessible to a degree that had been previously encountered only in biological molecules (Fig. 10).

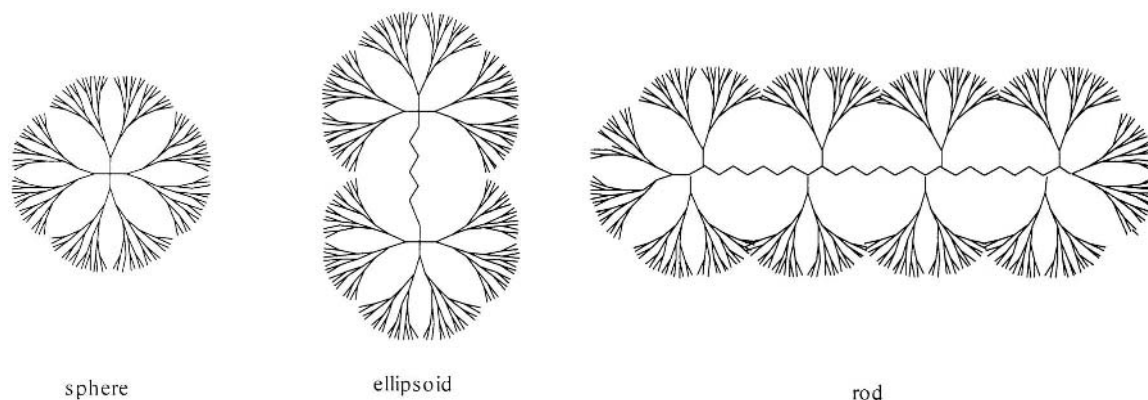

### B. Dendrimer–Carbohydrate Conjugates

Carbohydrate–protein interaction constitutes a crucial biochemical event in a wide range of key cell–cell interactions and infectious diseases. The multivalent character of the carbohydrate ligands compensates the intrinsic weak nature of this binding and is lately generating growing interest in the design of novel therapeutics.

Dendritic carbohydrates, also known as glycodendrimers (55), fill the dimensional gap between high molecular weight neoglycoconjugates and small clusters. Typically, but not necessarily, they are confined to the range of nanometers up to tens of nanometers.

One important class of dendritic carbohydrate agent targets the competitive inhibition of the protein–carbohydrate binding phenomena involved, for example, in various pathogenic infections.

The immune response against bacterial infections can be mediated by the mannose binding proteins (MBPs) which tag the mannose-rich surface of the bacteria and

**Figure 12.10** Shape and size control at the nanometer level with dendritic structures.

prompt the phagocytosis by macrophages. On the other hand, mannose-terminated glycoproteins serve as high affinity ligands for bacterial attachment, facilitating the invasion of the host cells. Since these interactions involve multivalent binding, the dendritic mannoses have potential in both therapeutic and drug targeting applications.

Multivalent mannoses 22 (refer to Fig. 11, only octavalent dendrimers shown) inhibited the binding of the yeast mannan (56) to concavalin A and pea lectins (57). Thus, it was shown that the binding potency of these inhibitors is influenced both by the dendritic chemical structure and its multivalency. The hexadecamannose polylysine (only 8-arm analog 22 shown) displayed a 2000-fold increase in overall binding (approximately 100-fold increase per sugar if compared to the monovalent mannose). A similar study was performed on the commercially available PAMAM dendrimers conjugated with mannose. The tetra-valent and octavalent carbohydrate achieved the optimum binding with a 30-fold increase binding per sugar (58). As these interactions are at the origin of the host infections by fimbriated bacteria, mannose dendrimers can form the basis of novel antiadhesin molecules.

Multivalent mannose glycomimetics have also been synthesized in order to inhibit the adhesion of *Escherichia coli* HB 101 (pPK14) to erythrocytes and yeast mannan (59). *E. Coli* strains are important pathogens in urogenital and gastrointestinal infections that use  $\alpha$ -mannoside specific fimbriae to adhere to the cell surface carbohydrates of the host cell. In order to allow for a broad variation in the structure of the glycoclusters the authors have considered both different attachment sites at the sugar ring and different linkage types between the sugar and the dendritic substrate. It is known from various other lectins that the hydroxyl groups in the 2, 3, and 4 positions of the pyranosides are essential to binding, therefore these sites were not used for attachment. Finally, the role of the aglycone

structure has also been investigated in this study. Based on the known affinity of the monomeric p-nitrophenyl mannoside aglycone to bind 80-fold stronger than the methyl glycoside it was expected that these clusters should display improved inhibitory properties.

The synthesis of the most potent inhibitor 31 is highlighted in Fig. 12. The six-amino methyl mannose 30 was coupled with the tricarboxylic acid 29 and then debenzoylated under Zémpfen conditions to afford the unprotected six-peptide bridged trimannoside 31 in quantitative yield. A structurally related inhibitor having a thiourea bridge instead of the peptide linker showed a considerably reduced inhibitory capacity, probably due to conformational effects.

The N-acetyllactosamine (LacNAc) and its simpler constituent N-acetylglucose (GlcNAc) characterize the lactosaminoglycans as tumor-associated antigenic carbohydrates. Various polylysine dendrimers bearing  $\beta$ -lactoside 25, N-acetyllactosaminide 26 (60), and  $\beta$ -D-N-acetylthioglucosamine 23 (61) (Fig. 11) were synthesized by chemical or enzymatic routes. All of these glycodendrimers showed enhanced affinities to their respective binding proteins.

One of the most widespread mammalian cell carbohydrate ligands is the N-acetylneuraminic acid (NeuAc), or sialic acid (62). Dendritic sialoside inhibitors of the Influenza virus hemagglutination to human erythrocytes have therefore been synthesized (24 in Fig. 11). The solid phase synthesis of sialidase-resistant N-linked  $\alpha$ -sialodendrimers has also been reported (63).

The more complex tetrasaccharide NeuAc $\alpha$ 2  $\rightarrow$  3Gal $\beta$ 1  $\rightarrow$  4[Fuc $\alpha$ 1  $\rightarrow$  3]GlcNAc, or sLe<sup>x</sup>, is a ligand for E-selectin endothelial receptors initiating the leukocyte adhesion, attachment, and extravasation in the inflammatory response. Traditional structure activity relationship (SAR) studies have led to the development of numerous sialyl Lewis<sup>x</sup> (sLe<sup>x</sup>) analogs without taking into account cluster

Figure 12.11 Polylysine-based dendrimer-carbohydrate conjugates (glycodendrimers).

**Figure 12.12** The synthesis of a multivalent mannose inhibitor for the adhesion of *Escherichia coli* HB 101 (pPK14).

or multivalency effects. The first example of enzymatic synthesis of sLe<sup>x</sup>-functionalized polylysine dendrimers 27 has been reported (64). These dendrimers are currently investigated as selectin antagonists and could provide important information regarding the rational design of anti-inflammatory drugs.

In the quest for a better understanding of the role played by the interligand distances on binding of neoglycoconjugates, a series of polydentate dendritic disaccharides were constructed on a PAMAM scaffold (65). Thus, 4, 8, 16, and 32 ligand-bearing dendrimers were assessed as inhibitors for the anti-B<sub>di</sub> immunoglobulin which causes rejection in pig to human xenotransplantation (32 in Fig 13). The results of molecular dynamic simulations suggested a match between the interligand distances of the 32-arm neoglycoconjugates and the antigen binding sites of the IgG immunoglobulin. Experimentally, it was found that the di-, tetra-, and octameric dendrimers bound as tight as the monomeric B<sub>di</sub> ligand. The 16 and 32 glycodendrimers however had an IC<sub>50</sub> about tenfold lower than the monomeric ligand, which may be indicative of a better fit in the topology of the ligand–receptor interactions.

While carbohydrates have mainly been used as end groups on dendrimers of a different chemical nature, fully synthetic carbohydrate dendrimers could also mimic a broad spectrum of polysaccharide structures and properties. The three-dimensional closely packed structure of highly branched dendritic oligosaccharides could be, for example, responsible for inclusion properties similar to those of cyclodextrines (66). Thus, the attachment of the heptasaccharide 33 to a central trifunctional core should afford a C<sub>3</sub>-symmetrical glucodendrimer made entirely of carbohydrate moieties.

Carbohydrates can be also used as multivalent cores for dendritic molecules. Allyl α-D-glucopyranoside was O-

perallylated to the corresponding tetra-allyl derivative 34 (Fig. 14). The rich chemistry of the allyl ether group was subsequently exploited to provide uniformly functionalized spacer glycosides. The new “octopus glycosides” 35–38 are useful core molecules for the synthesis of glycoclusters and carbohydrate-centered dendrimers.

### C. Dendrimer–Peptide Conjugates

Synthetic peptides conjugated to carrier proteins can stimulate the production of antibodies leading to an immune response to a certain amino acid sequence. The carrier protein has generally a low and random surface density of the peptide antigen, and the control of the protein functionalization is often difficult. Complications from cross-reactivity of the antibodies with the carrier protein can also often arise.

The concept of multivalent interaction has been successfully applied to elicit a stronger immune response to a certain peptide sequence. Multiple peptide–antigen systems (MAPS) (67) have been mounted on dendritic polylysine structures similar to 28 and yielded results normally obtained at much higher concentrations of the monomeric vaccine preparations (68). The peptides are presented with high surface density, and the homogenous nature of the dendrimers should ensure a highly reproducible effect. Remarkably, the branching polylysine dendrimers did not cause any immunological response (69), thus avoiding cross-reactivity complications. Unlike the peptide-carrier protein vaccines, the MAP system accounted for approximately 90% of the total molecular mass of the dendrimer–peptide conjugate.

Functional groups on the surface of the dendritic structures show increased chemical reactivity in comparison to other polymer homolog reactions (70). Biologically active

**Figure 12.13** Examples of sugar-coated and sugar-made dendrimers.

molecules should therefore react under milder reaction conditions to yield various dendritic conjugates without diminishing their activity due to degradation.

This hypothesis has been confirmed by the synthesis of dendrimers bearing sensitive proteins (71). Thus, the activation of the surface groups of Starburst® dendrimers to various electrophilic and nucleophilic groups (as in 44 and 45, Fig. 15) was reported. Both the amino- and carboxyl-terminated dendrimers could be reacted with alkaline phosphatase to form a protein–dendrimer conjugate of type 41, which in turn was further conjugated with the Fab' fragment of an anticreatine kinase MB isoenzyme antibody to yield 43.

Antibodies are ideal vectors for targeting specific cells due to their selective interactions with antigens expressed on the surface of the cellular membrane. Consequently, antibody conjugates with radioisotopes are under active investigation for applications in radioimmunodetection and radioimmunotherapy of cancer.

PAMAM dendrimers were reacted with 2-(p-isothiocyanatobenzyl)-6-methyl-diethylene triamine pentaacetic acid

(1B4M) to generate a dendrimer–chelating agent conjugate. This was further chemically bound to an anti-Tac (72) IgG(HuTac) monoclonal antibody and finally complexed with  $^{111}\text{In}$  and  $^{88}\text{Y}$ . Unfortunately, the immunoreactivity and the biodistribution of the radiolabelled dendrimer chelate and the antibody–dendrimer chelate did not compare favorably with the radiolabelled antibody alone due to significant accumulation in the liver, kidney, and spleen.

More encouraging results were obtained in the use of dendrimers for the “pretargeting” approach to cancer therapy (73). In this approach the tumor-selective targeting of monoclonal antibodies (mAbs) is retained, but the delivery of the radionuclide is relegated to another molecule, which is often a radiolabelled biotin, avidin, or streptavidin molecule (Fig. 16). Thus, it is hoped that the immunoreactivity and biodistribution of the mAbs would be better preserved, while the selective tumor localization of the radiolabelled biotin would be secured by the strong biotin–streptavidin binding. In addition to improving the pharmacokinetic distribution of the therapeutic radionuclide, the biotin/streptavidin–based reagents may provide a method for the step-

**Figure 12.14** Octopus glycosides are useful core molecules for the synthesis of glycoclusters and carbohydrate centered dendrimers.

wise increase of the amount of radioactive metal bound to cancer cells in vivo.

In order to achieve this goal, PAMAM dendrimers conjugated with biotin are particularly attractive due to their compactness, multifunctionality, and size control (Fig. 17). These parameters are essential for reaching the optimal balance between tumor penetration and rapid increase in the bound radionuclide. Thus, various generations of Starburst® dendrimers were reacted with N-succinimidyl p-tributylstannyl benzoate **47** (in Fig. 17) followed by per-biotinylation with the new reagent **48**. Iododestannylation allowed the radiolabelling of the Starburst® dendrimer **49** (Fig. 17).

#### D. Dendrimer–Oligonucleotide and –Nucleic Acid Conjugates

PAMAM dendrimers have been investigated regarding their ability to transfer biomolecules into several mammalian cell lines (74). Their use as gene transfer vectors in achieving a highly efficient transfection exploits the electrostatic interactions that occur at physiological pH. In this environment, the protonated amino terminal groups interact with biologically relevant polyanions, such as nucleic acids. Thus, synthetic polycationic dendrimers can serve as mimics of naturally occurring macromolecules with a vital biological function, such as histones and spermidines.

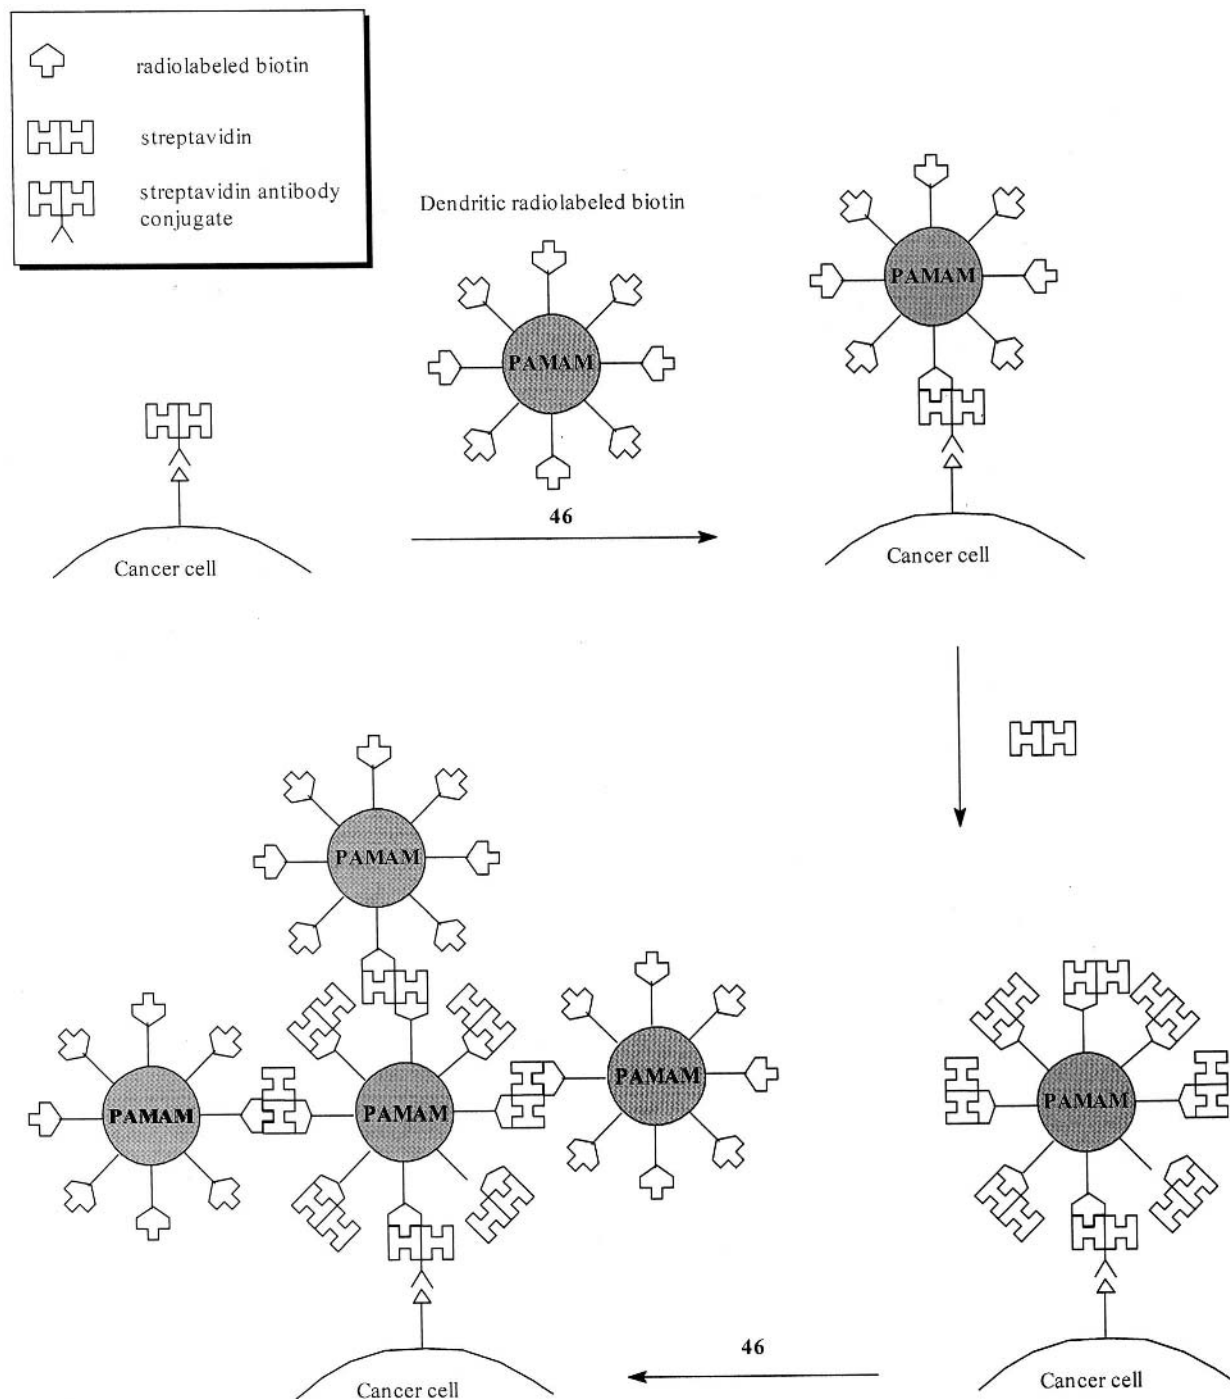

**Figure 12.15** Activation and reactions of dendrimers containing terminal carboxyl groups.

New studies (75) analyzed the interactions between the Starburst® dendrimers and polynucleotides such as calf thymus DNA, poly(AT), poly(GC), and double-stranded oligonucleotides of 12 base pairs (DNA-12mer). These interactions were studied by EPR spectroscopy employing nitroxide radicals as spin labels (covalently bound to dendrimers). Computer-aided analysis of the EPR spectra provided information on the mobility of the labels and their partitions in different environments. This type of interaction is extremely important in understanding the mechanism of PAMAM-mediated gene transfer in mammalian cells. Spectral analysis of the investigated polynucleotides indicated that the DNA-12mer presented the strongest interaction, presumably due to its short length. Given the fact that dendrimer–DNA interactions depend on the degree of protonation of the external amino groups, their dependence on the pH of the environment was investigated. Small dendrimers at low pH showed significant interaction with the polynucleotides. At higher concentration of dendritic mol-

ecules the interaction decreased due to self-aggregation. By contrast, the large dendrimers suffer a partial swelling as a result of the electrostatic repulsion of the charged surface groups. This destabilization can be lowered by the interaction with the polyanionic DNA leading to much stronger interactions.

Studies have also shown plasmid DNA (76) conjugation with block copolymers containing methoxy-poly(ethylene glycol) (mPEG) and poly(L-lysine) dendrimer. The shape and particle size distributions of the copolymer–plasmid complex at various charge ratios were examined by atomic force microscopy. It was shown that this novel linear dendrimer–polymer block copolymer can self-assemble with plasmid DNA at physiological conditions, forming a compact and water-soluble polyionic complex. The nuclease resistance of the complex proved that the copolymer increased the stability of the plasmid DNA suggesting that these materials could be valuable for the delivery of genetic material such as antisense or plasmid DNA.

**Figure 12.16** The pretargeting approach to cancer therapy. A streptavidin–antibody conjugate initially identifies the cancer cell and then a radiolabelled dendritic biotin binds strongly to this substrate. Thus, in just a few steps one can bind a lethal amount of radionuclide to the cancer cell.

Figure 12.17 Synthesis of the radiolabelled dendritic biotin reagent for cancer therapy.

### III. CONCLUSIONS

As it is increasingly evident that multivalent interactions play a key role in various biological phenomena, this field will continue to flourish in the years to come. Any biological surface interacting with another biological entity through multivalency can in principle become the target for the design of a new polyvalent drug.

Dendrimers can provide unique opportunities in the rational design of nanomolecular scaffolds for the attachment of active biological ligands. Thus, by controlling the chemical nature of the dendritic layers, the presentation of the end groups on the surface may change. The core functionality, the length, and the functionality of the monomer are important parameters controlling the surface density and the topology of the end groups.

The results obtained so far predict that breakthrough applications can occur in the design of inhibitors for the attachment of both viruses and bacteria. Other applications in the fields of gene therapy and new cancer treatment protocols based on multivalent dendritic conjugates may follow.

The field of dendrimer chemistry is currently in the exponential growth phase, as demonstrated by Fig. 1 of this brief review. Important applications will certainly mushroom across the spectrum of the medical sciences and have the potential to generate significant intellectual property rights.

## Biocompatibility of Elastomers

### I. ELASTOMERS

#### A. Introduction

Elastomers, like plastics, are polymers. The term *elastomer* is currently used to designate all rubbers, i.e., natural or synthetic macromolecular materials with rubberlike elasticity. Medical applications for elastomers appeared soon after they began being produced on an industrial scale (1) following the discovery of vulcanization (crosslinking) in 1839 by the American Charles Goodyear. Over the past 15 years, the literature on biomedical applications for elastomers has grown considerably and reports have appeared regularly (2,3). Yoda (1) recently published a detailed review.

##### 1. Definition

While they are members of the broad family of polymers, elastomers behave differently than plastic materials or plastomers. Generally speaking, for materials to be considered elastomers they must be

- Flexible, i.e., have low rigidity (several megapascals)
- Highly deformable, i.e., are able to withstand strong deforming forces without rupturing and have an elongation at rupture over 200%, while possessing relatively high tensile strength at ultimate elongation
- Elastic or resilient, i.e., are able to return to their original shape and size after the deforming force is removed and quantitatively release the energy used to deform them (Table 1) (4).

Many so-called biomedical elastomers do not meet the second criterion. While it is difficult to set an elastic limit beyond which a polymer stops being a plastomer and becomes an elastomer, we will use the broadest medical definition and refer to all polymers with sufficient elasticity to return to their original shape after a substantial deformation as elastomers (5). However, it will occasionally be more appropriate to talk about elastic polymers than true elastomers.

##### 2. Classification

###### a. *The Various Families of Elastomers*

There are some 15 families of elastomers, some of which include 10 to 20 different grades. Modern polymerization processes increasingly allow the manufacture of customized products that address specific application problems and provide specific elastomeric properties.

The current classification system separates elastomers into four categories (the acronyms are based on the ISO 1629:1995 standard):

- General-use elastomers.* Includes natural rubber (NR), synthetic polyisoprene (IR), styrene butadiene copolymers (SBR), and polybutadienes (BR)
- Special elastomers.* Includes ethylene propylene and diene copolymers (EPM, EPDM), isobutylene and chloro- and bromoisobutylene isoprene copolymers (IIR, BIIR, CIIR), nitrile butadiene copolymers (NBR), and polychloroprenes (CR)
- Very special elastomers.* High thermal and/or chemical

**Table 13.1** Some Commercially Available Elastomers Arranged by Tensile Strength

Elastomer	Trade name	Supplier	Tensile strength (PSI)	Tensile strength (MPa)	Ultimate elongation (%)
Butyl rubber (polyisobutylene)	Butyl	Polysar Inc., Akron, OH	700–1500	4.8–10.3	200–250
Polyisoprene	Santoprene	Monsanto Co., Akron, OH	1640	11.3	520
Silicone rubber	Silastic	Dow Corning, Midland, MI	500–1500	3.4–10.3	200–1000
	Med	McGhan NuSil Corp., Carpinteria, CA	750–1750	5.2–12.1	850
	SM	Sil-Med Corp., Taunton, MA	500–1500	3.4–10.3	250–900
Silicone rubber copolymers	C-Flex	Concept polymer, Inc., Clearwater, FL	1000–2000	6.9–13.8	200–600
Polyvinylchloride (PVC)	Goodtouch	B.F. Goodrich, Cleveland, OH	1700–1850	11.7–12.7	430–460
	Tygon	Norton Perform Plastic, Wayne, NJ	1200–2300	8.3–15.9	375–410
Ethylene vinyl acetate (EVA)	Ulathene	U.S. Industrial Chemical Co., New York, NY	2000	13.8	700
Acrylonitrile butadiene	Krynac	Polysar Inc., Akron, OH	500–2250	3.4–15.5	150–650
Polyhexene	Hexsyn	Goodyear Tire Co., Akron, OH	1500–2400	10.3–16.5	250–350
Polychloroprene	Neoprene	Du Pont, Wilmington, DE	1000–2500	6.9–17.2	200–600
Fluoroelastomers	Fluorel	3M, St. Paul, MN	1500–2500	10.3–17.2	100–400
Styrene butadiene rubber (SBR)	Krayton	Shell Chemical Co., Houston, TX	750–2650	5.2–18.3	550–850
	Plioflex	Goodyear Tire Co., Akron, OH	200–2825	1.4–19.5	290–900
Ethylene vinyl acetate (EVA)	EVA	Du Pont, Wilmington, DE	3200	22.1	600–750
Natural rubber (cis-polyisoprene)	Natsyn	Goodyear Tire Co., Akron, OH	2200–3450	15.2–23.8	500–600
Polyester terephthalate glycolated	Hytrel	Du Pont, Wilmington, DE	4000–6800	27.6–46.9	350–700
Nylon (amorphous)	Pebax	Atochem Polymers, Philadelphia, PA	4200–7400	29.0–51.0	350–680
Thermoplastic polyether urethanes	Tecoflex	Thermedics, Inc., Woburn, MA	3000–6000	20.7–41.4	250–600
Thermoplastic polyester urethanes	Estane	B.F. Goodrich, Cleveland, OH	4000–8000	27.6–55.2	400–600
Thermoplastic polycarbonate urethane	Corethane	Corvita Corp., Miami, FL	4500–9000	31.0–62.1	250–500
Chlorotrifluoroethylene	Aclar	Allied-Signal, Morristown, NJ	7500–11000	51.7–75.8	200–300
	Saran	Dow Chemical, Midland, MI	8000–16800	55.1–115.8	70–90

resistance elastomers, including silicone elastomers (VMQ), fluoroelastomers (FPM), chloropolyethylenes and chlorosulfonyl polyethylenes (CM, CSM), polyacrylates (ACM), ethylene vinyl acetate elastomers (EVA), ethylene methyl acrylate (EAM), hydrogenated nitrile elastomers (HNBR), and epichlorhydrin elastomers (CO, ECO, GECO)

*Thermoplastic elastomers.* A separate category indicating that they do not need to be vulcanized since they can be used like any thermoplastic material.

The first two families of elastomers account for 97% of total world consumption. The third family includes high thermal and/or chemical performance elastomers, which are experiencing strong market growth. The vast majority of elastomers are polymerized from petroleum monomer derivatives.

#### b. Very Special Elastomers

Polysiloxanes, or silicone elastomers, are the most abundantly produced very special elastomers. The backbone of

these elastomers is not a chain of carbon atoms but an arrangement of silicon and oxygen atoms. Their most remarkable quality is their outstanding thermal performance. They retain their service properties from  $-85$  to  $250^{\circ}\text{C}$ . However, their mechanical properties are relatively weak. They are used for a broad range of applications in the electrical, electronic, and automotive industries. Their physiological inertness makes them well suited for use in the biomedical field.

Fluorocarbons are another family of high-performance elastomers, containing 70% fluoride that gives them outstanding resistance to heat and chemicals. They can be used at temperatures up to  $250^{\circ}\text{C}$ . Their cold resistance, however, is less than that of silicones ( $-30^{\circ}\text{C}$ ). Because of their passivity and their insolubility they are useful in the biomedical field.

Polyacrylates were specially designed to resist oils containing sulfur-based additives. They have high heat ( $180^{\circ}\text{C}$ ) and oil swell resistance. They are used as components of grafted or linear biomedical elastomers [polyurethane (PU), styrene–ethylene/butylene–styrene (SEBS)].

Chloropolyethylenes and chlorosulfonyl polythylenes compete with polychloroprenes because of very similar chemical compositions. The high chemical saturation of the polymer chain gives them better heat resistance (120 to 130°C), and they are often used for wires and cables.

Hydrogenated nitrile, one of the most recent elastomers to arrive on the market, has hydrogenated double bonds, which provide it with better heat resistance (150°C) than conventional nitrile rubber as well as with excellent resistance to oils and ozone.

### c. Thermoplastic Elastomers

Polymers are commonly defined by their thermal properties, i.e., as thermoplastics and thermosetting materials. *Thermoplastics* are composed of independent, linear molecules (which may have side branches). They can be melted (e.g., polyethylene) and are processed by heating. *Thermosetting materials* are composed of networks of covalently linked chains. They are initially polymerized at room temperature or by heating and cannot be remelted once they have solidified (e.g., silicone elastomers). It is actually a little more complex since certain elastomers have intermediate structures and properties (Fig. 1).

Many types of thermoplastic elastomers (TPE) are being developed. They have certain advantages with respect to classic elastomers and are replacing them in some applications. Thermoplastic elastomers can be defined as materials that combine the flexibility or elasticity of rubber compounds with the thermoreversible versatility of thermoplastic polymers. Most require little or no formulation. If formulation is required, it can be performed by the producer or by an intermediary between the producer and the processor—the compounder. Thermoplastic elastomers are relatively simple to use and require fewer processing steps than thermosetting elastomers (no mixing or crosslinking), thus reducing costs. Processing time is also much shorter, reducing energy consumption. Processing methods are nonspecific and more numerous, being the same as those used for plastomers. Unlike classic elastomers, thermoplastics can be recycled. Manufacturing scraps and clippings can be reused with little or no change in their properties. Despite these numerous advantages, most of these

elastomers do have drawbacks, including their temperature sensitivity. In 1995, the international thermoplastic market totaled 900,000 tons (according to Rapra Technology Ltd.), including 329,000 in Europe. Only 2 to 3% were used for medical applications.

## 3. Chemistry and Synthesis

### a. Structure

Elastomers are composed of macromolecular chains that occasionally exceed 100,000 atoms in length, fold back on themselves when at rest, and have a very high degree of self-cohesion (bond energies of several hundred kilojoules per mole). On the other hand, cohesion between different chains is weak because of the small number of bonds and their relatively low energy (covalent, van der Waals, polar bonds). Because of their ability to rotate around their carbon-carbon or silicon-silicon catenary backbones, the chains can twist into various shapes and are thus very flexible at their service temperature. When subjected to a deforming stress, these entangled macromolecular chains begin to unfold, sliding over each other, and separating along the direction of the stress, giving the material its elastomeric property. The greater the number of bonds between chains and the more chemically stable the bonds (crosslinking), the less likely the material is to deform under stress. What limits rotation of the catenary backbone and sliding is the formation of chemical bonds (generally covalent) between the chains, thereby leading to the formation of a stable, three-dimensional network. The greater the crosslinking, the more rigid the polymer. The formation of chemical bonds produces various active sites on the macromolecular chains (double bonds, hydrogen atoms, labile halogen atoms, etc.). From a thermodynamic perspective, when an elastomer is subjected to a tensile stress, it may stretch to several times its free length when the macromolecular chains unfold. The energy transferred to the elastomer makes it thermodynamically unstable. When the stress is removed, the macromolecules return to their initial, energetically stable, intertwined state, releasing most of the input energy.

### b. Polymerization

True polymerization only involves the formation of macromolecules by the creation of multiple carbon-carbon bonds. However, in a larger sense, it simply means the formation of macromolecules. Monomers with accessible double bonds, i.e., bonds that are not obstructed by large substituents may form giant molecules. The double bonds can be rearranged by catalysts such as radiation, oxygen, and free radicals (like those produced by the dissociation of peroxides), giving a new radical that attacks another

**Figure 13.1** Schematic drawing of thermoplastic and thermosetting elastomer structure.

Figure 13.2 Example of branched homopolymer: polyethylene.

monomer, in a chain reaction. This is called *free radical polymerization*:

The catalyst may attack the main chain, producing side chains (Fig. 2). However, in principle, bridges never form between two chains (see, crosslinking subsection). Certain molecules with different functional groups can combine into a single molecule, e.g., acid and alcohol or aldehyde and amine. Molecules with different functional groups can combine into macromolecules. Molecules with identical functional groups can also react with other molecules with antagonistic functional groups to produce macromolecules. Siloxanes are an example of this. They condense to form polysiloxanes:

Silicon elastomer

Another example is carbonyl chloride (phosgene) and bisphenol A, which combine to produce polycarbonate:

In the two examples, for each bond created a small molecule ( $H_2O$ ,  $HCl$ ) is lost in a reaction called *polycondensation*. In other cases, as with the formation of urethanes and other forms of polysiloxanes, no molecules are lost:

This is referred to as *polyaddition*.

A wide variety of catalysts (specific to each reaction) are involved in free radical polymerization reactions (polyaddition or polycondensation), all of which lead to long polymers that concatenate either the same monomer (homopolymers) or different monomers (copolymers).

**Homopolymerization.** The linear bonding of structurally identical small molecules (monomers) leads to the formation of homogeneous polymers. Most commonly used biomedical elastomers are homopolymers (Fig. 2). However, the possibility of mixing different monomers and/or small polymers is leading to the synthesis of new polymers with infinitely varied properties, which, because of their improved performance, are increasingly replacing homopolymers for specific applications.

**Copolymerization.** Different types of monomers can be copolymerized or mixed with small reactive polymers to obtain alternating (-A-B-A-B-A-B-), sequential (-A-A-A-B-B-B-A-A-A-B-B-B-), or random (A-B-B-A-B-A-A-B-) copolymers with different block structures containing two, or occasionally more, identical monomers (Fig. 3).

Other types of monomers or small polymers can also be attached to existing chains to create branched or grafted copolymers (Fig. 4). Alterations to the catenary or terminal structures of copolymers change their properties, creating new types of elastomers, some of which have potentially interesting biomedical applications. It would be more accurate to talk about bi- and terpolymers when a reaction involves two or three types of monomers, but the term co-

Figure 13.3 Different blocks of a terpolymer segmented polyetherurethane: pellethane® (A-(Bn)-C).

Figure 13.4 Monomers attached to existing chains to create branched or grafted copolymers.

polymer is used to describe all polymers containing two or more different types of monomers.

**Crosslinking.** When polymers have reactive sites within the chain (e.g., the double bonds of unsaturated polyesters) or at the terminal (e.g., the hydroxyl group of polyols), they can be reacted with a polyfunctional agent to create a network in a process referred to as crosslinking or vulcanization. Such agents are generally called catalysts, hardeners, or coupling agents, and the initial polymer is called a prepolymer (Fig. 5).

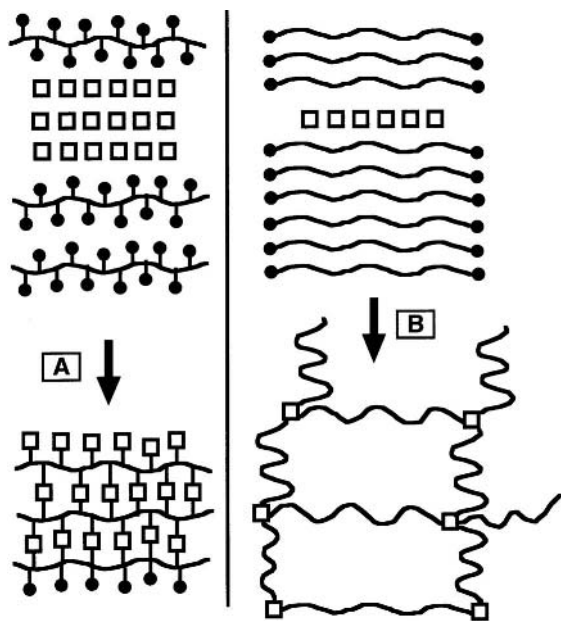

Figure 13.5 Crosslinking of a polymer. (A) Crosslinking of a polymer with reactive side groups; (B) crosslinking of a polymer with reactive terminal groups.

Crosslinking can be performed by free radical polymerization using organic peroxides, which greatly increases the thermal resistance of the network by creating very strong carbon-carbon bridges. Other types of crosslinking agents can be used, especially for elastomers with specific reactive groups (carboxyls, halogens, etc.).

d. Formulation

Apart from a few rare exceptions, the properties of “green” elastomers do not allow them to be used as is. Various additives, all with well-defined functions, must be incorporated. This is what is called formulation. Despite a certain empirical approach, formulation requires a great deal of know-how to compensate for the occasionally antagonistic properties required by certain applications. A standard formulation contains

- Elastomer(s). Specific properties, especially chemical properties, must address application specifications. A mixture of elastomers may be used.
- Filler(s). Fillers are used to provide superior mechanical properties, and also to improve handling and to lower production costs. Precipitated silica is the most common additive in biomedical elastomers. Chalks and kaolins are also occasionally used.
- Plasticizers. Plasticizers are used to make processing easier and improve low temperature flexibility. Heavy solvents, oils, and esters are generally used.
- Protective agents. These are used to protect the macromolecular chains from oxygen, ozone, and ultraviolet radiation. Amine and phenol derivatives are generally used.
- A crosslinker. These allow the formation of a stable, three-dimensional network without which the elastomer would be useless.
- Various other ingredients. Numerous other ingredients, such as colorants, conditioning agents, swelling agents for manufacturing cellular elastomers, with very specific functions may be used.

It is clear that the release of additives like plasticizers, antioxidants, initiators, catalysts, fillers, etc., by biomedical elastomers may have a significant impact on host tissues.

e. Elastomer Reinforcement

Reinforcement fillers are quite often added because elastomers have fairly low breaking strengths at ambient temperature. Adding more precipitated silica enhances breaking strength, but decreases flexibility. The amount of filler can be changed to generate variable stress-strain curves and produce elastomers with specific properties. Fillers like semireinforcing kaolins can be used to generate economi-

cal, clear mixtures. The same is true of chinks, which are considered as diluents. Elastomers are also occasionally reinforced by the addition of bulk fibers or tissues (glass, carbon, aramide) for very specialized aeronautics and medical applications for example.

## B. Silicone Elastomers

### 1. Introduction

Silicones (a contraction of silicon ketone) make up a vast family of polymers with remarkable properties due to the presence of both silicon–oxygen and silicon–carbon bonds. Depending on the nature of the functional groups attached to the silicon atoms, silicone polymers may be resins, oils, or elastomers, making them well-suited for diverse applications in a wide variety of areas. Silicon elastomers are composed of very long polymers containing several thousand silicon atoms per molecule (6). The first biomedical applications for silicone elastomers can be traced back to the 1950s, while industrial-scale manufacturing dates to 1965 (7,8). Today, silicone elastomers are the most widely used polymers in medical applications (1) because of the strong, very mobile bonds of their Si–O–Si (siloxane) catenary backbone, which provide elevated chemical inertness and exceptional flexibility. They are also very stable over time and at body temperature, show little tissue reactivity, and are highly resistant to chemical attack and heat, which allows them to be autoclaved. They also have exceptional mechanical properties such as high tear strength, outstanding elasticity, and high gas permeability, which makes them suitable for many medical applications such as contact lenses, special dressings, and air/blood filter membranes. (Table 2) (9,10).

### 2. Manufacture

Chlorosilanes, especially dichlorosilanes and trichlorosilanes (where R is an organic radical), are the basic building blocks of silicone elastomers:

The main organic radicals used are methyl (–CH<sub>3</sub>) and phenyl (–C<sub>6</sub>H<sub>5</sub>) groups. Others (ethyl, vinyl, etc.) are used for special application silicones. Chlorosilanes are complicated and costly to produce. They react with water to give silanols, which, being unstable, lose water molecules and condense into polymers—polysiloxanes:

Depending on the dichlorosilane/trichlorosilane ratio, different polymers are obtained. The greater the percentage of dichlorosilane, the more linear the polymer; and the greater the percentage of trichlorosilane, the more branched the polymer. Depending on the reaction conditions, polymers with varying molecular masses can be produced. The terminal hydroxyl groups can react with other components or with each other in the presence of catalysts. It is the termination reaction that produces the final silicone product:

**Table 13.2** Properties of Silicones for Use in Biomedical Applications

Good elastomeric and relatively uniform properties over a wide temperature range
Physiological indifference
Good low temperature resistance and stability at high temperatures
Excellent resistance to biodegradation
Excellent resistance to oxidation and ultraviolet light
Moderate biocompatibility
Outstanding resistance to aging
Excellent dielectric behavior over a wide range of temperatures

The properties of the finished product depend on the nature of the organic radicals grafted onto the catenary backbone, meaning that an infinite number of chemical structures—and properties—are possible.

The end products of this industrial process are polycondensates of basically linear or weakly branched polysiloxane molecules of varying molecular mass and consistency with terminal reactive groups such as —Cl or —OH. These reactive polycondensates or prepolymers serve as the raw materials to produce the final silicone products by room temperature vulcanization (RTV) or high temperature vulcanization (HTV).

### 3. Homopolymerization of Silicone Elastomers

Most commonly used biomedical silicone elastomers are homopolymers. Increasingly, however, various polysiloxane prepolymers as well as other types of prepolymers with varying properties are being combined to synthesize copolymers for the biomedical market. Different polymerization processes can be used to produce a variety of silicone elastomers.

#### a. One-Component RTV Silicones

These result from a reaction between atmospheric moisture and a mixture of polycondensates and catalyst. Crosslinking thus occurs from the outside in, limiting the useful thickness:

Such silicones are only used for adhesives, coatings, and sealants. Their biomedical utility arises from the absence of fillers and additives, which gives them an excellent biocompatibility (11).

#### b. Two-Component RTV Silicones

These result from a reaction between a polycondensate and a crosslinker added to initiate the reaction. They are used in the medical field for limited production runs of molded products.

Crosslinking can occur by polycondensation of a relatively low molecular weight polydimethyl siloxane with a reactive hydroxyl group in the presence of tin octoate (i.e., condensation cure):

Or crosslinking can occur by polyaddition of a relatively low molecular weight vinylsiloxane, a polysiloxane with a terminal hydrogen, and an organometallic catalyst like chloroplatinum acid [e.g., RTV 71556 Silbione from Aventis formerly Rhône—Poulenc]:

#### c. High Temperature Vulcanization Elastomers

These are produced by heat vulcanizing similar but higher molecular weight polycondensates premixed with crosslinkers (peroxides):

They are used in small- and large-scale industrial production runs by injection molding, extrusion, calendaring, etc. (e.g., MDX 44210 Silastic from Dow Corning).

### 4. Copolymerization of Silicone Elastomers

Silicone elastomer copolymers can be produced by addition or condensation. Condensation generally involves low to medium molecular weight prepolymers. For example, vinyl polymethylsiloxane is condensed with hydroxy polymethylsiloxane to create a new prepolymer—siloxylethanol ether—which can in turn be condensed with di-isocyanate to produce silicone urethane copolymers whose blood compatibility and stiffness have been improved to the point where they can be used as blood catheters or blood pump coatings. Examples of different reactive Silicone prepolymers include the following (12):

The copolymerization reaction is (12):

Condensation has also been used to produce silicone polycarbonate copolymers designed to transport ions (12):

Their good mechanical resistance and high stability in aqueous environments make them useful for microelectrodes.

Certain linear silicone elastomer copolymers are also prepared by addition curing. These are generally higher molecular weight polymers that can be processed or molded using industrial processes. Siloxane and methacrylate copolymers were developed to improve the properties of elastomeric contact lenses by increasing their hardness, stiffness, transparency, wettability, and gas permeability by combining the properties of the various monomers used to produce the copolymer (12):

Graft silicone elastomer copolymers can have two types of grafted side chains, one type on all the molecules in the elastomer and a second added by graft polymerization at the surface (see section I.B.) Silicone elastomers can be mixed relatively easily with numerous copolymers [styrene-butadiene-styrene (SBS), SEBS, Polypropylene (PP), SEBS, PU]. Silicone elastomer copolymers are all very biocompatible because the addition of silicone gives them the elasticity that only the incorporation of plasticizers (phthalates) would otherwise provide. They are suitable for large-scale production runs by molding or injection because of the thermoplasticity provided by the SBS, SEBS, and PP copolymers. They also combine the surface properties of silicones with the intrinsic mechanical performance of the added copolymers. Polyurethanes are good examples of copolymers with greatly enhanced blood compatibility and mechanical strength. Polyurethane products are produced by mixing a vinylsiloxane polycondensate with a curing agent (crosslinker) followed by injection into an appropriate mold. The components crosslink to form a thermoplastic silicone-polyurethane network with remarkable physical and biomedical properties. These biomedical silicone elastomers can be further modified by the addition of other components before the final cure. These components may or may not be involved in the crosslinking, and they can have an impact on the physical and chemical properties, and thus the biocompatibility of the final elastomeric products (13,14).

## 5. Fillers

Biomedical silicone elastomers may be considered composite materials in the sense that they are composed of organomineral polymer matrixes containing fillers that are more or less linked to the network. Fillers are used to improve the mechanical performance of elastomers, notably to increase tear and tensile strength. They are generally mineral in nature, but may also be organic, like high molecular weight polyacrylic acid (15). Amorphous silica is the most widely used filler and may be modified using a coupling agent that improves adherence to the polymer matrix (sizing). This is generally done by silanization because the most common coupling agents are silanes like  $\text{X}_3\text{Si}(\text{CH}_2)_n\text{Y}$ , where  $n = 0$  to 3,  $\text{X}$  = hydrolysable group, and  $\text{Y}$  = organic group selected on the basis of the polymer matrix. Silica with reactive Si-H covalent bonds can be obtained by a reaction with methyldichlorosilane for example (1). Other more specific treatments have been reported

like the attachment of antithrombogenic heparinoid substances to amorphous silica (16,17). Fibers (glass, aramide, carbon, etc.) can also be used to reinforce the structure of biomedical silicone elastomers. Sizing the fibers ensures good adherence between the reinforcement and the matrix (18).

The fillers must never reduce material biocompatibility, either because they are not biocompatible themselves or they are released in situ due to insufficient bonding to the polymer.

## 6. Surface Treatments

Changes to the basic silicone elastomer may be insufficient for special applications. The desire to improve the materials has led to a number of surface treatments to optimize the biocompatibility of surfaces in contact with living tissue, to seal in undesirable residues or additives using a coating, and to regulate excretion and/or absorption by the sealed elastomer using a selectively permeable surface (19). Silicone elastomers are hydrophobic and have high coefficients of friction, which in combination with their low surface energy (10 to 18 dynes/cm) ensures low wettability (5,20). While these biophysical characteristics can be advantageous (no tissue adherence to mammary implants, no bacterial adherence, no sliding of urethral stents or blood catheters due to surface friction caused by contact with living tissue), they can cause numerous biological and technical problems in need of solving in other applications. Various surface treatments can be performed using a variety of techniques.

### *a. Plasma Deposition of Simple Substances or Composites*

Heating a gas to a very high temperature using an electric arc (electric glow discharge) causes extreme atomic excitation resulting in partially or almost totally ionized gases, or plasmas. When the ions come into contact with a "cold" surface, they are deposited and become chemically bonded to the surface. Exposure of elastomers to such plasmas (He, Ar, etc.) allows the deposition and chemical bonding of monomers or polymers to the exposed surface in a process called plasma polymerization (or glow discharge polymerization to avoid confusion with blood plasma). The atomic, molecular, or macromolecular deposits obtained using this technique create a thin, smooth film several angstroms to several hundred angstroms thick. Most polymers with suitable biological or technical properties (polyethylene, polyvinylchloride, polytetrafluoroethylene, polycarbonate, polymethylmethacrylates, polysiloxanes, etc.) can be applied to silicone elastomers.

The plasma deposition of  $H_2^+$ ,  $N_2^+$ ,  $O_2^+$ , and  $Ne^+$  ions breaks existing chemical bonds on the surface and creates new radicals:  $=C=O$  using  $O^+$  plasma, for example. The affinity of certain proteins (albumin, fibrin) for the surface of silicone elastomers modified in this way creates a layer of adsorbed protein that prevents the adherence of other blood constituents by steric repulsion, a well-known effect in colloidal chemistry (21). The result is a powerful anti-thrombogenic effect.

The deposition of ionic oxygen, argon, carbon dioxide, or ammonia makes the silicone elastomer surface more hydrophilic. However, the migration of free polymer to the elastomer surface affects the durability of such treatments (22,23). The deposition of these ions also allows for polymer grafting on the elastomer surface.

### *b. Surface Polymer Grafting*

This is a more long-lasting solution, but more technically complicated. After activation by an argon plasma or a solvent, the silicone elastomer is placed in a reactor containing a monomer solution (acrylic acid, hydroxyethyl methacrylate, bis amino polyethylene oxide, etc.). Heating promotes chemical bonding of the monomers to the elastomer and crosslinking among the grafted monomers, producing a smooth, continuous coating of grafted copolymer (polyacrylic or polyethylene, for example) covering the elastomer surface. By alternating the chemical treatment of the various surfaces of an elastomer, a bifunctional, homobifunctional, or heterobifunctional material can be created (Fig. 6). Such treatments have been used to improve the adherence and growth of corneal epithelial cells by grafting 2-hydroxyethylmethacrylate to the outside surfaces of silicone elastomer corneas and to prevent adherence by grafting bis amino polyethylene oxide to the inside surfaces (24).

### *c. Denucleation of Silicone Elastomers*

This treatment helps remove the micro air bubbles in the surface irregularities of the elastomer. The goal is to remove air/blood interfaces to prevent complement activation and platelet aggregation. The procedure is relatively long but technically simple. It involves rinsing the elastomer in double distilled water for 12 h, soaking in 99% ethanol for 24 h, soaking in a buffer solution with vacuum degassing for 6 h, then gradually replacing the buffer solution with ethanol over a 6-h period. The elastomer is then stored in the buffer solution until use (25). This treatment helps increase hemocompatibility without modifying the structure or composition of the silicone elastomer surface.

**Figure 13.6** Schematic diagrams for grafted silicon rubber surfaces.

#### d. Acylation or Hydroxylation of the Silicon Elastomer Surface

This process increases the affinity for serum proteins (26). Hydroxylation is performed by an oxymercuration/demercuration reaction, or hydroboration, which transforms the polydimethylsiloxanes on the surface into hydroxymethylvinylsiloxane. Acylation of  $\text{—OH}$  groups is achieved through simple esterification of exposed carbons on the siloxane side chains (26).

### C. Polyurethane Elastomers

#### 1. Introduction

The first polyurethanes were developed by Otto Bayer in the late 1930s. They now make up the largest family of thermoplastic and thermosetting plastics. They range from very rigid to very flexible and from compact to cellular, and are used to produce varnishes, fibers, textiles, plastics, and elastomers. Polyurethane elastomers were studied in great detail in the 1950s and 1960s (27–29). Their use for biomedical applications was proposed by Pangman (30) and Boretos (31), not to mention Yoda (1). They have been

widely used in the medical field for over 25 years now (31–36). They are the products of polyaddition reactions between polyisocyanates and polyalcohols (polyols). Broadly speaking, all elastomers are isocyanate derivatives.

#### 2. Manufacture

Polyurethane elastomers are formed by reactions between isocyanate and substances with mobile hydrogen ions, generally polyols, amines, and water:

Alcohols give urethanes:

Nontertiary amines give ureins or substituted ureas:

Water also give ureins together with carbon dioxide:

In most cases, the components (i.e., the raw materials, the catalysts, and the adjuvants) are mixed as liquids and then injected into molds or cavities. Aromatic polyisocyanates are the most frequently used raw materials. Toluenediisocyanate (TDI) is used as is or is dimerized in order to synthesize elastomers with high tear resistance; diphenylmethanediisocyanate (MDI) and naphthylendiisocyanate (NDAI) are used to produce polyester elastomers:

2-4

2-6

Toluene diisocyanate

Diphenylmethane 4-4'-diisocyanate

Naphthylene 1-5-diisocyanate

Polyethers are the most frequently used polyols and result in polyetherurethanes; polyesters are used less often but the resulting polyesterurethanes are much more chemically stable:

Formation of polyether polyols

Formation of polyester polyols

Pellethane® is a poly(ether urethane) that has been used for many years in the medical field, and is the result of a reaction between MDI and polytetramethyleneglycol (PTMG), which produces a soft segment ending in an isocyanate that reacts with the diol moiety of butanediol to extend the chain (Fig. 7) (1).

The greater the number of reactive groups on the polyols used to synthesize the polyurethane, the more the end

Figure 13.7 Polyetherurethane-segmented Pellethane.

product is crosslinked and thus rigid. The polyols with the highest molecular mass and the least crosslinking give the most flexible elastomers. To improve the mechanical resistance of certain polyurethane elastomers, all or part of the polyol may be replaced by a reactive diamine [e.g., methylene dianiline (MDA), methylene *bis*-ortho-chloroaniline (MOCA), ethylene dianiline (EDA)], giving rise to segmented polyetherurethaneurea elastomer such as Biomer® or Mitrathane®, which are used in cardiovascular applications. Prepolymer processing (foaming) using expansion agents produces cellular elastomers: either water is reacted with isocyanate to produce a urein and carbon dioxide (chemical expansion) or low boiling point inert liquids are added and subsequently expelled by degassing during high temperature polymerization (physical expansion). Adjuvants are also required for crosslinking: catalysts (tertiary amines, organic tin salts), surfactants (silicones), fillers, reinforcements, pigments, etc. During manufacture (whatever the process) and storage, polyurethanes must be kept in a dry environment because their affinity to and reactivity with water can result in changes to their composition and/or create defects in the end product.

### 3. Mechanical Behavior of Polyurethane Elastomers

The hard segments crosslink among themselves within the mass of the elastomer to form agglomerations that act as fillers, improving the mechanical resistance of the material. The soft segments remain free and randomly arranged (Figs. 8 and 9). Under a tensile stress of 150% (29), the polyether soft segments line up along the elongation axis, displacing the urethane hard segments so that they are more or less perpendicular to the vertical axis. Soft segments brought into close proximity with each other by a stress crystallize, a process that becomes complete when elongation reaches approximately 250% (Fig. 10). When the elongation increases even more (~500%), the chemical bonds crosslinking the hard segments break down and the now separate hard segments align along the vertical axis. At this point, the soft segments relax because of the stretching due to the release of the hard segments (Fig. 11).

Segmented polyurethane elastomers thus have elastic behavior under low stress (deformation) conditions, which becomes plastic when the hard segment network breaks down. Deformed samples do not immediately return to their original shape following removal of the stress. However, rearrangement of the hard segments eventually results in a total or partial return to the initial shape, depending on the elastomer structure. The greater the concentration of hard segments, the more plastic the defor-

Figure 13.8 Linear polyetherurethane chain. (From Ref. 63.)

Figure 13.9 Distribution of hard and soft segments in a polyurethane elastomer. (From Ref. 63.)

mation. On the other hand, the lower the concentration of hard segments, the more elastic the behavior.

Chemical properties also depend on the soft/hard segment ratio. A large proportion of hard segments makes the material harder and provides better stress resistance, but decreases elasticity and resistance to abrasion (37). The presence of long polyether or polyester soft segments provides superior break elongation but makes the material more sensitive to oxidation and degradation by biological fluids and thus to failure under repeated stress (Table 3).

#### 4. Biodegradation of Polyurethane Elastomers

In vivo degradation of polyurethane elastomers occurs via four main mechanisms: calcification, macromolecular chain breakdown (1), hydrolysis, and environmental stress cracking. Calcification involves the deposition of calcium hydroxyapatite on the surfaces of implanted elastomers (38). Macromolecular chain breakdown of polyurethane elastomers occurs via oxidation reactions with the soft segments and at the junctions between hard and soft segments (39). Corrodable metallic residues favor oxidation by acting as catalysts in vivo (4,40). Hydrolysis depends on the susceptibility of the urea and urethane bonds and the concentration of hydrolytic enzymes at the cell-polymer interface. The extreme sensitivity of polyesterurethanes to hy-

**Figure 13.10** Crystallization of soft segments under a weak vertical stress. (From Ref. 63.)

**Figure 13.11** Reorientation of hard segments and relaxation of soft segments under a strong vertical stress. (From Ref. 63.)

hydrolysis limits their use in biomedical applications as opposed to polyetherurethanes, which are more resistant (1). However, polyurethane elastomers in general cannot be autoclaved because of the risk of hydrolysis.

Environmental stress cracking (ESC) occurs when mechanical stresses are combined with interactions with living tissue (41) and can lead to the complete destruction of the implanted material. Three phenomena must coincide for ESC to occur: the presence of enzymes as a result of an inflammatory response at the interface (42–45), a susceptible poly(ether urethane) elastomer, and a mechanical stress on the elastomer (41,46). Environmental stress cracking, which has never been observed with polyurethanes *in vitro*, does not occur if a single factor is missing (37), and seems to be due to the oxidation of the methyl group on the soft segment polyether chains (Figs. 12–14) (37).

Chemical properties are not the only factors at play. The hardness, mechanical resistance, and morphology or microstructure, as well as the affinity for proteins, also influence sensitivity to biodegradation (47). The microporous surfaces of polyetherurethane vascular devices promote tissue colonization, neointima formation, and fibrotic capsule formation that in turn favor biodegradation by increasing the size of the biological interface with respect to the volume of the device (48,49).

##### 5. Biostable Polyurethane Elastomers

The impact of environmental stress cracking on polyetherurethanes has stimulated research into polyurethane elastomers that do not contain ether groups and that remain stable when subjected to environmental stresses *in vivo*, i.e., biostable polyurethanes (37,50,51). Coury et al. (52) have filed a patent for a polyurethane that contains no ether groups. An aliphatic complex replaces the soft segment polyethers with a very rigid biostable skeleton that makes the polymer much too hard for many applications. Numerous attempts have been made to modify or replace the soft segments in order to improve biostability. Soft segment polyethers have been replaced by polybutadienes and polymethylsiloxanes (39,53,54), polycarbonates (55,56), and aliphatic hydrocarbons (55). Polysiloxanes are attractive substitutes for polyethers because of their low toxicity, good thermal and oxidative stability, low coefficient of friction, good hemocompatibility, and that fact that they do not affect the mechanical properties of the polyurethanes because their modulus of elasticity is similar to that of the soft segment they are replacing. Polycarbonate soft segments are also less sensitive to oxidation, although the hydrolysis of carbonate linkages *in vivo* is always possible (Fig. 15) (4,55–60).

Source: Ref. 1.

The complementary qualities of polyurethane and polyvinylsiloxane elastomers led to the idea of producing ‘‘alloys’’ in the hope of creating new polymers with enhanced resistance to biodegradation. The copolymerization of aromatic poly(ether urethane urea) and polydimethylsilo-

loxane (acetoxyl-terminated siloxane blocks linked to unsubstituted urethane nitrogen) produces a heterogenous elastomer composed of 10% water-vulcanizable polymethylsiloxane and a 90% polyurethane matrix in which phase separation (soft/hard segments) of the polyurethane mass is prevented by the interpositioning of the silicone-urethanes formed during the polymerization process (1,61,62). This complex mixture of polyurethane and silicone (Cardiotane 51®) is difficult to process because it is neither soluble nor thermoplastic (63).

## 6. Grafted Polyurethane Elastomers

The biomedical properties of polyurethane elastomers can be improved by encapsulation to isolate them from living tissue. Grafting polysiloxane molecules on the surface makes the material hydrophobic and protects the soft segments from oxidation and hydrolysis in vivo (64–66). Grafting alkyl or polyethylene [oligoethylene monoalkyl (aryl)alcohol ether] groups to the sodium atoms of urethane hard segments or incorporating sulfate groups by nucleophilic molecular displacement of N-H urethane groups creates sulfonate polyurethane anionomers with chemical

properties that limit biodegradation and thrombogenicity (67–74). Researchers have also grafted proteins and other molecules on polyurethane elastomers in an attempt to improve hemocompatibility—albumin (75), heparin (76), adenosine diphosphate (77), fibronectin, and gelatin (78). The grafting processes, or impregnation in the case of gelatin, are complex and require numerous steps. Collagen grafted to carboxyl group-enriched polyurethanes via 1,2-bis(2,3-epoxypropoxy)ethane links allows better epithelial cell growth than raw polyurethanes (79).

Seeding the lumen of microvessel vascular prostheses prepared by glow discharge allows the in vivo proliferation of a multicell layer close to but distinct from the elastomer wall. The cell layer is histologically similar to a native artery with antithrombogenic endothelial cells on the surface (80).

Plasma processing can be used to modify surfaces by depositing metallic silver (81–85), fluorinated films (86), nitrogen, and hexamethyldisiloxan polymers (83) to, among other things, improve the antithrombogenic and antibacterial properties of cardiovascular implants.

## 7. Modified Polyurethane Elastomers

Solvent extraction (toluene, acetone, methanol, etc.) of small molecular weight surface polymers (which are different in composition from the bulk polyurethane) increases the molecular weight of the surface fraction and enriches it in hard segments, making it more polar and improving hemocompatibility (36,87,88).

Since biodegradation mainly affects the ether bonds of soft segments, which are very sensitive to oxidation, certain biomedical polyetherurethanes contain high concentrations of antioxidants (89). Unfortunately, these elastomers (or their degradation products) may be toxic to host tissues (90). Researchers have recently begun examining

**Figure 13.15** An example of a biostable polyurethane: Corethane® (polycarbonate urethane), produced by reacting poly(1,6-hexyl 1,2-ethyl carbonate)diol with MDI. (From Ref. 4.)

natural antioxidants like vitamin E as possible alternatives to industrial additives.

Attempts to inhibit tissue responses have also been made. Adding hydroepiandrosterone (DHEA) to poly(etherurethane urea) reduces biodegradation by limiting macrophage activation. However, the effect is dose-dependent, and since DHEA is very hydrosoluble, it rapidly diffuses away, making it useless for long-term protection (91).

Toyo Cloth Co. recently announced that it had prepared a high molecular weight poly(ether/urethane/amide) from polytetramethylene oxide, MDI, ethylene glycol, and Nylon 66. The addition of calcium chloride to this polyurethane-nylon polymer modifies its physical and biomedical properties (92) by increasing water permeability, hydrophilicity, biocompatibility, thrombogenicity, and elasticity, and decreasing breaking strength (tensile modulus). An affinity for calcium ions points to potential thrombogenic or antithrombogenic applications for heparinized versions of the elastomer (76).

While polyurethanes may themselves be encapsulated, they can also be used to coat medical devices like pacemakers and endovascular stents (93–95). Such coatings have various degrees of hemocompatibility (96) and occasionally shift because of a lack of adherence to vessel walls (95).

The development of biodegradable polymers is a major advance in the research on biomaterials. Designed to gradually degrade in vivo over the implantation period, these polymers are used in numerous medical and surgical applications. Biodegradable polyesterurethane have been developed in recent years (97–99). DegraPol/btc® is a polyesterurethane copolymer with polyhydroxybutyric acid hard segments and polycaprolactone soft segments (Fig. 16).

The hard and soft segments can be replaced by a variety of substitutes that make the end product more or less biodegradable in vivo. By selecting the right substitute, it is possible to design cellular polyesterurethanes with varying de-

grees of rigidity and with degradation rates suitable for osteoblast colonization of bone implants (98). They can lose half their mass within several months of implantation. They are not strictly speaking elastomers, but lengthening their soft segments may provide new mechanical properties and open the door to soft tissue applications.

#### D. Saturated Polyesters and Copolyesters

These thermoplastic polymers have long been used in textiles (Dacron®, Tergal®) and plastic films; polyethylene terephthalate (PET) holds the lion's share of the market:

Poly(cyclohexylenedimethylene terephthalate) (PCT)

Polyethylene terephthalate was first used as a medical elastomer when Du Pont introduced Hytrel® copolymer in 1972. Together with PET, polybutylene terephthalate, which is used in injection molding, polycyclohexylenedimethylene terephthalate, and polyester-glycol copolymers (ethylenes and cyclohexane dimethanols) are excellent elastomers (polyesters and copolyesters) for biomedical applications. They are used as surgical field, bag, flask, bottle, and bandage-backing materials. Polyethylene terephthalate and PBT are especially suitable for making copolymers with polycarbonate, and are also available with fiberglass reinforcements (~30%). Both these polymers, which theoretically can be esterified on their diacid or dialcohol groups, are in practice obtained by transesterification of dimethylterephthalate by ethylene glycol and butylene glycol with the release of methanol:

**BLC: Poly[ $\{\alpha,\omega$ -dihydroxy-(poly(*R*)-3-hydroxybutyrate-co-(*R*)-3-hydroxyvalerate)-block-ethylene glycol)-block-((*S*)-2,6-diisocyanato methyl caproate)-co- $\{\alpha,\omega$ -dihydroxy-(poly( $\epsilon$ -caprolacton)-diethylene glycol-( $\epsilon$ -caprolacton)-block-((*S*)-2,6-diisocyanato methyl caproate))]**

Figure 13.16 Example of a biodegradable polyurethane. (From Ref. 99.)

The reaction is controlled by gradually increasing the temperature until the desired molecular mass is obtained. They are easy and cheap to produce on an industrial scale. They are sensitive to hydrolysis but are chemically resistant to a wide range of chemicals and solvents, are relatively non-toxic, contain no plasticizers, can be easily washed and sterilized (autoclave, gamma radiation), are very rigid, have the lowest coefficient of friction of any thermoplastic, and are very esthetic (smooth surface, very translucent). Thin films are permeable to water vapor and are very flexible and tear resistant (100). When copolymerized with polycarbonate, they are very easily colonized by endothelial cells and may see use as vascular prostheses in the future.

### E. Polyvinyl Chlorides

Polyvinyl chloride (PVC) is a widely used polymer, and PVC products can be produced with a broad range of properties (flexible, rigid, cellular). It has been widely used in the medical field for some 40 years (gloves, tubes, tubing, catheters, bags, etc.) because of its low cost and ease of processing. The structure of PVC:

The high pressure polymerization of vinyl chloride monomer, which is a gas at room temperature and pressure, is activated by the addition of an initiator (peroxide) and controlled using temperature, mixing, and surfactants. The result is a white pulverulent polymer whose structure varies depending on the process (bulk, suspension, or emulsion polymerization). Vinyl chloride monomer lends itself to copolymerization, especially with vinyl chloroacetate (VCA). Copolymers PVC/VCA generally contain 5 to 15% vinyl chloroacetate. They can be processed at lower temperatures and pressures than PVC alone; more filler can be added; and they can be used to produce very transparent products. Polyvinyl chloride is almost never used on its own. Small amounts of specific adjuvants such as heat sta-

bilizers (to protect the resin during processing) and lubricants (to facilitate or make the processing possible) are often added. Fillers, pigments, reinforcing agents, light stabilizers, antioxidants, etc., may also be added. In addition to the adjuvants mentioned above, PVC elastomers also contain plasticizers (5 to 70 parts per 100 parts of resin). Since conventional plasticizers (phthalates) are incompatible with biomedical applications, PVC elastomers intended for biomedical applications are specially designed not to release toxic products (101,102). Phthalate-free PVC elastomers either contain plasticizers that are not released or are nontoxic (azelate, phosphate ester and polyester, citrate) or they are made without plasticizer by combining PVC with other elastomers to produce copolymers (polyurethanes, vinyl chloroacetate) or simple phase mixtures. The elastomer phase plasticizes the rigid PVC (polyadipates, polyesters, polyacrylonitrile-butadiene) (103). The surface properties of PVC elastomers can be altered by plasma treatments and hydrophilic monomer grafts (carboxylation, acrylic and metacrylic acid, vinyl pyrrolidone) (104). Single-use antithrombogenic endovascular materials can be produced by grafting PU/SI copolymers on the surface of PVC tubing.

### F. Polyolefins

Polyolefins are polymers produced by the polymerization of ethylene molecules where the hydrogens are replaced by various hydrocarbon groups. Ethylene ( $\text{CH}_2=\text{CH}_2$ ) can be used to produce polyethylene, polypropylene, etc., by simple substitution of the side group (H,  $\text{CH}_3$ ,  $\text{C}_2\text{H}_5$ ,  $\text{C}_4\text{H}_9$ , etc.):

Polyethylenes are produced by polymerizing gaseous ethylene under different conditions. Polyisobutylenes (PIBs) for example are polymerized in the presence of catalysts. Propylene/ethylene copolymers (often called polypropylene copolymers) are elastomeric in nature and have improved shock resistance properties (block copolymers).

Random copolymers are especially well suited for manufacturing plastic films, hollow objects, plates, etc. Polymethylpentenes (PMPs) are obtained by high pressure polymerization in the presence of a catalyst. They have good water and gas permeability and superior physicochemical properties, making them resistant to autoclaving and inert to most pharmaceuticals. Numerous compounds may be added to facilitate processing. Polymethylpentenes must, however, be washed to eliminate potentially toxic residues. They are used for all sorts of packaging materials as well as for flexible tubing, stoppers, implants, catheters, etc. The excellent resistance to flexural fatigue of polypropylene copolymers makes them more suitable than other elastomers for certain applications (extracorporeal pump diaphragms and synthetic finger joints made of Hexsyn<sup>®</sup>, for example). Grafting various monomers (vinyl pyrrolidone, ethyl methacrylate, acrylamide) on the surfaces of polypropylenes can provide excellent wettability while conserving their superior mechanical performance (105,106). The recent production of polypropylene homopolymers containing alternating isotactic and atactic segments (relative configurations of successive asymmetric elements in the polymer chain) by a new metallocene polymerization process opens the way to new medical applications for polyolefins (1).

### G. Styrene Copolymers

The styrene family contains a wide variety of polymers. Liquid styrene can be polymerized in two ways:

Bulk polymerization—delicate method

Suspension polymerization—fine droplets (0.1 to 10  $\mu\text{m}$ ) of styrene monomer dispersed in an aqueous phase

Styrene can be copolymerized with polybutadiene or ethylene/butylene to produce graft styrene-butadiene-styrene (SBS) and styrene-ethylene/butylene-styrene (SEBS), which are widely used in medical applications. These elastomers not only have improved shock resistance but also do not require additives. They are very flexible and pure and do not release any residues in situ (107). However, they are not very histocompatible and numerous attempts have been made to improve them. Polyhydroxyethylmethacrylate grafts improve blood compatibility; polysiloxane grafts impart the properties of silicone elastomers

(108); while  $\text{N}^+$ ,  $\text{F}^+$ , and  $\text{Ar}^+$  ions improve cell adhesion (109). The SBS and SEBS elastomers can be sterilized by heat, vapor, gamma radiation, or ethylene oxide without losing their physical properties. They are used to manufacture catheters, stoppers, nonrigid containers, surgical fields, condoms, gloves, etc.

### H. Natural Rubbers

Natural rubbers are the most elastic and resistant of all biomedical elastomers, but are also the least hemocompatible due to the release of accelerator (dithiocarbamate) residues (110). Many attempts have been made to improve their blood compatibility. Methylmethacrylate grafts have shown great promise because they make natural rubber more hemocompatible than many silicone elastomers (111). Another approach has been to vulcanize natural rubber by gamma radiation without additives. Natural rubbers polymerized in this way are very pure and demonstrate remarkably good histocompatibility. Untreated natural rubbers are mainly used to manufacture latex gloves, while treated natural rubbers are used to produce catheters and tubing. Latex gloves have been shown to prevent cross-infections (112). The well-balanced physical properties of natural rubbers (elasticity, tear resistance) make them ideal for this use. Hydrosoluble proteins are responsible for allergies associated with latex products. Simple washing is sufficient to completely remove the proteins and eliminate the risk of allergic reactions (113).

### I. Hydrogels

Biomedical uses for hydrogels first appeared over 30 years ago (114,115). A number of polymers can be designed to act as hydrogels and retain water. Polyvinyl alcohol is the most widely used such polymer in ophthalmological applications (1). Polyvinylpyrrolidone is a relatively nontoxic, hydrosoluble polymer that can be impregnated with water or organic solvents once it has been crosslinked (116). It can be grafted on the surfaces of silicone polymers (115) and polyurethanes to improve thromboresistance (117). It is also suitable for use in soft contact lenses (1). Polyurethane hydrogels contain asymmetric hard segments that leave enough space for the absorbed liquids, if hard segment coalescence is avoided. The soft segments are generally longer than those of classic polyurethanes. Translucidity can be improved by using polypropylene glycol instead of polyethylene glycol soft segments. Hydroxyethylmethacrylates are hydrophilic methylmethacrylate copolymers (e.g., Miragel<sup>®</sup>) (115,118–120). Polysiloxane-hydroxyethylmethacrylate copolymers are used in drug delivery systems. In addition to contact lenses and drug delivery systems, hydrogels are very occasionally used in

prosthetic devices. Their low strength means that they are frequently used to give more rigid elastomers (silicone, polyurethane, natural rubber) a thin hydrophilic coating (121).

### J. Polypeptide and Collagen Elastomers

Polypeptide elastomers of varying composition have been synthesized to mimic natural biological elastic polymers with different physical properties and can be designed to be either biostable or biodegradable (1). They contain polypeptides (synthetic and/or natural) copolymerized with artificial polymers. Collagen is the most widely used substance for producing bulk or graft polypeptide elastomers. Elastin is also used to synthesize elastomeric biological tissues for numerous promising biomedical applications (Table 4).

### K. Polyphosphazenes

Polyphosphazenes are polymers that have long flexible chains with alternating phosphorus and nitrogen atoms (1).

Synthesis of poly(dichlorophosphazene) and poly(organo-phosphazenes)

Several hundred different polyphosphazenes have been produced simply by changing the radical on the phosphorus atom. The flexibility of the chain provides good elasticity and superior flexibility. Fluorinated polyphosphazenes are very hydrophobic, which means they are theoretically weakly thrombogenic. Given their mechanical properties, they are used in external devices that come into contact with blood. Their good biocompatibility means that microporous polyphosphazene polymer matrices can be seeded with osteoblasts to serve as bone fillers or to induce bone regeneration. While they are also used to coat metallic vascular stents to improve biocompatibility, they can occasionally provoke strong tissue reactions (122). Certain polyphosphazenes with aminoester acid radicals are biodegradable (123).

### L. Polyamides

Polyamides have an amide ( $-\text{CO}-\text{NH}-$ ) bond that is the result of the condensation of an organic acid group on an amine. They make up a large family of textile fibers and widely used technical polymers. The first polyamide (Nylon 66), which was invented by Carothers, is a member of the group of polymers obtained by reactions between diacids  $[\text{HO}-\text{CO}-(\text{CH}_2)_b-\text{CO}-\text{OH}]$  and diamines  $[\text{NH}_2-(\text{CH}_2)_a-\text{NH}_2]$ . Two other types, derived from polycondensation reactions between neighboring caprolactam and amino acid molecules ( $-\text{CH}_2-\text{COOH} + \text{H}_2\text{N}-\text{CH}$  and  $-\text{CH}_2-\text{CO}-\text{NH}-\text{CH}_2-$  +  $\text{H}_2\text{O}$ ), appeared a little later. Gradual heating to  $250^\circ\text{C}$  results in the elimination of the water and an increase in molecular mass. Diacid-diamine polyamides (e.g., nylon 66) are pro-

duced by isolating and purifying a crystalline intermediate (nylon salt), which then undergoes polycondensation. A wide variety of copolymers can be produced in this way. Polyether block amides (PEBA's) are very large family of copolymers that have alternating sequences of crystalline polyamides and amorphous polyethers. These thermoplastic copolymers are intermediates between plastics and elastomers. Ferruti et al. (124) have produced numerous functional polyethylene glycol and polyamidoamine polymers that are used as grafts on a number of elastomeric biomaterials. Polyamide elastomers are used in a wide variety of applications: sterile packing material, cardiovascular surgery, and perfusion and transfusion materials.

### M. Polyacrylics

Polyacrylics are the result of polymerization of methylmethacrylate:

*Emulsion polymerization* is catalyzed by adding peroxide to an aqueous monomer emulsion. The result is a low molecular weight white powder ready for molding.

*Molding polymerization* involves heating a monomer and catalyst in an oven between two glass plates, which act as the mold. Thermoplastic objects are rarely obtained directly by polymerization. The higher molecular weight (compared to emulsion polymerization) facilitate thermomolding by increasing the temperature range of the rubber platform.

Polymethylmethacrylate

Polymethylmethacrylate (PMMA) is mainly known for its exceptional optical properties. This amorphous polymer is remarkably transparent (92% light transmission). A 3-m thick block of PMMA only absorbs 50% of incident light. This makes it ideal for use in ophthalmological devices (contact lenses, crystalline lenses). It is also very biocompatible (125,126). The addition of plasticizers (phthalates) provides PMMAs with elastomeric properties, enabling them to be used for odontological applications (maxillofacial prostheses, mouthguards) (127). They are also used in combination with other biomedical elastomers (polyurethanes, SEBS, etc.) to produce linear and graft copolymers. They can only be sterilized using ethylene oxide or gamma radiation (128) since they melt at low temperatures (80 to 100°C).

### N. Fluorinated Elastomers

Fluorinated elastomers are a group of technical polymers with exceptional properties. Replacing the hydrogen with fluorine greatly improves heat and chemical resistance. Industrial fluorinated monomers are gases that liquefy at very low temperatures. They are polymerized at very high pressures using radical catalysts, generally by suspension or

**Table 13.6** Typical Research Concerning Small Diameter (<6 mm i.d.) Vascular Grafts

Material	Important design feature
1a. Polyetherurethane	Tube walls are porous and microfibrinous three-dimensional mesh composed of polyurethane fibers of 1 $\mu\text{m}$ diameter. Penetration depth of living tissue cell is limited to about 20–30 $\mu\text{m}$ .
1b. Polyetherurethane	Graft with pore size 30–100 $\mu\text{m}$ .
1c. Polyetherurethane	Grafted with albumin and adenosine-cyclic monophosphate. Surface has better blood compatibility. Modified the surface further with urokinase.
1d. Polyetherurethane	Microporous graft prepared by an excimer laser ablation technique. The pore size (100 $\mu\text{m}$ ) and the pore-to-pore distance (200 $\mu\text{m}$ ) are constant.
1e. Polyetherurethane	Made by a filament-winding technique comprising Lycra™ elastomeric fibers embedded in an elastomeric matrix of Pellethane™.
2a. Polyetherurethane urea	It is of sufficient porosity to permit tissue ingrowth. Its stress–strain curve is similar to that of the thoracic aorta.
2b. Polyetherurethane urea/silicones	Microporous replamine form graft (20–30 $\mu\text{m}$ pore size) composed of silicones was coated with commercial Biomer™.
2c. Polyetherurethane urea	Fibrillar microporous hydrophobic graft made from commercial Mitrathane™.
3a. Degradable, aliphatic polyesterurethane	It has well-defined chemical and physical properties and controlled rates of degradation. It induces the growth of functional neoartery, which has a cellular structure similar to that of the native artery.
3b. Polyesterurethane (Vascugraft™)	Made from commercial polyesterurethane free from migrating additives such as catalysts and stabilizers. Microfibrinous, open pore structure.
4. Expanded Teflon-coated with silicones	Platelet accumulation was reduced by coating the graft surfaces with a smooth layer of silicones.
5a. Polyurethane/poly(L-lactide)	Microporous, compliant, and biodegradable. Function as a temporary scaffold for the generation of small-caliber arteries.
5b. Polyurethane/poly(L-lactide)	Microporous and biodegradable graft consisted of two layers: the inner layer made from aliphatic polyetherurethane, the outer ply constructed by precipitating a physical mixture of polyesterurethane and poly(L-lactide).
5c. Polyurethane/poly(HEMA-block-styrene)	Polyurethane modified by coating with poly (HEMA-block-styrene) from solution.
5d. Polyurethane/endothelial cell	The hybrid artificial graft made of an endothelialized microporous polyurethane.
5e. Poly(carbonate urethane)/pentapeptide	Glycine or fibronectin are covalently bound to polyurethane surface by succinyl dichloride coupling.
5f. Biodurable poly(carbonate urethane) (ChronoFlex™)	Microporous grafts with excellent physical and mechanical characteristics. Self-sealing and maintenance of compliance.
6. Copolymers of MPC	Copolymers of 2-methacryloyloxyethyl phosphorylcholine (MPC) with hydrophobic alkyl methacrylates.
7. Polyester/human vein	Vascular graft made of human vein and a highly porous polyester fabric vascular prosthesis.

aqueous emulsion polymerization in order to control the strong exothermic reaction:

The very strong electronegativity of the PTFE fluoride ions protects the carbon chain and gives these elastomers their extreme chemical stability. They are inert and insoluble (6,129). They are naphthalene-plasticized resins and are extruded and made microporous for vascular graft prostheses (Teflon®, Impra®, Goretex®) (130,131). Their vascular biocompatibility is adequate but less than that of polyurethanes (132). They are used in orthopedic surgery to reduce friction between metallic and/or composite joint prostheses (133) both alone and in combination with polyurethanes.

## O. Elastomeric Medical Devices

See Tables 5–10 and Fig. 17 for information on the use of elastomers in medical device applications.

## II. BIOCOMPATIBILITY EVALUATION OF ELASTOMERS

### A. Introduction

Most medical devices use synthetic biomaterials as their principal component. A biomaterial is a nondrug substance for inclusion in a physiological system that augments or replaces the functions of a bodily tissue or organ. Elastomers, like others biomaterials, must be compatible and inert, must interact with the assorted tissues and organs in a nontoxic manner, and must not destroy the cellular constit-

**Table 13.8** Implant Applications for Medical Grade Silicone Elastomers

Treatment	Application
Plastic and reconstructive surgery	Reconstruction of nose, chin, ear armature, etc.
	Breast reconstruction
Ophthalmology	Correction of detached retina
	Prosthetic eye

**Table 13.10** Typical Materials for Contact Lenses

Classification	Polymer and characteristics
Hydrogel soft lenses	Poly(hydroxyethyl methacrylate) (PHEMA). Generally crosslinked with ethylene glycol dimethacrylate, at a level of 26–42%, sufficient to give water content in equilibrium. It may be copolymerized with other hydrophilic monomers, such as N-vinyl pyrrolidone, acrylamide, and methacrylic acid.
Elastic soft lenses	Polydimethylsiloxane and its copolymers. They have good flexibility and very high oxygen permeability, but strong hydrophobicity results in considerable discomfort for the patient. Surface treatment may improve wettability. Perfluoropolyethers and its copolymers have attractive combinations of flexibility and gas permeability.
Rigid lenses	Poly(methyl methacrylate) (PMMA) has good properties: very clear optically, good biocompatibility, and good handling characteristics. The main problem relates to poor oxygen permeability. There have been attempts to introduce arrays of very small holes (15 μm) to facilitate oxygen transport.
Gas-permeable rigid lenses	Cellulose acetate butyrate and others. The butyrate is a highly oxygen-permeable and relatively rigid material. The copolymerization of siloxany alkyl methacrylates of fluorosilicone methacrylates with methyl methacrylate provides a rigid methacrylate backbone with rubbery, highly permeable alkylsiloxane side groups.

Source: Ref. 1.

uents of the body fluid with which they interface (134). A battle takes place between the organism and the implanted elastomer. Possible outcomes include acceptance, slow digestion of the implant, or rapid ejection accompanied by undesired secondary effects (135). Medical devices must thus be designed to prevent rejection. This has led to the development of a new class of materials called biomaterials, which includes elastomers used in the medical field. The ability of biomaterials to fulfill their role in medical devices depends on their degree of biofunctionality and biocompatibility.

It is hard to talk about the biocompatibility of elastomers since they are only in contact with physiological systems in the form of medical devices. In addition, the bio-

**Figure 13.17** Medical device in the human body. (From Ref. 1.)

compatibility of elastomers depends on the type of device and its function. Theoretically, an evaluation of the biocompatibility of an elastomer would include

- The behavior of the host tissue and the host itself in the presence of the biomaterial
- The behavior over time of the biomaterial in the host environment

However, in practice, in vivo studies of all these parameters are difficult if not impossible to conduct, which is why the evaluation of biocompatibility begins with in vitro testing. Briefly, biomaterials have evolved through three generations:

1. Technical performance (necytotoxic = tolerance)
2. Biological performance (cytocompatibility)
3. Biological performance (biofunctionality)

Four trends currently dominate the evolution of biomaterials:

Providing materials with a surface that mimics the biological properties necessary for the intended application. This requires fundamental knowledge of cellular reactions at the material–tissue interface.

Taking implantation in young subjects into account, which implies long-term use and the need for immunological, mutagenic, and carcinogenic evaluations. Decreasing animal testing, which requires the development of alternative methods.

Setting up marketing regulations, which includes the development of standard tests.

Elastomers are very important in the manufacture of medical devices that may come into contact with host tissues for varying periods of time. Exposure times have been arbitrarily divided into three categories: limited exposure (<24 h), prolonged exposure (24 h to 30 days), and permanent exposure (>30 days). The tests used to evaluate biocompatibility depend on exposure time. It is thus easy to understand why elastomers used to make implants have to meet stricter standards than those used for dental impressions. This classification system is only a guide; since elastomers may be used for short, but repeated periods, biocompatibility testing must be based on the maximum exposure time. It must also take into account how the material will be used and the type of contact. Differing standards apply to medical devices that are

- In contact with surfaces like the skin or mucous membranes other than the skin
- In direct or indirect contact with other tissues, including blood
- Implantable devices

## B. Testing

### 1. Cytotoxicity

In vitro cytotoxicity testing evaluates lysis, growth inhibition, and other impacts on cells by medical devices, component materials, and leachates using morphological, biochemical, and metabolic criteria. These techniques have well-defined standards for material preparation, sterilization, cell lines, and the type of testing required. Whatever methods are used, controls must be included.

#### a. Material Preparation

The shape of the material used for biocompatibility testing varies greatly from author to author. Generally speaking, however, elastomers are tested as discs of the size of multiwell plates used for cell cultures. Menconi et al. (136) used 10-cm<sup>2</sup> discs. Saad et al. (99) used 14-mm diameter

100- $\mu$ m thick discs to evaluate polyesterurethanes. Other techniques involve producing 10-cm<sup>3</sup> blocks, which are then cut into 300- $\mu$ m thick slices using a microtome (98). Special attention must be paid to the cut surface, which must not only be identical in test products and controls, but must also resemble the surface of the finished product. It is often preferable in the industrial research phase to test materials that correspond as closely as possible to the finished product. On the other hand, in the development and marketing phases, evaluations can be performed on randomly selected elastomeric “parts” to avoid testing bias.

Many studies have been conducted on the cytotoxicity of finished elastomeric products. Extracts are prepared on the basis of recommended normative standards. A range of extraction protocols are available: dynamic extraction, static extraction, and heat extraction.

The chemical substances extracted from elastomeric articles are usually residues from accelerators (e.g., mercaptobenzthiazole, tetramethylthiurim disulfite), activators (e.g., zinc oxide), inert filler materials (e.g., wax), plasticizers (e.g., oil), lubricants (e.g., stearic acid), and vulcanization products (e.g., zinc stearates and dithiocarbonate zinc salts). In order to minimize the amount of residue extracted from elastomeric items, the items must be either cleaned or coated, or both. Polyurethanes (PUR) and silicones are the elastomers from which the smallest amount of material is extracted (137).

#### b. Sterilization

The sterilization protocols for the various items used for cell cultures vary depending on the elastomer being evaluated. Most authors report using ethylene oxide (500–540 mg/L EO in 80% CO<sub>2</sub> at a relative humidity of over 35% for 3 h at 35–41 °C). Others have used gamma radiation (2.5 Mrad for 5 h) (86,98), dry heat or autoclaving (138), antiseptic solutions (136,139), antibiotics occasionally combined with UV radiation for 48 h (136), and immersion in 70% ethanol for 30 min followed by immersion in phosphate-buffered saline containing antibiotics (140). Albanese et al. (76) tested three different sterilization methods (gamma radiation, ethylene oxide, and formaldehyde) to evaluate the effect on the cytotoxic potential of PUPA both in native and heparinized form. PUPA and heparinized PUPA sterilized by gamma radiation are no more cytotoxic than materials sterilized by ethylene oxide or formaldehyde. Ethylene oxide gas is widely used for sterilizing elastomers since it can be employed at low temperatures with short exposure times. The exposure is followed by a degassing period, usually 10 h in a 55°C air chamber. Most elastomers are able to survive these conditions with minimal property loss. In recent years, sterilization by exposure

to gamma irradiation has increased in popularity with device manufacturers because it does not produce toxic residues. All polymers are affected to some degree by irradiation, with crosslinking and molecular scission reported (141). Bouet et al. (142) compared the effect of sterilization on the cytotoxicity of PUR and various latexes and showed that while some differences may show up *in vivo*, no differences could be detected *in vitro*. While there have been reports that sterilization of polymers influences their performance in cell cultures, certain authors do not mention the sterilization method used. There is an international standard for the management of residues following sterilization by ethylene oxide, glutaraldehyde, and formaldehyde (ISO 10993—Parts 7 and 17 (143,144)), but there are no standards regulating sterilization procedures *per se*.

### c. Cell Lines

Fibroblast cell lines (3T3, L929) are frequently used in cytotoxicity tests (76,86,99,145,146). Tests based on the medical end uses of materials are conducted with cell lines that are as similar as possible to the cells or tissues that will be in contact with the elastomers *in vivo*. For example, MC.3T3.E1 osteoblast cell lines (98) and J774 macrophages (98) are used for testing materials that will be in contact with bone, and SV-HUC1 cells for materials that will be in contact with the urinary tract (147).

Primary cultures are more suitable for cytotoxicity testing. Bone cells from rat tibias (98), endothelial cells from cow thoracic aortas (136), and endothelial cells from microvessels in the abdominal fat of various animals (148), as well as human primary cultures of scaphoid bone cells (149), urothelial, ureter, and bladder cells (147), and vascular smooth muscle cells strained by inborn aortic coarctation surgery (109) have been successfully used to evaluate the toxicity of elastomers. While primary cultures, especially those derived from human tissues, provide superior biocompatibility testing results (137) because they are only one step removed from *in vivo* conditions, they do not allow interlaboratory comparisons to be made. Ideally, researchers should include both an established reference line and a primary culture in their studies, as was the case with Pariente et al. (147).

Certain authors have reported using organotypic cornea and skin models (23,150) to evaluate polyoxyethylene films. Others have used the culture supernatants of monocytes activated by biomedical polymers to evaluate cytotoxicity using fibroblast cultures.

### d. Tests

The crystal violet, neutral red, or trypan blue cell viability screening tool developed over 30 years ago for evaluating the toxicity of plastics is the most commonly used test

(151). Whatever the cell type, two methods are used: direct tests, where the cells are placed in direct contact with the material, and indirect tests, where samples are extracted in the medium used to culture the cells and the extract is then placed in contact with prepared cell culture either by diffusion across a membrane or an agar overlay (141,152). While the incubation period can vary from 24 h to 6 days, depending on the protocol, it also depends on the type of cells used. Generally speaking, the incubation period can be longer for established cell lines than for primary cultures. A tetrazolium-based colorimetric assay (MTT) is often used to evaluate polymer cytotoxicity, or more precisely the metabolic activity of cells in contact with the material. This assay has largely replaced those using  $^3\text{H}$ -thymidine (153) and other isotopes. The MTT assay is simple, reproducible, and does not use radioisotopes. Tests can be carried out using a fully automated microtiter plate system, making it possible to economically test polymers of limited availability (154). It has also been used to evaluate polyurethanes (98), polyesterurethanes (99), elastomers (127), and urinary stents (147).

In addition to cell viability and metabolic activity assays, cell morphology is also verified to complete the first-phase screening of elastomers. The impact on cell morphology is generally determined by scanning electron microscopy, which is a relatively limited technique because it relies on obtaining images of cell adherence to the material and intracellular organization (79,136,155). In most studies, samples are dehydrated by critical point drying and then metalized with colloidal gold. Controls involve elastomers that have not been in contact with the cells. While cell viability and morphology tests provide a first screening for cytotoxicity, many researchers have been working to examine the biofunctionality of cells in contact with elastomers and elastomer extracts. Various tests have been used, including protein synthesis and mRNA expression. Such tests obviously depend on the end use of the elastomer.

The very concept of biocompatibility is based on the interaction between a material and a biological environment, most often expressed as an inflammatory response. When an elastomer is implanted, the tissues provoke an inflammatory response, which initiates the process of tissue repair and regeneration. Several cell types are involved in tissue repair, including fibroblasts, macrophages, PMNs, and endothelial cells. Certain authors (99) have reported a more complex response to elastomers involving lymphoid and myeloid cells. Activated macrophages produce cytokines such as interleukin 1 (IL-1), interleukin 6 (IL-6), interleukin 10 (IL-10), and tumor necrosis factor  $\alpha$  (TNF $\alpha$ ), which are involved in regulating the inflammatory and repair processes. In addition to cytokines, activated macrophages also produce nitric oxides (NO). Macrophages are

also involved in the biodegradation of foreign materials (156).

The size, surface morphology, wettability, physicochemical properties, and degradation of elastomers are key factors in the intensity and duration of the inflammatory response and repair process. Various *in vitro* tests have been developed to evaluate the inflammatory response and repair phases. The most frequently reported tests in the literature on the biocompatibility of polyurethanes are measurements of amounts of NO and TNF $\alpha$ , substances produced when macrophages and osteoblasts interact with polyesterurethanes (98,99), various types of fibronectin and collagen (24,98,99), and protein adsorption. Most of these tests are conducted by ELISA.

Osteoblast cultures are used to evaluate bone tissue biocompatibility. Alkaline phosphatase activity and vitamin D3 stimulation responses can be measured. Osteocalcin levels can be evaluated by RIA or immunofluorescence (98) and mineralization by SEM or Von Kossa staining for calcium (98,149). These assays can also be combined with more advanced, specific fluorescence techniques using devices with very low detection thresholds. Patel et al. (145) have proposed using fluorescence probe response (FPR) to evaluate biocompatibility. This technique can be used to discriminate between functional and dead cells, and is essentially based on differences in cytoplasmic membrane permeability (145,157). While these tests are commercially available (Molecular Probe, among others), they are yet not cited in the literature as reference techniques. Kirkpatrick and Mittermayer (141) published an article on the scope and limitations of *in vitro* systems and proposed some guiding principles for the *in vitro* evaluation of biocompatibility, including the use of relevant cells types and biological parameters, and stressed the need to use dynamic conditions.

Techniques based on molecular approaches are being developed to characterize the interactions between cells, biological fluids, and biomaterials. These mRNA-based techniques analyze cell functions, especially the ability to synthesize an extracellular matrix. Very detailed protocols have been published, especially that of Menconi et al. (136). Most of these techniques have become more accessible with the arrival of commercially available molecular biology kits.

#### e. Controls

The tests cannot be valid or objective unless internal controls are included. Tissue culture plastic is a commonly used negative control, although silicone rubber has also been used (158). Asbestos, phenol, and latex, which cause major disruptions to metabolic activity, are often used as

positive or cytotoxic controls (147,155). It should be noted that latex has been used as both a negative and positive control. Its cytotoxicity arises from the presence of accelerators and oxidants used during the vulcanization process (137). As indicated by Park and Park (21), in the absence of clear criteria for evaluating biocompatibility, many materials were mistakenly thought to be biocompatible and were used as controls. Silicone rubber is a case in point. For a long time, silicone rubber was believed to be totally biocompatible. It is clearly necessary to reevaluate the biocompatibility of existing biomaterials and *a fortiori* the negative controls. Positive controls are not reported in many studies, which undermines the validity of the results and proposed evaluation technique.

## 2. Sensitization Assays of Irritation or Intercutaneous Reactivity from Implantation

Even today, there are no totally satisfactory *in vitro* elastomer evaluation systems. While such assays provide a first screening, *in vivo* testing on animals is required before implanting, injecting, or using elastomers in humans. A nonexhaustive search of the literature between 1990 and 1999 reveals that too many animals have been sacrificed just to study the implantation response of elastomers. It is vitally important that researchers meticulously plan their studies to extract the maximum amount of information from each animal.

### a. Material Preparation

For solid implants, the physical properties (shape, hardness, surface finish) must be identical for each implant, except if one of the parameters is being singled out for study. The chemical and morphological aspects of elastomeric surfaces must be controlled (159). All contaminants must be removed from the implants, which must then be sterilized using the method that will be applied to the finished device. Tests on nonsolid materials such as powders, liquids, and particles (including mixtures) can be conducted in PTFE tubes. However, Williams (160) disputes the suitability of PTFE as a negative control, especially as regards surface properties. Control tubes must have the same physical properties as test tubes.

### b. Animals

The choice of animal depends on the size of the implant, the test period, and known differences in biological responses of soft and hard tissues. Rats are the animal of choice for many studies. Implants are placed bilaterally in the back muscles. Two animals per material per implant period are used with a minimum of two implants per ani-

mal (101,102,130,139,161–163). When rabbits are used, 8 to 10 implants are placed in the back muscles (81,164). Dogs are used to study new materials for vasectomies and arteriovenous fistulas (95,121). Dogs are also used to test materials for temporary replacement organs. The number of animals used varies greatly depending on the type of research and the complexity of the procedure. Because of the differences, few studies can be compared.

#### *c. Implantation Period*

The implantation period varies greatly depending on the animals used and the material being evaluated. In the few chronic inflammation studies that have been reported, positive controls that could lead to a major inflammatory response within a 12-week period are missing. Generally speaking, observations are made over a 30-day (102) or 12-week (121,130,139) period. The implantation period must be chosen to obtain a stable biological reaction, which depends on the nature and properties of the material and the damage caused by the surgery.

#### *d. Evaluation of Biological Reactivity*

Evaluation of biological reactivity begins with an analysis of the state of health of the animal (vigilance, nutrition, coat, weight, temperature, etc.). The macroscopic and histopathological reactions are evaluated over time. The histopathological examination includes the degree of inflammation, the number and type of inflammatory cells (leukocytes, PMNs, lymphocytes, plasmocytes, macrophages, polynuclear cells, etc.), necrosis, and the presence of material debris, granuloma, fat, and calcified tissue.

#### *e. Irritation and Sensitization Assays*

Irritation is a nonimmunological inflammatory reaction. Sensitization assays (contact allergies) and delayed hypersensitivity reactions involve the immune system. These assays are vital to understanding acute toxicity. Rabbits are often used for skin irritation assays with observations at 1, 24, 48, and 72 h. The test period may be prolonged in the event of persistent lesions to determine whether the lesions are reversible or permanent, but must in no case exceed 14 days. Less than 0.2 mL of extract is injected intradermally. Irritation is scored based on the level of edema and erythema. Generally speaking, ten injections are made on the anterior and posterior portions of the trunk (including controls). Ocular and oral mucosal assays may also be conducted. To evaluate immune responses, tests developed for other purposes such as research on autoimmune disease animal models and conjunctive tissue pathologies are used. These tests are based on delayed hypersen-

sitivity reactions induced by a given autoantibody (thyroglobulin), anticollagen (165), etc. In the research reported by Naim et al. (165), silicone gels were tested for toxicology, antigenic, and adjuvancy properties. According to Brautbar et al. (166), more rigorous *in vivo* animal testing is required before concluding there is a relationship between silicone breast implants and autoimmune disorders.

#### *f. Implantation*

All elastomers act as foreign bodies when they are implanted, leading to an acute inflammatory response and the accumulation of phagocytes. Elastomers are relatively inert, unreactive, and nontoxic. It is thus difficult to understand how they are detected by the immune system and how they provoke an inflammatory response. However, considering the mechanisms involved in such responses, a good starting point would be the initial interaction between the biomaterial and proteins in the surrounding host tissue. Immediately after implantation, hydrophobic polymers like polyurethanes, polyethylenes, polydimethylsiloxanes, and dacron become coated with host protein. Plasma and interstitial fluid proteins rapidly colonize the implant, binding together to form a disorganized matrix on the implant surface (167). The behavior is probably the result of a progressive denaturing of the proteins. After several hours, the proteins adsorbed to most biomaterials cannot be removed, even with powerful detergents. Implants are thus spontaneously coated with a random layer of partially or totally denatured proteins. Since proteins rapidly adsorb to the surface of the biomaterial, host inflammatory cells and fibroblasts cannot come into direct contact with the implant. This protein coat determines future cell reactions to the implant and it is undoubtedly this initial phase that is key in determining biocompatibility. Albumin, immunoglobulin G, and fibrinogen are the most important proteins coating the surfaces of implants. Conventional histological techniques involving hematoxylin, eosin, Von Gieson, and Schiff periodic acid stains are often used to study the inflammatory response. The inflammatory cells, which include macrophages, PMNs, and lymphocytes, are identified based on morphological criteria. The distribution of these cells around the implant provides a qualitative description of the response. A more quantitative evaluation is provided by making cell counts based on morphological criteria and scoring the response, generally on a scale of 1 to 5. This evaluation method depends on subjective evaluations by the operator, which can lead to cell typing and counting errors. A number of assays using computer assisted image analysis have been developed (163,168,169). Discriminating between different cell types has also

greatly evolved with the arrival of specific monoclonal antibodies. Specific enzymatic assays and signal amplification kits (avidin, biotin, etc.) have considerably enhanced the ability to gauge implant inflammatory responses (163). These techniques have been used to evaluate numerous elastomers (81,95,121,130,139,161,162,168,169) using more or less complete cell screening panels. In addition to these histochemical staining, immunocytochemical, and counting techniques, certain authors have published *in situ* hybridization techniques to evaluate inflammatory protein production (TNF $\alpha$ ) and detect the expression of TNF $\alpha$  mRNA (139). These techniques give a clear picture of the intensity of the inflammatory response. The reaction of TNF $\alpha$  and other growth factors or enzymes must reflect a balance between the tendency to promote biocompatibility and the tendency to cause inflammatory damage and implant rejection (139,170).

A number of researchers have analyzed the quality and quantity of the inflammatory exudate using the *in vivo* cage implant system originally developed by Marchant et al. (171). The exudate is removed before the animal is sacrificed and is analyzed using a hemocytometer. Different stains are used to discriminate between the various cells, including Wright staining and nonspecific esterase staining (66,101,161,162). A number of biochemical tests (protein analyses, albumin concentration, extracellular enzymes) are also possible (164). The exudate may also be analyzed by cytofluorometry for quantitative results (102,130). Flow cytometry appears to be particularly well suited for studying exudate cell composition. The literature on exudate cell responses is relatively meager compared to that on tissue reactions. To our knowledge, there have been no reports correlating tissue inflammation (as measured by histomorphometric image analysis) and cellular response (as measured by flow cytometry). The analysis of the inflammatory responses that occur during biocompatibility testing are now commonplace. All materials provoke a more or less intense response, and understanding the mechanisms at play in the initial colonization phase of the implanted material helps reduce the inflammatory response. McNally and Anderson (172) made a first step toward this understanding by demonstrating the participation of the C3 complement fraction in the adherence of monocytes to fluorinated, nitrogenated, and oxygenated surfaces.

### 3. Hemocompatibility and Blood Interaction Assays

#### a. General

Only materials in prolonged or permanent contact with blood pathways must be subjected to this type of testing, which can be divided into five categories depending on the primary process (thrombus, coagulation, platelet aggrega-

tion) or biological system (blood, immune) involved. Various standards determine which tests will be used to evaluate hemocompatibility depending on the type of device:

Devices whose surfaces are not in direct contact with the blood

Devices whose surfaces are in direct contact with the blood

Implantable devices

In certain cases, it is difficult to determine whether biocompatibility and/or hemocompatibility tests should be performed. In general, experience has shown that materials that are hemocompatible will also be biocompatible. However, not all biocompatible materials are also hemocompatible. The situation is even more complex because there has been a tendency to designate materials as being biocompatible on the basis of toxicological tests, while others have been designated as being hemocompatible on the basis of a single whole blood clotting test (173).

#### b. Tests

A given material may be adequate for one type of application but not for others. Differences between arterial and venous blood, varying blood flow patterns, and the design and mechanical operation of a medical device are among the parameters that influence the performance of materials when they are in contact with blood. Most biomaterial researchers would like to be able to predict biological performance using simplified methodologies. However, no single procedure is adequate for this purpose. Tests that merely measure the amount of thrombus give only the final result of the blood coagulation sequence without any insight into the initial events. A recently developed rheology-based test (71) now allows the sequence of events to be measured over time. ISO 10993 guidelines for the biological evaluation for implantable medical devices (174) list a number of recommended *in vitro* and *in vivo* tests that can be used to study hemocompatibility. The ISO guidelines recommend the hemolysis test as the standard screening method. However, hemolysis is mainly the result of mechanical blood cell trauma from high flow conditions that cause local turbulence and rupture of erythrocytes (175). Axisymmetric drop shape analysis—profile (ADSA-P), as described by Rakhorst et al. (175), is of special interest, especially for studying plasma protein–material interactions and is destined to become a standard test.

Many researchers use the acute *ex vivo* canine femoral arteriovenous series shunt technique, which allows the testing of a number of materials under similar physiological and hematological conditions for *in vivo* hemocompatibility studies (71,88,146,176,177). High levels of platelet and fibrinogen deposition are generally associated with a

more thrombogenic polymeric surface. The morphology of the adherent platelets examined by SEM also provides interesting information. A measure of thrombogenicity is the tendency of a surface to cause adherent platelets to change shape and activate.

Hemocompatibility tests include evaluations of platelet adhesion, aggregation, activation, and release reactions under dynamic blood flow conditions together with measurements of protein adsorption and coagulation factor activation. The adhesion of human blood platelets to vascular catheters has been studied using a perfusion chamber. Polyurethane catheters were exposed to extracted human blood for different periods (up to 20 min) and at different wall shear rates ( $190\text{--}330\text{ s}^{-1}$ ), and the rate of adhesion was determined using In-labelled platelets by electron spectroscopy for chemical analysis (ESCA) (178). The most common test for evaluating platelet adhesion uses fresh blood from healthy donors. The platelets are isolated and a standard microscopic analysis is performed (96,146). Platelet counts can also be determined using the petri disc model with flat sheet membranes. Complement activation and release reactions have also been explored. To evaluate the extent of *in vitro* complement activation by elastomers, the concentration of C3a des Arg was measured according to the method of Wagner and Hugli (179) using radioimmunoassay kits available from a number of manufacturers (103).

Tests evaluating contact activation, the intrinsic coagulation system, the Hageman factor (f XII) and dependent kinin formation and fibrinolysis pathways have been developed. A quantitative measurement of the activation of the contact system is required in studies examining the effect of artificial surfaces on blood. Van der Kamp and Van Oeveren (180) proposed analyzing these cascades by using the kallikrein inhibitor aprotinine to calculate the activity of factor f XII and kallikrein.

One approach to improving the hemocompatibility of biomaterials has been to immobilize anticoagulants like heparin at the interface (76). Most such attempts have used one of the following strategies set out by Dumitriu (135):

- Ionic binding of heparin to the material surface
- Covalent attachment of heparin to or in the material
- Chemical modification of the material surface to confer heparinoid properties

Tests including clotting assays (TT, reptilase time, and anti-XA activity), coagulation time, platelet counts, and resonance thrombography (RTG) have been used (76).

#### 4. Biodegradation Assays

These assays are used to evaluate both biodegradation and biostability. Degradation products are generated by the de-

composition or chemical degradation of a material. Biodegradation is the degradation of a biological material involving a loss of integrity and/or performance during exposure to a physiological or simulated environment. Elastomer degradation is studied using toxicokinetic modeling. Many types of surgically implantable devices and drug delivery systems that only function for a relatively short time *in vivo* can be made from polymers that are eliminated from the body by hydrolytic degradation and subsequent metabolism after serving their intended purpose. Biomaterials made of biodegradable polymers are designed to degrade *in vivo* in a controlled manner over a predetermined period. The main *in vivo* degradation mechanism of polymers is hydrolytic degradation in which enzymes may play a role. *In vivo* cell culture and animal models may also be used (181,182).

So-called nonbiodegradable biomaterials may be slowly degraded over time by the organism. One example is the failure of PU medical devices like pacemaker leads, which are manufactured from poly(ether) polymers. Failure of PU consistently occurs 5 to 10 years after implantation. The mechanism of this process is still not well understood. Although *in vitro* studies have been performed with single enzyme systems, which showed release of products, the *in vivo* situation involves complex biosystems that act synergistically (43). Other assays using sophisticated technology such as attenuated total reflection-Fourier transform infrared spectroscopy (ATR-FTIR) (66), transmission Fourier transform infrared analysis (T-FTIR), and SEM (91) have also been developed. Using these techniques to evaluate inflammatory responses can throw light on the entire degradation process of a biomaterial.

Some research has been published reporting the use of autoradiographic techniques following the injection of animals with tritiated thymidine. This allows cell proliferation around the biomaterial (macrophages, foreign body giant cells, fibroblasts, bone cells) to be measured over time (172). Labow et al. (183) have studied on the effect of phospholipids on the biodegradation of polyurethanes by lysosomal enzymes. Labow et al. (183) have also studied the effect of enzymes like CE (cholesterol esterase) phospholipase A2 on biomaterial surfaces *in vitro*.

#### 5. Reproduction and Embryo Development Assays

It is not known whether implant materials can have an impact on reproduction and embryo development. The few tests that have been conducted in this area involve the functional testing of biomaterials used for preparing sperm prior to artificial insemination, *in vitro* fertilization procedures, and embryo transfers (184). These assays can be conducted *in vitro* (e.g., spermatozoid cultures) or *in vivo* (e.g., sperm penetration tests using hamster ova and mouse

embryo compatibility studies) (185). To our knowledge, no standards have been established for these assays.

## 6. Genotoxicity

ISO 10993 is a set of criteria based on the intended use of a product or device and establishes testing guidelines depending on the implantation period and the nature of the contact with the biomaterial. The criteria stipulate that any material or implantable device placed in contact with mucosal, bone, or oral tissue, when the contact exceeds 30 days, must be subjected to genotoxicity testing prior to commercialization. The tests are intended to detect genetic anomalies (mutations, chromosomal alterations) in cells (prokaryote, yeast, mammalian) placed in contact with the material. A review of the literature has revealed that four main techniques are used to evaluate genotoxicity: the sister chromatid exchange method, the micronucleus test, the Ames test, and the chromosomal aberration test (186,187). A study conducted in 1995 by Purves et al. (188) showed that the pharmaceutical industry uses this wide range of genotoxicity tests and protocols. New genotoxicity tests have been reported (189). However, few studies on elastomers have reported using eukaryotic cells to detect DNA damage. Further work in this area is thus required. Our team is currently investigating an in vitro test.

## 7. Biocompatibility Testing in Humans

Clinical tests are better indicators of biocompatibility and also help improve biomaterials. While implantable devices are supposed to be biocompatible based on in vitro testing, in vivo clinical testing is the only way to be sure. Human tests are conducted using ethical research practices. These tests can be included in randomized clinical research protocols (126,190) and in medium- to long-term epidemiological studies (133,191,192).

## 8. Biocompatibility Testing— Microbial Colonization

As for assays in the area of reproduction and embryo development, there are no bacteriological standards or compulsory tests. Elastomers used in implantable medical devices are by definition sterile. Nevertheless, certain authors have included microbial (including yeast) adherence and colonization in their battery of tests (13,14,193). Such testing is recommended for certain elastomers for which implantation failure may be caused by bacterial infections (194–196). The plasma proteins deposited on implant surfaces may mediate bacterial adherence, especially that of *Staphylococcus aureus*, a pathogen associated with recur-

rent infections. Bacterial adherence testing is conducted in radial flow chambers mounted on the motorized stage of a video microscopy system. Image processing software is used to perform automated data collection and image analysis (73). A simpler technique for quantifying adherence involves submerging the material in a bacterial suspension of known concentration. After 24 h, the material is rinsed until the rinsing liquid is sterile. The material is then placed in a culture medium (86). The agar disk diffusion test may also be used, notably for biomaterial extracts (82). Bacteria-induced infections in the presence of polymers have been studied in animals (168,169). It would be of interest to determine how bacteria adhere to polymer substrates and, in certain cases, to evaluate the efficacy of antibiotic treatments. A better understanding of bacterial genomes should also lead to a better understanding of virulence factors produced by bacteria. These virulence factors may vary depending on the biomaterial as suggested by changes in bacterial phenotypes (unpublished data).

## III. BIOCOMPATIBILITY OF DIFFERENT CLASSES OF ELASTOMERS

### A. Elastomers in General

Biomaterials are materials designed for use with living tissues and/or biological fluids in order to evaluate, treat, modify, or replace a tissue, organ, or bodily function (25). For materials to be biocompatible, they must not provoke allergic, inflammatory, or immunological reactions; they must be nonthrombogenic, nontoxic, and noncarcinogenic; and they must not damage surrounding tissues, plasma proteins, or enzymes (25,181). However, in most cases, it is not a lack of response that is important but rather an appropriate host response to the specific application for which the biomaterial was designed. Biocompatibility is thus defined by the response of the biological system to the biomaterial, which is seen as a foreign body and which provokes a cascade of interrelated reactions both systematically as well as locally at the interface with the biomaterial (181). Host responses to biomaterials can be divided into two categories: (1) acute, compulsory events or local reactions and (2) delayed, secondary responses or general reactions (Fig. 18). All implanted materials adsorb proteins and other macromolecules, which in turn mediate biological activities from cell attachment to inflammation to other physiopathological processes (13).

These interactions are influenced by the nature and use of the material as well as implantation site and duration (91,99). Biomaterials may thus lead to numerous undesirable side effects (inflammation, thrombosis, tissue necrosis, carcinogenesis, etc.). These undesirable side effects are

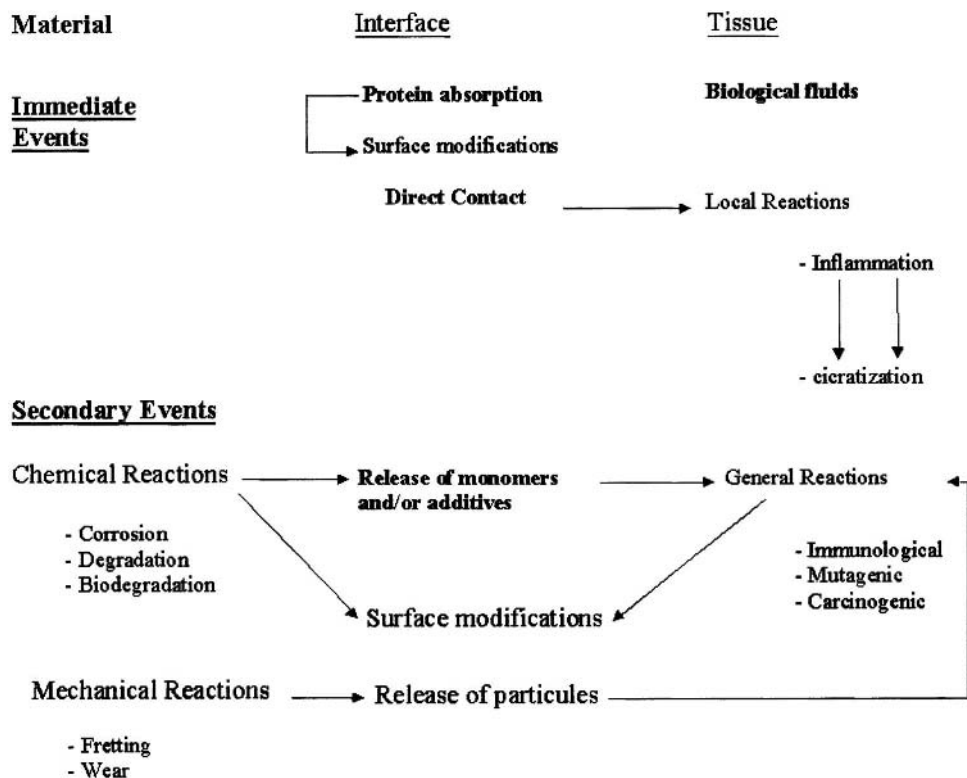

Figure 13.18 Interactions of biomaterial and tissue.

especially exacerbated by elastomers that, notwithstanding their surface biocompatibility, readily release additives (initiators, emulsifiers, plasticizers, etc.), unreacted monomers and/or oligomers (181), and degradation products in situ.

**B. Local Reactions**

When a biomaterial comes in contact with an intra- or extravascular system, the first interaction with host tissue is protein adsorption via noncovalent, nonspecific van der Waals forces and electrostatic bonds. Proteins compete to adsorb. The most strongly adsorbed then change their three-dimensional structures depending on the physicochemical surface properties of the biomaterial. The nature of the protein film determines the course of subsequent events such as the coagulation cascade, fibrin formation, complement activation, and the adherence and activation of inflammatory cells (72,181). Activated cells migrate and establish specific ligand-receptor bonds with the biomaterial and/or adsorbed proteins, the second step in the adhesion process. The bonding can occur in three ways: focal contacts with 20-nm separations, closed contacts with 50-nm separations, or extracellular matrix contacts with 100-

nm separations (16). The host response to adherence is inflammation, an intense, local response that is the beginning of the cicatrization phase (21,162,181).

1. Protein Adsorption

Polymers, especially elastomers, are available in a wide range of shapes and formats. Depending on the end use, their surface properties such as wettability, hydrophobicity, surface charge and energy, polarity, distribution of reactive chemical groups, and surface state (smooth, rough, porous) can be chemically, physically, and/or biochemically altered. All these features, which are selected on the basis of the intended application, are subject to change under the pressure of the environmental conditions to which the biomaterial is exposed. They must, however, be preserved for the duration of the implant time because they play an essential role in the biocompatibility of the materials by directly influencing protein adsorption and host inflammatory responses (13,14,16,17,126,130, 162,181).

Albumin, IgG, fibrinogen, and fibronectin are the first proteins to adsorb (167). Albumin does not attract inflammatory cells because it does not have the peptide se-

quence required to bind to the cell membrane receptors. It also does not activate the coagulation or complement cascades because it cannot bind to the appropriate enzymatic sites (167). IgG antibodies produced by mature B lymphocytes or plasmocytes activate the complement system, the humoral mediator of inflammation. The complement cascade can follow either the classical pathway or the alternative pathway. Activation via the classical pathway requires an antigen–antibody complex where the antibody is either IgG or IgM. The alternative pathway is activated by microorganisms (viruses, bacteria, yeasts, parasites), tumors, nonimmune substances (bacterial polysaccharides and endotoxins, hemoglobin, etc.), or immune IgA or IgG complexes (197). When IgG adsorbs to an elastomer surface and activates the complement, an inflammatory response occurs, which can lead to increased vascular permeability, chemoattraction of polynuclear neutrophils and monocytes, leukocytosis, and/or phagocytosis (Fig. 19) (167,198).

Fibrinogen is indirectly activated by the Hageman factor (factor XII) when it comes in contact with the biomaterial (Fig. 20). The contact system is the first step in the coagulation cascade via the intrinsic pathway, which is activated when blood comes into contact with a surface other than that of an endothelial cell (subendothelial, foreign).

The Hageman factor (XII), the Rosenthal factor (XI), and the prekallikrein/kallikrein and kininogen/kinin systems are involved in this activation pathway (199). Factor XII and prekallikrein (Fletcher factor), which are minor clotting factors *in vivo*, become very active when they interact with the surface of a biomaterial (Figs. 21 and 22) (25,180).

The Hageman factor, a serum enzyme, is activated in the presence of bacterial endotoxins, certain enzymes (trypsin, plasmin), immune complexes, collagen released by proteolysis, or by binding to subendothelial surfaces exposed by injury. Activated Hageman factor in turn activates prekallikrein, complement, coagulation, and fibrinolysis (Fig. 23) (200,201). Fibrinogen adsorbed to the surface of the biomaterial is converted into fibrin and fibrinopeptides by thrombin. The fibrinopeptides cause vasodilation and have a chemoattractant effect on leukocytes (167,200).

Fibronectin is intimately involved in cell–substrate interactions (16). Fibronectin is an adhesive protein that adsorbs to the surfaces of biomaterials. It is a high molecular weight glycoprotein that is soluble in plasma and insoluble in connective tissue. This adhesion protein enables cells to bind to each other and to adhere to artificial surfaces (13,14).

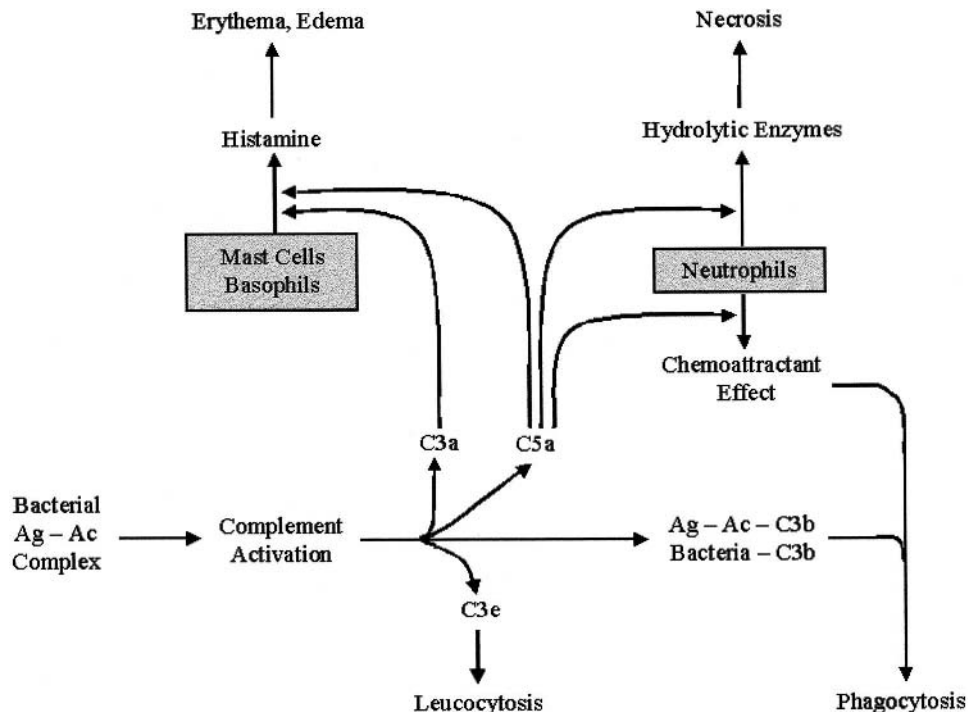

Figure 13.19 Role of complement in inflammation. (From Ref. 198.)

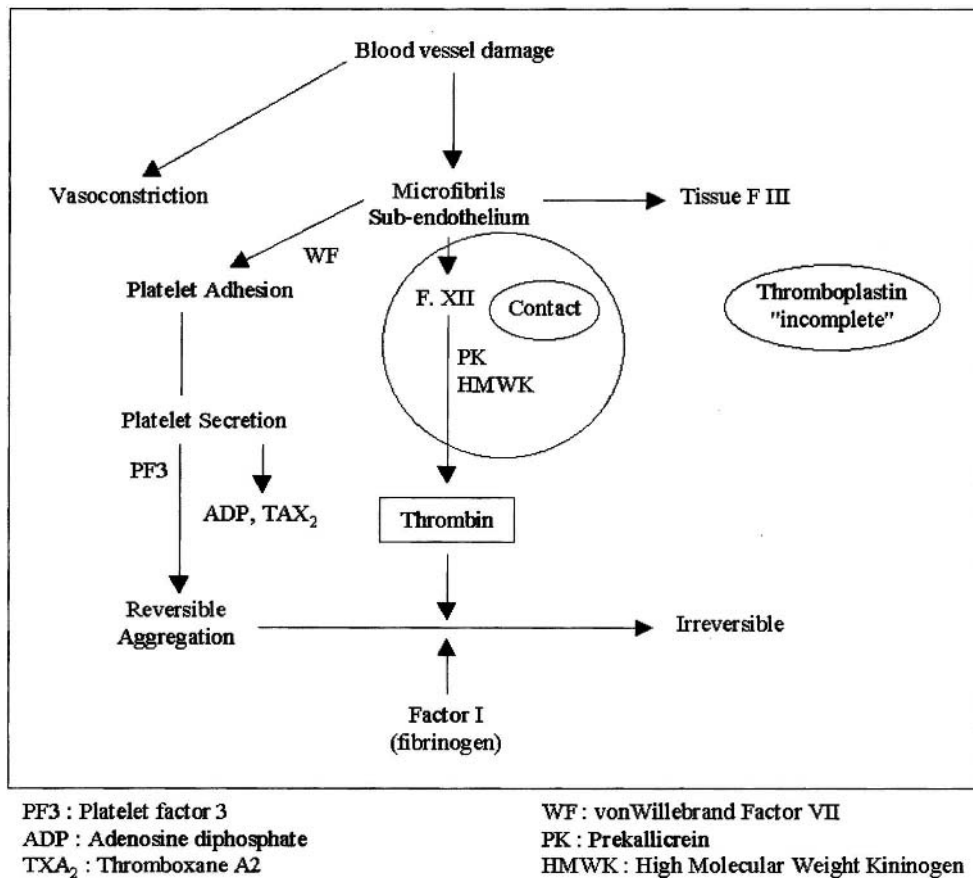

Figure 13.20 Classic coagulation mechanism.

2. Adherence and Activation of Inflammatory Cells

Leukocyte diapedesis at the implantation site is the last step in the vascular reactions involved in inflammation (91,200). Their in situ fate determines the intensity and duration of the inflammatory response because they release

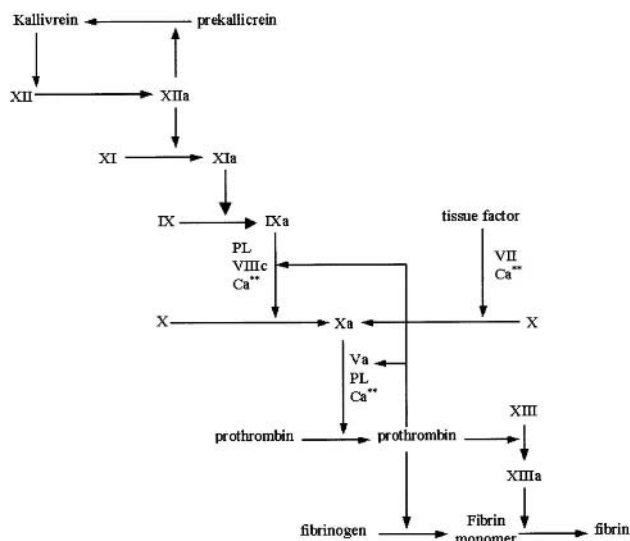

Figure 13.21 In vivo hemostasis. (From Ref. 199.)

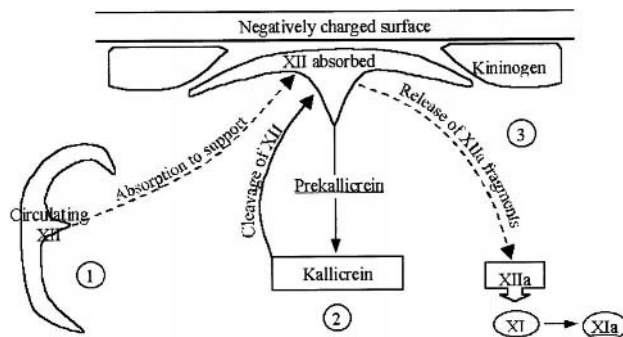

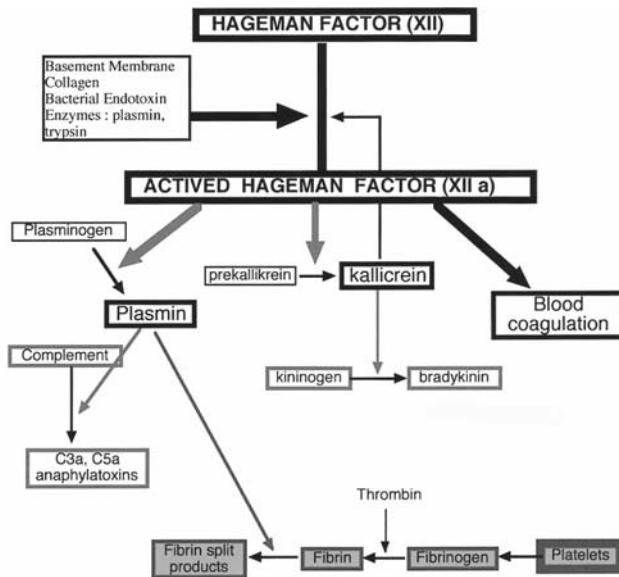

Figure 13.22 Coagulation contact phase.

**Figure 13.23** Role of activated Hageman factor in several systems.

and activate numerous cellular and humoral mediators (162). Polynuclear neutrophils and eosinophils appear in the early stages of inflammation and are followed by monocytes, which will become macrophages and lymphocytes. The macrophages activate the reticuloendothelial or reticulohistiocytic system, which helps remove foreign substances and triggers cell and humoral immune responses by activating lymphocytes (99,138,200). All phagocytes contain lysosomes, intracellular organelles that contain a great variety of proteolytic enzymes. When liberated in situ, these enzymes can destroy the extracellular matrix supporting connective and epithelial tissues. Lysosomes also release vasodilating substances and activate the complement and kallikrein/kinin systems, coagulation, and fibrinolysis (25,175,180,200).

Platelets, which are very important in homeostasis, can act as inflammation mediators via substances in their intracytoplasmic granules (201). When a biomaterial is exposed to the intravascular system, protein adsorption to the surface of the substrate is followed by platelet adhesion and spreading (21). The substances released by the platelets promote interplatelet adhesion, the first, reversible step in aggregation. This process becomes irreversible when thrombin causes the formation of a fibrin network of varying thickness called a clot (21,181,199).

Connective tissue histiocytes, mast cells, and fibroblasts also participate in the host response to biomaterials (200). During cell–elastomer interactions, fibroblasts synthesize

collagen and other matrix molecules (138). Under normal conditions, a fibrotic capsule quickly surrounds the implant (167). Host inflammatory response to contact with a biomaterial are normal reactions. In certain cases, local complications may occur, the most frequent being the formation of a thrombosis on contact with blood, the formation of a fibrotic hyperplasia around the implant, and bacterial infections (21,167).

### 3. Local Complications

While platelet aggregation may be a normal reaction when a biomaterial comes in contact with blood, it may become iatrogenic with the formation of a thrombus and the risk of emboli (Fig. 24) (21,181).

Factor XII activates the complement system. Activated fractions C3a and C5a cause platelet aggregation. C3b promotes cell adherence, increasing the risk of thrombosis (25,72).

Certain authors have reported that hemocompatibility is influenced by the type of proteins adsorbed to the surface of the implant. Albumin seems to prevent the adhesion of platelets, thus providing acceptable hemocompatibility, while fibrinogen and gamma-globulin increase platelet adhesion, leading to bioincompatibility (135). It has been shown that albumin specifically adsorbs to hydrophilic domains while gamma-globulin adsorbs to hydrophobic domains (202). Hydrophilic biomaterials are thus more hemocompatible than hydrophobic polymers (203).

Contact with the vascular system may lead to large variations in the surface wettability of biomaterials. This change from a hydrophobic to a hydrophilic state has more of an impact on hemocompatibility than initial wettability (175). More hydrophilic surfaces tend to activate factor XII, the coagulation cascade promoter, while hydrophobic surfaces tend to show a preference for activating the kallikrein/kinin system (180). When vascular grafts are implanted, the response of endothelial cells is crucial because they play a role in maintaining the antithrombogenicity of the prosthesis. To achieve optimal integration of a vascular implant, the endothelialization of the prosthesis lumen must be quick and complete. A rapid migration of endothelial cells prevents the formation of blot clots and vascular occlusion. On the other hand, the proliferation of these cells must not be excessive in order to avoid hyperplasia and occlusion (132).

The formation of a fibrotic capsule is a normal reaction to the implantation of a foreign body. The process may become pathological if the fibroblasts proliferate too extensively and cause fibrotic hyperplasia. An intense host inflammatory response on exposure to a biomaterial stimulates phagocytes, especially macrophages, which are

Figure 13.24 Blood response. (From Ref. 4.)

attracted in large number and produce a cytokine, interleukin 1. Interleukin 1 stimulates fibroblast proliferation and thus regulates the duration and extent of fibroblast activity and can also lead to fibrotic hyperplasia, and thus has a direct impact on graft success or failure (21,138,167).

A lack of implant–tissue adherence and the space between the two surfaces cause a certain amount of friction that results in the accumulation of serous fluid and inflammatory cells. The intense inflammatory response at the interface would explain the fibrotic hyperplasia (16). The contraction of the fibrotic capsule around the implant, which is more frequent with silicone elastomers than polyurethanes, is a common complication with implanted biomaterials (167). Inflammation and the various humoral and cell mediators play a clear role in the contraction of the fibrotic capsule. Good acceptance of an implant means a more moderate inflammatory response and less contraction. The structure of the implant also plays a role in this phenomenon. Contraction of capsules surrounding porous polyurethane implants occurs at a very low rate (1 to 5%) compared to smooth implants (70%). The phagocytic activity of macrophages and foreign body giant cells prevents the formation of linear capsules around implants. Fibroblasts migrate through the pores in implants, dissipating vectoral forces. Numerous microcapsules replace the linear, continuous fibrotic capsule, thus preventing contraction (167,191).

Bacterial infections are frequently associated with implanted biomaterials. Fibrinogen is known to mediate the adhesion of *Staphylococcus aureus*, the main pathogen in-

involved in implant-associated infections. Fibrinogen can act as an opsonin and promote the aggregation of bacterial cells, especially *Staphylococci* and *Streptococci* (201). The access route for catheter-related infections remains a point of contention. Certain authors (204–206) have suggested that infections involving percutaneously inserted catheters are due to contamination of the external surfaces. Others have suggested that the contamination of the catheter hub can lead to intraluminal colonization and catheter-related septicemia (84). Bacteria and fungi colonize on the polymer surface, forming an adherent biofilm. The microorganisms embedded in these highly adherent films may in the long term secrete products that degrade certain substrates (169). In addition, biofilms make antibiotic treatments and host defense mechanisms less effective (13,14,73,82).

Silicone elastomers, however, do not seem to be affected by infections. Analyses of fibrotic capsules around silicone implants, whether or not there was a deliberately induced *Staphylococcus aureus* infection, did not reveal any differences in fibrotic capsule composition or thickness. Analogous results with porous polyurethane also showed that biocompatibility was not significantly altered by infections (169).

### C. General Reactions

#### 1. Degradation

Degradation is a complex mechanism that affects all elastomeric biomaterials and depends on the chemical, physi-

cal, and structural properties of the implant and the inflammatory response of the host (4). Degradation operates at the molecular, macromolecular, microscopic, and macroscopic levels (161). All implanted materials provoke an inflammatory response from the host when it attempts to attack, destroy, and reject the foreign body. Leukocytes, especially macrophages and FBGCs, are involved in this mechanism which leads to the degradation of the elastomer (37,167).

Macrophages appear to play a predominant role in the degradation of elastomers. They are involved in the pinocytosis and phagocytosis of cell and tissue debris as well as polymer contaminants on the surfaces of biomaterials. Phagolysosomes digest the particles they have ingested and the degradation products are then released into the extracellular environment together with lysosomal enzymes, peroxides, and hydrogen ions (37,91,162,167). Lysosomal enzymes have often been implicated in the degradation process despite the difficulties in analyzing this phenomenon *in vivo* (161). Two lysosomal enzymes have been shown to participate in the chronic inflammation phase following the implantation of polyurethane devices. They are cholesteroesterase (CE) and phospholipase A2 (PLA). Cholesteroesterase catalyzes the hydrolysis of amphipathic molecules (183). It was shown in a study on polyurethane elastomers that the products generated by the lysosomal enzymes (CE and PLA) as well as the physicochemical properties of the elastomer affect the biodegradation of polyurethanes (183). The release of lysosomal enzymes, peroxides, and hydrogen ions, which are very concentrated at the cell–polymer surface interface, leads to significant degradation at this site. The degradation is faster for porous elastomers than dense elastomers. Stress and tension combined with the chemical effects of the elastomer are also involved in the degradation process (91). Degradation leads to surface cracking and a loss of molecular weight, which in turn results in a loss of tensile strength (4).

## 2. Carcinogenic Reactions

The carcinogenic potential of materials implanted in rodents has been recognized since 1950. This process is called the Oppenheimer effect. Many substances have been shown to induce foreign body carcinogenesis at the implantation site (4). In 1975, Brand et al. (207) described the various steps in foreign body tumorigenesis:

- Proliferation and tissue infiltration
- Progressive formation of a fibrotic tissue capsule
- Quiescence of the tissue reaction

- Direct contact of clonal preneoplastic cells on the foreign body surface

- Maturation of preneoplastic cells

- Sarcomatous proliferation

Tumorigenesis is controlled by a number of very controversial factors. Foreign body carcinogenesis is influenced by physical features like shape, size, hardness, and porosity (4,34,158). Implant size is critical. Tumorigenesis does not occur unless the implant is of sufficient size. The bigger the implant, the greater the probability that preneoplastic clones will attach to the foreign body surface (207). Other researchers have reported that chemical properties play an important role in tumorigenesis (158). Nakamura (158) concluded that the chemical release of decomposition products and the hardness and physicochemical surface properties of biomaterials play a role in the long-term tissue response. Numerous studies have examined the incidence of tumor formation as a function of substrate and, in particular, polyurethanes and silicones. Polyurethanes appear more carcinogenic than silicones. Differences between the two elastomers in terms of cell adhesion and thus cell proliferation are important factors in the carcinogenic process (158,208,209). The higher thermal sensitivity and water absorption of polyurethanes with respect to silicones also play an important role in this process (34). In addition, a degradation product of polyurethane (MDA or 4,4'-methylene dianiline) has been implicated in the development of cancer in rats (4,158,167,210). Heat (autoclave) and gamma radiation sterilization have also been implicated in the formation of this toxic, carcinogenic compound (1). The mechanism remains very controversial. On the other hand, a 1995 study produced no evidence that sterilization leads to the formation of MDA (211). The tumorigenesis mechanism is not clear despite numerous studies on the carcinogenic potential of biomaterials. Nakamura and his team (158) have tried to provide an explanation by suggesting a two-step mechanism: initiation followed by promotion. The initiation step depends on active oxygen species produced by cells like macrophages and foreign body giant cells or on initiators in the biomaterial (208,209). This step may be triggered by the hard segment of the chemical moiety such as MDU, which is associated with leachable and biodegradable oligomers (158). The promotion step then occurs, with polyether soft segment moieties such as PTMO inhibiting gap junction intercellular communications. The soft segment moiety is derived from leachable oligomers and degradation by direct cell–material interactions (208,212). The role of surface properties in the promotion of tumors has been examined by gap junction intercellular communication inhibition studies using

collagen immobilized on polyethylene film. The studies have shown that the inhibition of gap junction intercellular communication reduces the tumorigenic potential of polyethylene by decreasing tumor promotion activity (213).

#### D. Silicones

While the belief that silicone elastomers are inert is no longer a point of discussion, the biocompatibility of these elastomers remains an open question. Undesirable effects from silicone implants have been reported. Silicone particles have been shown to migrate to synovial fluid, bone tissue, and peripheral lymphatic organs via the vascular and lymphatic systems. Chronic inflammatory reactions, with and without fibrotic hyperplasia, have also been reported (214). Silicone elastomers have elevated coefficients of friction and low surface energies, which, combined with their hydrophobic nature, give them a low wettability index (5,20). As early as 1979, *in vitro* cytotoxicity studies provided contradictory results. Cytotoxicity is the result of the release of cytotoxic compounds and/or the surface state of the silicone elastomer. The hydrophobic/lipophilic behavior of silicone is a major problem for *in vitro* studies because it makes cell adhesion difficult. One study has shown that cell adhesion and growth increased when talc was applied to the elastomer surface to make it more hydrophilic. This was not due to a decrease in the release of toxic substance but improved adhesion resulting from a change to the surface of the biomaterial (215–218).

An analysis of epithelial cell adhesion to various elastomers has revealed similar results for all samples (silicones, polyurethanes). However, cell growth was poorer on silicone elastomers than on polyurethanes. These results tend to minimize the role of cell adhesion to the substrate. Cytotoxicity is more likely related to the release of toxic substances (219). Scanning electron microscopic analyses of the behavior of cells grown in contact with silicone elastomers have shown that the cells grow in aggregates with little spreading and produce numerous adherence structures linking them to one another, but few binding them to the substrate (127). The properties of silicon elastomers described affect cell adherence to the substrate and thus cell growth, but have no effect on viability.

*In vivo* studies on the biocompatibility of elastomer implants have shown that a moderate inflammatory response occurs with the appearance of low numbers of FGBC (129,220,221).

Hemocompatibility studies on silicones have shown that albumin and fibrinogen strongly adsorb to these elastomers and that platelets also adhere in large quantities. Wet-

tability can be calculated using contact angle measurements. There is a very large decrease in the contact angle of silicone elastomers over time, changing them from hydrophobic to hydrophilic biomaterials. According to the authors of one study (175), variations in wettability have a greater impact on hemocompatibility than initial wettability. When the biomaterial comes in contact with blood, the intrinsic homeostasis pathway is triggered and the Hageman (XII) factor and prekallikrein/kallikrein and kininogen/kinin systems are activated. The Hageman factor stimulates coagulation while the kallikrein/kinin system causes vasodilatation (180,199). A study on these systems during biomaterial–blood contact has shown that silicones preferentially activate the kallikrein/kinin system. The ratio of Factor XII to the kallikrein/kinin system was 1:2. The wettability of biomaterials plays a role in the activation of these systems. The kallikrein/kinin system is more active on hydrophobic surfaces, which leads to vasodilatation, platelet aggregation, and an increase in permeability (180). Various treatments have been attempted to improve the hemocompatibility of silicones. The elimination of micro air bubbles on the surfaces of the elastomer by denucleation reduces complement activation and platelet aggregation (25). The affinity of albumin, which acts as an activation inhibitor of various biological reactions, can be increased by a number of different processes. This reduces inflammatory cell migration, greatly improves hemocompatibility, decreases complement activation, and prolongs contact time *in vivo* (26,222). The presence of fibers in polymethylvinylsiloxane does not modify hemocompatibility (223).

Free radicals released by polymers were implicated as early as 1960 in immune disorders caused when polymer particles are phagocytosed by macrophages. The macrophages can die or release antigenic substances, which lead to the production of antibodies in the reticuloendothelial system (6). Animal experiments have confirmed this and have reached the conclusion that injected silicone can precipitate an immune response. The silicone is transported by the lymphatic system to the liver, spleen, kidney, and pancreatic lymph glands of the reticuloendothelial system (166). Foreign macromolecules that are phagocytosed and presented as antigens may provoke a humoral or cellular immune response (13). This immune response is mediated by the nature of the protein film adsorbed to the surface of the substrate as well as the nature of the substrate itself. Bonfield and Anderson have shown that the adsorbed protein film has a major impact on the behavior of cultivated human mononuclear cells (224). Monocytes and macrophages secrete more functional IL-1 $\beta$  when grown on a protein film of fibrinogen and fibronectin than on a surface

without a protein film. It has also been shown that the substrate itself plays a role in the production of IL-1 $\beta$ . In the presence of an identical protein film on different substrates, monocytes/macrophages produce more functional IL-1 $\beta$  when grown on silicone than on Teflon, Dacron, polyethylene, or Biomer (224). The nature of the substrate and the adsorbed protein film also plays a role in molecular conformation (13). Silicone elastomers are immunogenic, but the involvement of silicone mammary implants in immunological and conjunctive tissue diseases remains controversial (166,210,225–227). Chronic diseases, especially cancers, may be the result of immune system disruptions caused by silicone elastomers (210).

While silicone elastomers are hydrophobic, very thrombogenic, and occasionally result in catheters that are difficult to insert without breaking (20), they are very stable over time, are highly resistant to attacks by the host and microorganisms, provoke minimum tissue reactions, and can be sterilized by autoclaving (1).

### E. Polyurethanes

Polyurethanes have found a number of medical uses because of their acceptable level of biocompatibility, their high mechanical resistance, and their elastomeric properties (1). Polyurethanes, together with silicones, are among the few elastomers than can be implanted for long periods in humans (4). Other authors prefer polyurethanes to silicones because of their often superior mechanical properties and comparable biocompatibility. They are materials of choice for soft tissue and cardiovascular applications, especially for catheters (20,37,132). Polyurethanes have also been cited as the best biomaterial for applications requiring a combination of hardness, durability, biocompatibility, and biostability (228). They are divided into two main families: polyetherurethanes and polyesterurethanes. Since the ester bonds of the polyesterurethanes are subject to hydrolysis (vascugraft), these elastomers are used less frequently in medical applications. Another class of polyurethanes includes poly(ether urethane urea), in which the diol group has been replaced by a diamine.

Numerous studies have compared the biocompatibilities of the various polyurethanes. In vitro biocompatibility analyses comparing polyurethane elastomers (polyether and polyester) and copolymers (polyether–polyester) have shown that epithelial cells have the same growth patterns and explant morphologies as cells grown on control substrates. Comparable results were obtained with the “artificial aging” technique (219). There is strong endothelial cell proliferation within 1 week despite slower spontaneous endothelialization compared to other polymers like

PTFE (148). The biocompatibilities of a polyetherurethane and a porous copolymer (polyether–polyester) have been studied following implantation in rats. The degradation of these polyurethanes, which is less rapid than other elastomers, does not result in the release of toxic products. The proliferation of fibroblasts and the growth of fibrous and bone tissue are signs of acceptable implant fixation despite the presence of macrophages and foreign body giant cells (168).

A number of biocompatibility studies have been conducted to evaluate the role of wettability and implant structure (porosity) on cell adhesion, endothelial cell proliferation, inflammation, and cicatrization. The studies evaluated a polyesterurethane (vascugraft) with interconnected pores and two polyetherurethaneureas (Mitrathane), one hydrophilic with closed pores and the other hydrophobic with open pores. Following implantation in rats, the histological analysis revealed a slight cell reaction to the polyether and a medium reaction to the polyester. The fibrotic capsule surrounding the polyester implant pointed to good cicatrization (130). Cell adhesion to the polyester was weak, slightly stronger to the hydrophobic polyether, and equivalent to the control substrate for the hydrophilic polyether. Cell proliferation followed the same pattern, although a uniform monolayer of endothelial cells formed on the polyester, while multiple layers formed on the hydrophilic polyether (130,155). Similar results were reported in a study on hydrophilic and hydrophobic polyetherurethaneureas. The formation of cell monolayers on a hydrophobic substrate is facilitated more by the presence of interconnecting pores than wettability (131). A porous structure promotes fibroblast proliferation and the production of new collagen on polyester. Tissue growth is a function of material porosity (130,229). If there are no interconnecting pores, a thin but linear fibrotic capsule is deposited around the implant, but fibrotic tissue does not form within the implant (230,231). Open pores should allow the development of fibrotic tissue within the implant. A porous structure thus prevents deformation and reduces the risk of infection and contraction of the capsule around the implant (130,167,191). These reports show the importance of the physical properties of substrates such as porosity and surface wettability in elastomer biocompatibility.

Polyetherurethanes can be aromatic or aliphatic. When aliphatic they are produced using hydrogenated methylene diisocyanate (HMDI) rather than MDI, they no longer release 4-4'-methylene dianiline as a decomposition product, which has been shown to be carcinogenic in the rat. In addition, these aliphatic polyetherurethanes are not affected by ultraviolet radiation (1). As for hemocompatibility, platelet adherence is similar for both aromatic and ali-

phatic polyetherurethanes although more fibrinogen is deposited on the aliphatic (203). Aliphatic polyetherurethanes are more difficult to synthesize and have slightly weaker mechanical properties than the aromatic (1,203).

There are no differences in endothelialization or neointimal formation between aliphatic polyether-coated stents (Tecoflex) and uncoated stents. On the other hand, the inflammatory tissue response associated with aliphatic polyetherurethane-coated stents may be an indication of low biocompatibility (96). A new type of aliphatic polyetherurethane (UTA) has been shown to increase the speed of cell adhesion, equaling that of hydrophilic polyetherurethane urea. After 1 week, both the UTA and hydrophilic polyetherurethane surfaces were covered by multiple cell layers, while the hydrophobic polyetherurethane was only covered by a monolayer (131). Extraction cytotoxicity analyses revealed that this family of elastomers does not release toxic contaminants and has no clear superiority in terms of biocompatibility over the other elastomers tested (polyetherurethane urea and PTFE, Goretex, Impra) (6). The author of this study also pointed to the role of biomaterial hydrophobicity in cell adhesion.

The degradation of polyurethanes has been studied in great detail and involves three main mechanisms: mineralization, oxidation, and environmental stress cracking. Mineralization or calcification (161) involves the incorporation of crystalline inorganic substances on the surface of the implanted material. This mechanism often results in hardening, distortion, and mechanical degradation of the elastomer (228). This mechanism most often comes into play when elastomers are in contact with the bloodstream or are in zones subject to dynamic flexing. Microdefects in the material can catch small particles of cellular debris, which in turn can act as nuclei for the formation and growth of calcium phosphate-rich crystals (1,37,228).

Oxidation is induced by free radicals that break bonds, opening the elastomer up to attack by oxygen molecules. This can be influenced by factors such as the flexibility of the medical device, the type of soft segment, and the ability to interact with ions (4).

Environmental stress cracking is mediated by various stress and environmental factors acting on the polymers such as oxidation, enzymatic activity, and mineralization. Three conditions are required for ESC to occur: a polyetherurethane device, enzyme activity, and mechanical stress. While this biological mechanism has never been described for polyetherurethanes *in vitro*, Szycher et al. (37) have mentioned the notion of BI-ESC. Cell- and humoral-mediated inflammatory responses may also be involved in the surface degradation of polyurethanes. Environmental stress cracking first occurs in the direction of the stress and

then takes on a three-dimensional aspect that may extend to the very heart of the material, leading to total failure (37). The problem with degradation has been minimized with the introduction of “biostable” polyurethanes. Coury (52) has synthesized polyurethanes with no ether functions. *In vitro* the absence of an ether bond removes a point of attack for enzymes and chemical oxidants, thus lowering the risk of degradation (4,37). Szycher et al. (37) detected no degradation, cracking, or failure in biostable PUs after 12 weeks of implantation.

Modified polyurethane elastomers (polycarbonate urethanes) have also been produced using polycarbonate glycol as a soft segment. While polyetherurethanes undergo significant degradation after 6 months of implantation, the surface of a polycarbonate urethane remains smooth and crack-free (4).

New elastomers such as polycarbonate polyurethanes and polyurethanes endcapped with polydimethylsiloxane have made their appearance. Studies have recently been published comparing the biocompatibility and biostability of these new PUs with classic polyetherurethanes and PTFEs. They show that all polyurethanes share the same biological reactions (acute and chronic inflammation). The hydrophobicity of polydimethylsiloxane leads to a smaller accumulation of FBGC on the material surface. Polydimethylsiloxane-endcapped PUs are less subject to biodegradation because the endcap provides protection against the oxygenated free radicals released by macrophages and FBGCs. The even greater biostability of polycarbonate polyurethanes has been attributed to their carbonate bonds (66). When used as vascular prostheses, polycarbonate polyurethanes become endothelialized much more quickly than PTFEs. In addition, chronic proliferation is lower than with PTFEs, decreasing the risk of hyperplasia and occlusion (132).

The biocompatibility of elastomers can be improved by modifying the surface or internal properties of existing polymers. However, these physical, chemical, and biological modifications must not affect their bulk properties. To quote Han et al. (74), “practically every physical and chemical material property has been suggested as being important in biocompatibility for areas such as thrombus, calcification and infection” (74).

The chemical and surface properties of biomaterials play a major role in cell and tissue responses on implantation. The production of factor TNF $\alpha$ , which regulates inflammation and cicatrization, has been measured using polyurethanes containing increasing quantities of sulfonate (10, 20, and 30%) and thus varying surface charges. Fewer neutrophils are observed from 2 to 12 weeks with the PU containing 20% sulfonate. However, after 12 weeks the

situation is similar for all polyurethanes, with a few neutrophils and the same number of macrophages associated with the elastomer. This indicates that surface charge may play a role in the acute inflammatory response during implantation (139).

Other techniques have been developed to improve the biocompatibility of polyurethane elastomers. The incorporation of glycerophosphocholine as a chain extender in poly(tetramethylene oxide)-based polyurethane significantly decreases bacterial adhesion and protein adsorption. The incorporation of dehydroepiandrosterone (DHEA) in polyetherurethane urea decreases macrophage adhesion and FBGC formation for up to 7 days. After 7 days, the biocompatibility of all PUs (with and without DHEA) is similar (91). The incorporation of vitamin E (tocopherol) generates a very stable PU, something that is not observed with DHEA (91). Calcium chloride added to poly(ether urethane amide) improves biocompatibility, hydrophilicity, and plasticity. However, it also increases thrombogenicity (92). Grafting collagen onto PU increases endothelial cell growth, which is dependent on the morphology and diameter of the collagen fibers. However, the collagen may also activate and aggregate platelets, making the material thrombogenic (79). Coating the prosthesis (PU + collagen) with a confluent monolayer of endothelial cells should resolve this problem. All these studies clearly demonstrate the complexity of the biocompatibility of elastomers in general.

While polyurethane elastomers have been used in a broad range of applications, the presence of microemboli and microscopic thromboses requires them to be modified to make them less thrombogenic (1). Rakhorst et al. (175) have shown that less albumin and fewer platelets attach to polyurethane elastomers than to polydimethyl siloxane or PTFE.

Manufacturing processes and the composition of polyurethane as well as surface properties play a role in polyurethane-blood interactions (203). The roles of the various components of polyurethanes have been studied. The nature of the soft segment makes polyurethane more or less thrombogenic. It has been shown that polyethylene oxide is more thrombogenic than polypropylene oxide or polytetramethylene oxide, with greater platelet retention (203). The nature of the hard segment is also important in the blood response. Aliphatic PUs do not have the same properties as aromatic PUs. They both attract platelets to an equal degree, but there is an increased fibrinogen response with aliphatic PUs (148). The quantity of soft and hard segments influences hemocompatibility. Polyurethanes with large proportions of hard segments are subject to rapid cell adhesion and sustained cell proliferation (203). The lower the proportion of hard segments, the weaker the

blood interactions (146). The molecular mass of the hard segment is important when such devices must be in contact with blood. It has been shown that PTMO 1000 is more hemocompatible than PTMO 2000 (146). This shows that both the concentration and conformation of the hard segment play a role in hemocompatibility (203). Two main types of chain extender can be used: diols (polyether urethanes) and diamines (polyetherurethane urea). Diamines provide enhanced thromboresistance and hydrophilicity (203).

Solvent casting affects the blood response by changing the orientation and/or conformation of the diisocyanate and the components of the chain extender (148). An analysis of the biocompatibility and the cell response of aliphatic PUs containing varying amounts of plasticizer has shown the important role played by plasticizers. The biocompatibility, durability, and adhesive properties of aliphatic PUs increase in line with the decrease in the amount of plasticizer (101).

To get around the problem of thromboresistance, researchers have tried adding and/or replacing components. Sulfonated polyurethanes (PEO SO<sub>3</sub>) produced by various techniques exhibit a lower level of platelet adhesion and platelet factor IV release from the time they first come in contact with blood until up to 12 to 24 h later (74,232). Hemocompatibility parallels bacterial repellence; the more hemocompatible a polymer, the more resistant it is to infections (74).

The hemocompatibility of sulfonated polyurethanes modified by a surface derivation technique using 2-acrylamido-2-methyl-propane sulfonic acid (AMPS) varies depending on the species, with *in vivo* and *in vitro* studies providing very contradictory results (72). While very hemocompatible *in vitro*, sulfonated polyurethanes attract large numbers of neutrophils when implanted in mice, increase macrophage recruitment to unexpected levels, and lead to the formation of thromboses when implanted in dogs (72).

The heparinization of polymers to prevent the deposition of fibrin has been studied in great detail. Applying a layer of heparin to PUPA [PU + poly(amido amine) + HMDI] provides excellent antithrombogenic properties, thus increasing hemocompatibility (76).

To reduce the risk of infections associated with medical devices, a number of metallic ions known for their bactericidal effect, especially silver, have been investigated. Numerous studies have examined the biocompatibility, infection rates, and thrombogenicity of silver-impregnated or silver-coated polyurethanes and silicones (81,82,84,85, 233). Coating polyurethane, silicon, and Dacron catheters with silver ions prevents microbial colonization both *in vitro* and *in vivo* (82,84,234). An animal implantation study (233) has shown that infection rates dropped when

silver-impregnated polyurethane catheters were used compared to untreated catheters. In vitro tests have shown that silver ions have no cytotoxic or thrombogenic effect and do not provoke an exaggerated inflammatory or tissue response. Biocompatibility also depends on the material to which the silver is bound (81,84,85).

#### F. Biodegradable Polyurethanes

The chemical properties of elastomers have also been modified to produce biodegradable products. Studies on biodegradable polyesterurethanes have shown that these elastomers have good cell compatibility and that cell–substrate interactions do not lead to the release of toxic substances or the activation of macrophages. Relatively strong adhesion and acceptable growth of macrophages and osteoblasts occur. Fibroblasts keep their phenotype for 12 days. The main problem seems to be the actual degradation of the elastomer, which results in the production of crystalline poly(*r*-3-hydroxybutyric acid), or PHB-P, particles. Macrophages, and to a lesser degree osteoblasts, may internalize the particles by phagocytosis. At high concentrations, these particles may be toxic for macrophages and osteoblasts at concentrations of 200 pg PHB-P/cell and 400 pg PHB-P/cell, respectively (98,99).

#### G. Polyesters

Dacron, or polyethylene terephthalate, which has been used since 1940 as a bone and cartilage substitute, is considered to be biocompatible (1,95). It is used in numerous medical applications, especially in vascular surgery and for stent coatings (95). But a chronic, systemic inflammation was reported following implantation of a Dacron device. Lymphocytes appear after 30 days and the size of giant cells increases over time (15,235–241). Their tendency to provoke intimal hyperplasia and platelet stimulation, and thus their thrombogenicity, limits their clinical use to blood vessels greater than 6 mm in diameter (1). Polyterephthalate-coated stents are preferred to polyurethane stents, which are much more subject to dislocation (95).

#### H. Polyvinylchloride

Polyvinyl chloride is increasingly being used for medical applications, with an annual increase of 5.4%. It has been used in the healthcare field since 1940 because of its broad biocompatibility, ease of manufacture, and low cost (1). A study in 1991 reported chronic inflammation associated with PVC (164). Two days after implantation, the inflammatory exudate around the PVC contains mainly neu-

trophils, while that around PU or silicone contains a mixture of neutrophils and monocytes (102).

Additives have often been implicated in harmful host responses. Additives include plasticizers, antioxidants, pigments, and UV stabilizers. Plasticizers in particular can release substances that are incompatible with biological applications (1). A study in 1994 (101) on the biocompatibility of and cell response to PVC has shown that there is a clear correlation between the amount of plasticizer and the host inflammatory response. Various processes have been used in an attempt to make PVCs more biocompatible. The most commonly used plasticizer is phthalic ester, but it can be replaced by trioctyl trimellitate, azelate, or phosphate ester, which are nontoxic and are not released (1).

The effect of plasticizers on hemocompatibility has been studied using PVC blood tubing manufactured with various plasticizers (phthalate alone, trimellitate or TD 360, and phthalate coextruded with polyurethane). The concentration of C3a anaphylatoxin and protein morphology were examined by electron microscopy. Phthalate-free PVC is more biocompatible, and polyurethane-coated PVC releases less C3a anaphylatoxin, although hemocompatibility does not change (103).

#### I. Polytetrafluoroethylene

Polytetrafluoroethylene is used for many medical applications, especially for peripheral vascular surgery (148). In vitro extraction and direct contact analyses reveal no cytotoxic contaminants (131). In vivo, the inflammatory response resorbs within 9 weeks, indicating acceptable biocompatibility (130,131). Fibroblasts respond to vascular PTFE prostheses by forming a thick external fibrotic capsule and a thin layer coating the pores (131,155). Despite an initial quick, spontaneous endothelialization process, complete endothelialization of the lumen of a PTFE prosthesis can take up to 6 months because of the rough surface, which, compared to polyurethanes, makes endothelial cell proliferation more difficult. Chronic proliferation is, however, significant. After 6 months, the cells are still dividing, increasing neointimal formation and thus the risk of hyperplasia and thrombosis (132,148). Surface texture also influences cell migration. Cell migration, which can prevent thrombosis and occlusion, is slow on PTFE (132).

Following a 500-min contact between human plasma and a PTFE prosthesis, variations in contact angle are minimal and there is little fibrinogen adsorption, while platelet adhesion is elevated (175). Blood contact with hydrophobic materials preferentially activates the kallikrein/kinin system, leading to vasodilatation, platelet aggregation, and an increase in vascular permeability (180).

## J. Hydrogels

Hydrogels have been used in a wide variety of medical applications for over 30 years, for contact lenses, prosthetic devices, and drug delivery systems (1). General properties include swelling in water, high mobility of surface chains, low interfacial tension, low surface friction, and appreciable elasticity, making them reasonably biocompatible. Their hydrophilicity and low surface tension decreases protein adsorption and cell adhesion, which makes them suitable for use in contact lenses. The low surface friction reduces fibroblast stimulation and prevents the formation of a fibrotic capsule (21). The high elasticity and low mechanical resistance means that they have to be combined with other more solid elastomers, providing hydrogels with excellent mechanical and biological properties.

## K. Polyethylenes

A 1983 study evaluated the cell response to polyethylene following implantation in the peritoneal cavities of mice (129). The rough surface of the elastomer becomes covered with numerous macrophages and foreign body giant cells. The tissue reaction to polypropylene oxide includes an acute inflammatory response involving numerous macrophages and lymphocytes. Polyethylenes are rapidly degraded within 5 months of implantation, and the resulting reactions point to the toxicity of the degradation products. The study by Bakker et al. (169) shows that polypropylene oxide cannot be used for alloplastic tympanic membranes. Hemocompatibility studies have shown strong albumin adsorption and weak platelet adhesion to high density polyethylene. In addition, analyses of the kallikrein/kinin system and the Hageman factor have shown that both systems are activated to the same extent, indicating acceptable hemocompatibility (175,180).

## L. Natural Rubbers

While natural rubbers are used in surgical gloves, urinary catheters, and tubing, their low hemocompatibility means they cannot be used in many other applications. Methylmethacrylate grafts can improve hemocompatibility (111,242). Natural rubber also cause cytotoxic and allergic reactions of various etiologies (113). The proteins in natural rubbers cause Type I, IgE-induced allergic reactions. It is possible to remove these proteins by simple washing. Gamma radiation vulcanization can be used to produce nitrosamine-free, low toxicity elastomers (1). It has also been shown that the cytotoxicity of natural rubbers is due to dithiocarbamates (110). Various improvements mean that

natural rubbers could soon see more frequent use in medical applications.

## ACKNOWLEDGEMENTS

The authors would like to thank Gene Bourgeau, Céline Allaire, and Christiane Péju for editorial assistance.

## Control of Cell–Biomaterial Interactions

Danielle C. Giliberti, Kyle K. White, and Kay C Dee  
*Tulane University, New Orleans, Louisiana*

### I. INTRODUCTION

An ideal implanted prosthesis or device would be quickly integrated and stabilized within the surrounding tissue. If tissue integration occurs too slowly, or is compromised over time, common clinical problems (such as loosening of the implant, pain, and loss of tissue near the implant site) may lead to subsequent, difficult reimplantation. Many recent strategies for avoiding these adverse outcomes are derived from the fundamental premise that *macroscopic tissue-level events are ultimately derived from, and thus could be controlled by, cellular- and molecular-level events at the tissue–implant interface*. An ideal implant could be designed to encourage quick healing and maintenance of tissue by controlling cellular- and molecular-level events (such as cell adhesion, differentiation, matrix deposition, etc.) at the tissue–biomaterial interface. Understanding how cells interact with biomaterials is a necessary prerequisite for the development of novel methods to control cell–biomaterial and, eventually, tissue–biomaterial interactions.

Controlling cell–biomaterial interactions is an important and relevant goal for the development of polymeric biomaterials because techniques are available for the fabrication of polymeric biomaterials with a wide range of bulk and surface properties. However, influencing even the most fundamental cellular functions (such as adhesion and migration) requires an understanding of a variety of topics, including cell biology, surface chemistry, and physical properties. The purpose of this chapter is, therefore, to pro-

vide an overview of key concepts and current research on controlling cell–biomaterial interactions, with the hope of stimulating further interest in this rapidly growing field of research.

### II. MEDIATING CELLULAR FUNCTIONS: BIOLOGICAL CONSIDERATIONS

Cellular anchorage (adhesion to a substrate) and migration are essential to the normal progression of many biological processes, including proper functioning of the immune system, embryogenesis, hemostasis, and maintenance of tissue integrity (1). The ability of cells to interact with each other and their surroundings in a coordinated manner depends on multiple cell–cell and cell–matrix adhesive interactions (2). For anchorage-dependent cells, adhesion to a substrate or matrix is a necessary prerequisite for viability and proliferation (3). Due to its fundamental biological importance, cell–substrate adhesion has been the focus of many studies, including much of the research on controlling cell–biomaterial interactions. Therefore, this chapter will focus primarily on cell adhesion, and will discuss biological, surface chemistry, and surface architectural/mechanical considerations involved in mediating cellular adhesion and related functions.

#### A. Cell Adhesion

Adhesion molecules are a versatile class of cell membrane receptors which function as links between cells and the

extracellular environment. Cell adhesion molecules can transmit both mechanical and biochemical signals bidirectionally across the cell membrane (2), from adjacent cells and/or from the extracellular matrix, thereby regulating cellular functions. Signaling via cell adhesion receptors mediates a variety of processes such as gene expression, differentiation, apoptosis (2), and cellular migration (4). The interdependence between cell adhesion molecules, growth factor receptors, and the extracellular matrix (demonstrated through initiation of biochemical signaling cascades and formation of intracellular multiprotein complexes) helps explain the need for multiple cell membrane molecules to be activated for normal cellular function (2). The following discussion focuses on four major superfamilies of cell adhesion molecules that function in cellular adhesion and intercellular signaling and are the focus of much current research: cadherins, selectins, immunoglobulins, and integrins.

### 1. Cadherins

Cadherins are a family of transmembrane glycoproteins whose purpose is to organize solid tissues and ensure tissue integrity (5,6). Cadherins are specialized for the maintenance of stable adhesive interactions through long-term, almost irreversible binding (7) and constitute the major component of adherens junctions (2,4,8). Mutations in cadherins can cause tissue disorder and cellular dedifferentiation and may even lead to malignancy (9). Cadherins generally exhibit homotypic adhesion (2,7,8); however, E-cadherin has been shown to bind integrin ligands (7,8). The integrin-binding site on the cadherin molecule is spatially separate from the sites that mediate homotypic binding, suggesting that heterotypic and homotypic binding can occur simultaneously (7). Cadherin adhesion is calcium dependent (2,7). Calcium ions serve to rigidify cadherin structure, induce conformational changes needed for adhesion, and confer resistance to proteolysis (7). Cadherins have a rather large extracellular domain, a transmembrane segment, and a short cytoplasmic tail (7). The cytoplasmic domain indirectly interacts with the actin cytoskeleton via linker molecules called catenins (2,7) that bind to  $\alpha$ -actinin and vinculin (4), which in turn interact with actin filaments. The cytoplasmic domains of cadherins are required for desmosome assembly and cytoskeletal filament anchorage (4).

### 2. Selectins

Unlike the stable adhesion demonstrated by cadherins, selectins provide transient adhesive interactions. For example, selectins are important for leukocyte–endothelium weak adhesion (8,10) and leukocyte signaling (11), and are therefore a focus for the development of anti-inflammatory

agents (7). Selectins also play a role in platelet adhesion (7,12). Selectin-mediated adhesion can occur under flow (7) and is regulated by divalent calcium ions (2). Selectins have five domains: three extracellular, one transmembrane, and one intracellular, or cytoplasmic (8). Selectins bind to carbohydrate-containing ligands (7) as well as to integrin ligands (8).

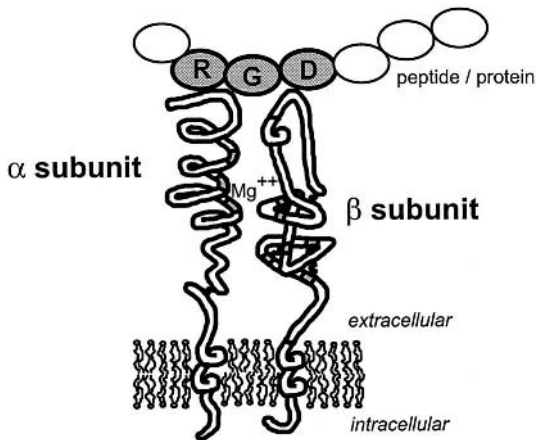

### 3. Immunoglobulins

Many members of the immunoglobulin superfamily are involved in cell adhesion, and play roles in platelet–endothelial cell adhesion, neural cell–matrix adhesion (13,14), vascular cell–matrix adhesion, and general intracellular adhesion in a variety of cell types (8). Immunoglobulins exhibit homotypic binding as well as heterotypic binding to integrin and extracellular matrix ligands (2). Dysfunction in immunoglobulin-mediated adhesion has been implicated in a variety of pathological disorders (8,15,16).

### 4. Integrins

Integrins are a significant family of cell adhesion receptors as well as a major focus of current biological and biomaterials research (and, therefore, this discussion). Integrin-mediated cell adhesion and signaling have been cited as crucial to a wide variety of physiologic and pathologic processes, including but not limited to embryonic development, fertilization, maintenance of tissue integrity, wound healing and angiogenesis, leukocyte recirculation and recruitment, antigen presentation, cytotoxicity, and phagocytosis (2). Cell–matrix interactions that take place through integrin ligation directly participate in the control of cellular differentiation, morphogenesis, proliferation, migration, and apoptosis, influencing such processes as wound healing, inflammation, and metastasis (3,17,18). Integrins have therefore been targeted for the development of novel therapies for inflammatory, neoplastic, and infectious diseases (8). In other words, in order to fully understand and potentially control select clinically relevant, macroscopic-level events (metastasis, wound healing, tissue integrity) it is important to understand the mechanisms of integrin-mediated cellular- and molecular-level events (receptor activation, intracellular signaling, cell adhesion, etc.).

Integrins are perhaps most widely recognized as the primary cell adhesion receptors for many proteins of the extracellular matrix, such as fibronectin, laminin, vitronectin, and collagen (19). The integrin family contains sixteen  $\alpha$  and eight  $\beta$  subunits which can combine to form at least 22 heterodimeric receptors. Both the  $\alpha$  and  $\beta$  subunits are type-1 transmembrane glycoproteins (2,4,8), containing a large extracellular domain, a transmembrane segment, and a short cytoplasmic tail (Fig. 1) (8). Cell surface expression of the mature  $\alpha\beta$  heterodimer can be regulated by modulat-

**Figure 14.1** Schematic of an integrin receptor. Each receptor has an  $\alpha$  and a  $\beta$  subunit, both of which span the cell membrane. The ligand binding site of the receptor is a “pocket” between the subunits; divalent ions also bind between the subunits. The ligand shown is a sequence of three amino acids, arginine–glycine–aspartic acid (RGD). The three-dimensional structure of the integrin subunits shown here is not definitive. (Adapted from Ref. 120.)

ing the level of  $\alpha$  chain expression (through, for example, chemical means such as inflammatory cytokines) (2). Cells can express more than one type of integrin receptor (4), and distinct integrin pairs can act to differentially regulate signals across the cell membrane (7,20). Due to interactions with the cytoskeleton, activated integrins can function as mechanotransducers between a cell and the surrounding microenvironment (4,7,21,22). Integrin activation leads to tyrosine and serine phosphorylation, increases in intracellular calcium, and changes in phosphoinositide turnover and gene expression (23,24).

#### a. Activation and Conformation

Integrins move between an inactive state, in which they cannot bind ligands, and an active state, in which ligation occurs. Altering integrin activation states through receptor conformation changes or spatial clustering, rather than by changing the number of receptors on a cell surface (2), can control adhesive properties of integrins and, therefore, the adhesive properties of a cell (7,25,26). Integrin *avidity* depends on the spatial arrangement of the receptors on the cell membrane (1,23); the *affinity* of integrin receptors for ligands is dependent upon receptor conformation (1,23). Conformational changes to the ligand-binding domain [which is a “pocket” between the  $\alpha$  and  $\beta$  subunits (7)] of an integrin receptor modulates the affinity of the receptor (1,25) and occurs through the interaction of the integrin cytoplasmic domain with intracellular factors (21,26). This

**Figure 14.2** Inside-out signaling. An intracellular complex interacts with the cytoplasmic domain(s) of the receptor, changing the receptor conformation to one which allows ligand binding. While a scissorlike conformational change is depicted here for the sake of illustration, the actual spatial rotation/translation may be different. (Adapted from Ref. 25.)

mechanism of affinity modulation is often termed “inside-out” signaling (Fig. 2) (2,3,8) and is thought to be primarily brought about by phosphorylation/dephosphorylation events, which subsequently allow association of other regulatory proteins (3). Calreticulin, for example, is a calcium-binding intracellular protein that is believed to function by binding to integrins, forcing the maintenance of a high affinity state (1,26).

There is a three-way interdependence between integrin conformation, divalent cation occupancy, and ligand binding (27). Integrin structure (and therefore function) is cation dependent, with cation specificity differing between integrins (2). Cation occupancy may regulate an opening of the integrin dimer to expose the ligand-binding domain between the  $\alpha$  and  $\beta$  subunits (27).  $Mn^{2+}$  stimulates ligand binding;  $Mg^{2+}$  also stimulates ligand binding, but not as strongly; and  $Ca^{2+}$  inhibits ligand binding in most integrins (21,23,25–28).  $Mn^{2+}$  and  $Ca^{2+}$  noncompetitively inhibit ligation (two distinct binding sites exist for these cations), whereas  $Mg^{2+}$  and  $Ca^{2+}$  can competitively inhibit ligation by binding at the same site (26).

#### b. Ligation

Integrin receptors recognize ligands that are components of extracellular environments they would often encounter (e.g., connective tissue matrix, basement membranes, mineralized matrix) (22). Ligands may be cell surface members of the immunoglobulin superfamily, microorganisms,

coagulation factors, or portions of extracellular matrix molecules (7,8,25). A classic example of an integrin ligand is the peptide arginine–glycine–aspartic acid, or RGD, which was the first ligand sequence identified for integrin recognition (7,17,21,22,28). The RGD peptide is present in a number of extracellular matrix components including fibronectin, fibrinogen, vitronectin, and von Willebrand's Factor (23).

Each integrin heterodimer type has a specific binding profile (2,4,7,8). Several regions from both the  $\alpha$  and the  $\beta$  subunits constitute the ligand-binding domain; therefore a particular ligand may bind at two or more distinct sites within the dimer (26). Integrin ligation elicits a variety of intracellular events such as the stimulation of protein kinase C, the  $\text{Na}^+/\text{H}^+$  antiporter, phosphoinositide hydrolysis, tyrosine phosphorylation of cellular proteins, changes in intracellular pH, and mitogen-activated protein kinase activation (18–21,29). The ligation of integrins also leads to an increase in intracellular calcium concentration (28). There is evidence that calcium signaling may be a “fine-tuning” mechanism in cell adhesion and migratory activity (28).

Cell adhesion to an extracellular matrix via integrin–ligand interactions is accompanied by integrin aggregation. Integrins are able to move laterally along the surface of the cell membrane to form localized clusters (1,23), often due to ligation of the  $\beta$  subunit (23). Signaling initiated through integrin clustering and ligation is often termed “outside-in” signaling (1) since the clustering can be viewed as a response to signals—the presence of ligands—from the extracellular matrix. “Inside-out” intracellular signaling, which remodels cytoskeletal linkages or alters receptor diffusion rates, can also regulate integrin clustering (1). Clustering appears to trigger increased tyrosine phosphorylation of a number of intracellular proteins (30) and may regulate many cellular processes (3), including gene expression, proliferation, and apoptosis (2,8). Integrins can cocluster with other membrane receptors and with intracellular proteins to form “focal adhesions” (18,24,30,31), which are essentially links between the cytoskeleton and the extracellular environment (Fig. 3) (26).

### c. Focal Adhesions

Integrins colocalize with the ends of stress fibers (actin filament bundles that span the interior of the cell) at focal adhesions (19,21,23,24). The formation of focal adhesions causes the formation of intracellular signaling complexes and the reorganization of the cytoskeleton to facilitate signal transfer (19).

At least 20 different intracellular proteins can be recruited to the ligand–integrin binding site to make up a

**Figure 14.3** Focal adhesions and the cytoskeleton. When integrins bind to an extracellular ligand, such as a specific region of a protein adsorbed to the surface of a biomaterial, a number of intracellular proteins (only a few of which are shown) localize at the integrin cytoplasmic domains. This intracellular complex, or focal adhesion, can anchor the actin cytoskeleton to the location of integrin–ligand interaction. Focal adhesions therefore provide a direct link between the extracellular environment and the cytoskeleton.

focal adhesion (30). The intracellular proteins F-actin, filamin, paxillin, tensin, and vinculin have been shown to associate with integrin cytoplasmic domains (26,32), and  $\alpha$ -actinin and talin have been shown to directly bind to these domains (23). Some focal adhesion proteins, such as paxillin, are phosphorylated in an integrin-dependent manner (24). Integrins lack intrinsic enzymatic activity; therefore, some integrin-mediated signaling is dependent upon nonreceptor kinases (17).

Focal adhesion kinase (FAK) is a nonreceptor tyrosine kinase that, as the name suggests, localizes in focal adhesions (17,18,29,33) and is tyrosine phosphorylated upon integrin binding (20,24,28,30,33). Focal adhesion kinase phosphorylation and activity appears to be triggered by the clustering of integrins (17,18,29,33), and FAK appears to play a large role in ligand binding (1,23,26,33). Talin,  $\alpha$ -actinin, and FAK can interact directly with the  $\beta$  subunit to form a focal adhesion complex with the cytoskeleton (1,19,23). Focal adhesion kinase activity also leads to the activation of mitogen-activated protein kinase (MAPK) and Ras, a family of small GTPases (17,23,29,33). This (FAK, MAPK, Ras) signaling cascade is initiated as cytoskeletal elements assemble to anchor actin filaments during the formation of focal adhesions (Fig. 4) (29). In this way, integrin ligation can lead to direct activation of MAPK and Ras, both of which have been associated with

**Figure 14.4** Integrins and cytoskeletal rearrangement. When integrins bind to an extracellular ligand, a number of signaling cascades are locally initiated, some of which participate in rearrangement and anchoring of the cytoskeleton.

the generation of mitogenic signals (Fig. 5). In other words, specific intracellular signaling pathways (such as FAK, MAPK, Ras) essentially constitute a line of communication between integrins and the nucleus (18,20,23,29). Activation of the MAPK signal transduction pathway is a common route leading to transcriptional regulation of genes (30). Anoikis (apoptosis that occurs when cells are detached from their matrix, and therefore integrins are de-

**Figure 14.5** Integrins and gene expression. Some of the intracellular signaling cascades that are initiated upon integrin ligation are known to mediate gene expression and cell proliferation. Cytokines and growth factors mediate cell proliferation via similar pathways, providing plausible locations for signaling convergence and cooperative amplification.

tached from their ligands) is regulated through FAK and MAPK (3,25).

The activation of MAPK leads to suppression of high affinity ligand binding by a number of integrins (30). The Ras family of small GTPases also modulates integrin affinity (1). Rho is a member of the Ras family that regulates actin stress fiber organization and assembly of the focal adhesion (17). The actin structures controlled by each Rho GTPases are associated with integrin clustering and other focal adhesion proteins (30). Activated Rho induces focal adhesion formation. However, integrin clustering can alter Rho localization (18,25). Rho GTPases are currently thought to be key parts of focal adhesion–dependent signaling pathways that control cell proliferation and gene transcription (30).

Formation of focal adhesions involves tyrosine phosphorylation events, clustering of integrins, integrin–ligand binding, and actin cytoskeletal integrity (20). Clustering of integrins without ligand binding localizes FAK and tensin to the integrin aggregation site. If tyrosine phosphorylation occurs at this point, signaling molecules such as Ras, MAPK, and PI3-kinase will also be found at the aggregation site. Clustering of integrins with ligand binding colocalizes talin,  $\alpha$ -actinin, and vinculin in addition to FAK and tensin. If tyrosine phosphorylation occurs at this point, paxillin and actin filaments are also recruited to the site, in addition to a number of signaling molecules (18,24). Integrins can bind ligands in the absence of FAK. In this case, vinculin,  $\alpha$ -actinin, and talin may colocalize to form a link to the cytoskeleton (23). Therefore, clustering of integrins is sufficient for some signal transduction, but ligand binding is required for cytoskeletal assembly. These results suggest that integrin–ligand binding changes the conformation of the integrin cytoplasmic domain (20,24,25,29, 33), allowing the initiation of focal adhesions. The intracellular events associated with integrin–ligand binding and focal adhesion formation may explain why integrins seem to synergistically enhance the effects of growth factors on cells (2).

*d. Growth Factors*

Integrins may enhance the actions of growth factors by increasing receptor clustering (20,25). The actin cytoskeleton and focal adhesion proteins may act as a scaffold that coordinates interactions between integrin– and growth factor receptor–tyrosine kinases (30). Focal adhesion kinase can be activated by growth factors or by integrins, so FAK is a plausible location for integrin and growth factor signaling pathways to converge (30,33). Integrins cooperate with growth factors in the activation of the MAPK pathway by increased clustering and phosphorylation of FAK (20,21).

Extracellular growth factors activate different Rho family small GTPases that are essential for the formation of F-actin cytoskeletal structures (18). Signal transduction mediated by Rho and Rac, in response to growth factors and extracellular matrix proteins, is required for actin cytoskeletal reorganization and assembly of focal adhesions (19). Convergence of the adhesion and growth factor pathways is important for cell proliferation and cell cycle progression (3,19).

## B. Cell Migration

Cell migration is dependent on rapid controlled changes in integrin-dependent cellular adhesion (1) and plays key roles in both normal physiology and disease. The ability of cells to migrate may be defined by four major factors: the amount of extracellular ligand present, the amount of integrins present, and the binding affinity and avidity of the integrins (34–36). The ligand concentration needed for a cell to migrate at its maximum speed has an inversely proportional relationship with the amount of integrin expression on the cell surface and the integrin–ligand binding affinity (36). Cellular migration may also be affected by the spatial representation or avidity of integrins on a cell surface. When integrins are clustered, the ligand density necessary for cell migration is greatly decreased (35). The attachment of integrins to the actin cytoskeleton couples

**Figure 14.6** Cell migration depends on adhesion. (A) The cell forms a protrusion to the front. (B) The protrusion adheres to the substrate; the cell pulls against that adhesion site to move forward. (C) As the cell continues to move forward, it begins to pull against an adhesion in the rear. (D) The adhesion site in the rear of the cell has been pulled away from the substrate; the cell is in a new position and the process begins again.

integrins to the actomyosin contractile system, which is necessary for cell motility (37).

In cellular locomotion, one end of the cell spreads while the other retracts; therefore this process may be considered to be a kind of polarized cell spreading (25). The basic mechanism behind cell locomotion is polymerization of the actin cytoskeleton (38). One main type of actin-based cell motility is known as amoeboid movement. Once a cell has adhered to a substrate, a lamellar protrusion is formed (Fig. 6) (38). Protrusion is tightly coupled with actin polymerization (38). This protrusion adheres to the substrate. The cell body and nucleus then move forward into this protrusion in a process known as traction (38), which involves the cooperation of actin and myosin cytoskeletal filaments. The cytoplasm left behind the cell body after movement is known as the tail. After traction occurs and the main cell body has moved forward, this tail de-adheres and retracts and the locomotion process begins again (38).

## III. MODIFICATION OF BIOMATERIAL SURFACES: CHEMICAL CONSIDERATIONS

Following the rationale that cellular- and molecular-level processes (such as cell adhesion, proliferation, and intracellular signaling) ultimately direct the healing and maintenance of healthy tissue around an implant, a great deal of current biomaterials research is devoted to understanding and controlling the cellular-level processes described in Section II of this chapter. Many investigators are utilizing knowledge of receptor–ligand interactions, particularly the present understanding of integrin–ligand interactions, and modifying surface parameters of biomaterials in attempts to understand and control the behavior of cells. If the “correct” ligands are present on a biomaterial, either as distinct biomolecules chemically immobilized on the surface or as conformationally available domains of adsorbed proteins, then cell membrane receptors should interact with the ligands. If the “appropriate” types and numbers of receptor–ligand complexes are formed, signals will be sent to the cell nucleus via intracellular signaling cascades, and consequently the functions of the cells on the biomaterial could be regulated. Currently, determining the correct ligands and the appropriate receptor–ligand complexes for particular biomaterial applications is a challenge. This section reviewing recent work on the design of polymer surfaces in order to control cellular behavior is divided into three categories of chemical surface modification strategies: physicochemical methods, biochemical methods, and morphological methods (39).

### A. Physicochemical Modifications

Cell adhesion, spreading, and migration on a substrate may be influenced by modifying the physicochemical surface properties of the material or by changing the surface charge, energy, and/or chemical composition of the material (39). One focus of much materials research is the hydrophilicity/hydrophobicity of surfaces, often characterized as wettability. A variety of cell lines including corneal epithelial cells, endothelial cells, fibroblasts, and bone-derived cells have demonstrated increased adhesion and spreading on hydrophilic surfaces (34,40–43). Webb et al. demonstrated that when materials were exposed to dilute serum, fibroblast attachment, spreading, and cytoskeletal organization were increased on hydrophilic (oxidized thiol-, quaternary amine-, and amine-modified glass) versus hydrophobic (thiol- and methyl-modified glass) surfaces (40). Differences in charge and wettability influenced only cell attachment on hydrophilic surfaces (40). In the absence of serum, positive charge had a large influence on the number of adherent cells, as demonstrated by the large number of cells adhered to the quaternary amine–modified glass and the small number of cells attached to the oxidized thiol–modified glass (40). Griesser et al. studied the effects of both surface hydrophilicity and nitrogen content (in the presence of serum) on human umbilical vein endothelial cell and human dermal fibroblast adhesion (43). Amine and amide compounds were polymerized onto fluorinated ethylene propylene copolymer using a low pressure gas plasma. The number of adherent cells increased with hydrophilicity, and in general the amide plasma polymers were the most adherent surfaces (although the individual monomer and the plasma parameters also affected cell attachment) (43). Dalton et al. studied the effects of surface hydrophilicity, in the presence and absence of serum proteins, on colonization and migration of human bone-derived cells (42). Vitronectin and fibronectin were used as model serum proteins, and the substrates tested were untreated polystyrene and sulfuric acid–treated polystyrene surfaces (possessing surface oxidative and sulfonic functional groups) (42). Results indicated that cells preferentially adhered to and migrated on hydrophilic surfaces; in fact, the cells would not migrate across a border between hydrophilic and hydrophobic surfaces (42). Vitronectin was found to stimulate cellular migration, while the same concentration of fibronectin was found to be insufficient for this activity (42). Evans and Steele studied the effect of hydrophilicity on corneal epithelial cell adhesion to tissue culture and untreated polystyrene, in the absence of fibronectin and vitronectin (41). A large amount of cell attachment and spreading was observed on the hydrophilic surfaces; however, a small number of cells also adhered to

the moderately hydrophobic untreated polystyrene surface (41).

Many polymers designed for the control of cellular functions use copolymer grafting and polymer coatings to elicit specific cell behaviors. Mayes et al. studied two different surfaces for the control of cellular activity and of protein adsorption. First, using silicone wafers with either end-grafted star copolymers or linear polymers of poly(ethylene oxide), it was found that star polymers provided good resistance to protein absorption; however, a combination of star and linear copolymers gave complete resistance to protein absorption at relatively low densities of poly(ethylene oxide) (44). The second substrate examined was a comb copolymer with a poly(lactide) backbone and poly(ethylene glycol) (PEG) teeth, which assumed a brush structure in water and showed excellent resistance to protein absorption (44). Due to its highly mobile chain conformation in water and large excluded volume, PEG is well known to repel protein adhesion and subsequent cell–surface interactions. Addition of bioactive ligands to PEG surfaces could be an opportunity to create surfaces which suppress nonspecific protein adsorption, yet still make the ligands of interest available for interactions with cells (44). Kao et al. reported that otherwise protein adhesion– and cell adhesion–resistant PEG networks could be grafted with interleukin 1- $\beta$  or a component of complement C3a to elicit macrophage adhesion, or with C3a and fibronectin to elicit fibroblast adhesion (45). Drumheller and Hubbell have created a polymer system incorporating PEG throughout a hydrophobic, densely crosslinked matrix; this retained the bulk properties of the substrate while still providing a substrate that resisted protein and cell adsorption (46). Du et al. prepared a PEG-grafted phospholipid bilayer surface; the PEG grafting greatly decreased the amount of surface-bound fibronectin, albumin, and laminin and also greatly decreased the number of surface-adherent erythrocytes, lymphocytes, and macrophages (47). Iwasaki et al. investigated the effects of phospholipid grafts on platelet and protein adsorption to polymer substrates in the presence of serum (48). Three  $\omega$ -methacryloxyalkyl phosphorylcholine (MAPC) polymers were grafted onto polyethylene backbones using a corona discharge treatment (48). The amount of fibrinogen adsorbed to the polymer surface decreased as the phospholipid density increased; the amount of adsorbed fibrinogen decreased with an increase in the length of the methylene chain (increasing hydrophobicity) on the MAPC unit (48). The number of platelets in serum attached to the polymer decreased as the density of the MAPC grafts increased; however, there was no clear relationship between the platelet adhesion and MAPC chain length (48).

The coating of substrates such as silicone and glass with

polymer films can completely hide the nature of the underlying substrates, allowing the creation of a biologically active surface (49). By using self-assembled monolayers and appropriate monomers and initiators, many surface compositions can be created in a very controlled manner (49) using thermal or photopolymerization procedures. Ruhe et al. demonstrated that surfaces modified with poly(methacryloyl oxypropyl (trimethyl ammonium bromide)) and poly(methyl methacrylate) promoted neuron adhesion and outgrowth through interactions of the cells with the surface positive charges (49). Recently, Zhang et al. synthesized a novel nontoxic biodegradable lysine-di-isocyanate-based urethane polymer (50). *In vitro*, this polymer has been found to support bone marrow stromal cell attachment and viability, opening the door for future synthesis of biodegradable peptide-based urethane polymers and new applications in cellular engineering (50).

Modification of polymer surfaces can involve the deposition of nonpolymeric materials. Khang et al. have studied platelet adhesion on gold sputter-coated polymer surfaces (51). Platelet adhesion to the substrate was decreased and cell adhesion and growth was increased due to the alterations in surface wettability as well as to the chemistry of the gold (51). Another group, Kaibara et al., has investigated the effect of carbon deposition as a means of controlling cells on polymer surfaces (52). The adhesion and proliferation of endothelial cells on a carbon-deposited polymer surface was greatly improved, most likely due to serum proteins preferentially adsorbing to the surface (52).

## B. Biochemical Modifications

The attachment of biomolecules to polymer surfaces could be an important tool for controlling cell–biomaterial interactions. Covalent immobilization of various integrin-binding peptides on a variety of materials has been shown to mediate the adhesion of many cell types [for example, osteoblasts (53–56) fibroblasts (57–63), endothelial cells (64–69), and neuronal cells (64,70–74)]. Increased cell adhesion, proliferation, and/or spreading has been obtained by grafting the specific peptide arginine–glycine–aspartic acid (RGD) to polymer surfaces (56,58,61,75–78). RGD is probably the most well-known integrin ligand and promotes adhesion of a number of cell types, including bone-derived cells (53,54,56), fibroblasts (58,61,75,77), macrophages (79), and aortic endothelial cells (76). Surfaces modified with peptides that mimic the adhesive activity of glycosaminoglycan-binding domains in cell adhesion proteins (and which are not integrin ligands) can also mediate cell adhesion via interactions with cell surface heparin or chondroitin sulfate proteoglycans (54,80,81). Biochemical surface modifications are not limited to the use of peptides;

entire proteins may be immobilized on surfaces as well. For example, polyurethane substrates with surface-immobilized heparin demonstrate excellent blood compatibility *in vitro* and *in vivo* (82), and enhanced human umbilical vein endothelial cell adhesion to a variety of fibronectin-grafted polymers has been reported (83,84).

To date, biochemical surface modification strategies show a good deal of promise for controlling cellular functions at the tissue–implant interface. However, a number of questions must still be answered to fully evaluate the potential applications of this emerging area of research. Can integrin-binding peptides reproducibly control cell functions other than adhesion? Can surface modifications be developed to allow selective control of particular cell types, even when multiple cell types are present at the surface? How will biochemical surface modifications fare during the complex wound healing processes which occur at the tissue–implant interface *in vivo*? Continued development of surface modification approaches, as well as of analytical methodologies to quantitatively characterize these novel surfaces and the resulting cell/biological responses, will help answer these questions.

## C. Morphological Modifications

Chemical micropatterning of polymer surfaces is a recent development in the pursuit of controlling cell–surface interactions. This approach allows very specific control of cell function, since micropatterned surfaces may contain areas supporting and areas inhibiting cellular adhesion (85). Cells will adhere preferentially to areas “patterned” to support cellular attachment and can migrate on these surfaces within the patterns supporting adhesion (85). Currently, most surfaces are morphologically modified using photolithographic patterning techniques. However, soft lithographic techniques such as microcontact printing, patterning using microfluidic channels, and laminar flow patterning (86) may provide advantages over photolithography since these techniques are relatively simple, inexpensive, and do not need extremely stringent environmental conditions (86). Most importantly, these techniques allow the patterning of surfaces with delicate ligands while providing control over surface chemistry and the cellular environment (86). Micropatterning techniques have been used in a number of studies of cell–biomaterial interactions. A few examples include investigations of human bone–derived cell preferential attachment and spreading on N-(2-aminoethyl)-3-aminopropyl trimethoxysilane-treated regions as opposed to dimethyldichlorosilane-treated areas (87) and the role of vitronectin on the attachment and distribution of these cells (88); the control of retinal pigment epithelial cell attachment, spreading, pro-

liferation, and morphology on microcontact-printed surfaces (89); and the use of microtextured membranes for cardiac myocyte adhesion and spatial orientation (90).

#### IV. MODIFICATION OF BIOMATERIAL SURFACES: ARCHITECTURAL AND MECHANICAL CONSIDERATIONS

The majority of current efforts to understand and influence cell–biomaterial interactions have focused on controlling the chemistry of the biomaterial surface. This approach is certainly logical, since it builds on the knowledge that cells respond to chemical stimuli; however, this approach neglects an important and broad class of cellular stimuli. In vivo, cells are typically exposed to, and thus must be able to respond to, a mechanically dynamic environment. Depending on cell type and maturation state, cells are able to detect and respond to mechanical strain, fluid shear, electromagnetic forces, etc. Researchers have, in some cases, chosen to exploit the natural cellular responses to mechanical stimuli by carefully choosing the mechanical and structural parameters of biomaterials presented to cells.

##### A. Surface Architecture

The term “architecture” is intended to refer to planned, three-dimensional surface structure and topography at the micron scale. Cellular responses to microtopographical features of substrates in vitro have been extensively studied over the past decade. It is widely accepted that the microtexture–cell interaction can be a powerful stimulus, especially in a controlled in vitro cell culture environment. Surface microtexture has been shown to influence cellular shape, proliferation, motility, and adhesion (91,92). Many attempts to control architectural parameters have involved adding microgrooves or micropores to the substrata used in cell culture (93,94), while other studies have attempted to correlate a general surface roughness to cellular responses (95). For an extensive discussion of cellular responses to topographical phenomena, see the excellent review by Curtis and Wilkinson (92).

##### 1. Microgrooved and Microporous Surfaces

In the presence of microgrooves, many cells undergo a phenomenon known as contact guidance. That is, the cells align or orient themselves in the direction of the groove. Various studies have attempted to determine optimal groove width (96), groove depth (97), and groove ridge (98) dimensions to influence cellular functions. Because the contact guidance response varies according to cell type (99), recommended values for these surface structure pa-

rameters will probably vary depending on the intended application of the biomaterial.

The incorporation of micropores in tissue engineered scaffolds for corneal epithelial cells has been shown to allow essential nutritional fluxes (94). Researchers are currently investigating cellular and tissue responses to various physical parameters of microporous surfaces. For example, Nakayama et al. conducted an in vivo canine study which correlated pore density with neointimal tissue thickness and thrombus formation in polyurethane cardiovascular stents (100). Pore diameter was held constant in this study at 30  $\mu\text{m}$ ; increased micropore density (percentage of total pore area per unit area: 0.3, 1.1, and 4.5%) aided tissue ingrowth, reduced the thickness of thrombus layer, and resulted in a thinner neointimal layer (100). Cell responses to materials incorporating micropores of various sizes (ranging from 0.1 to 30  $\mu\text{m}$ ) have also been investigated (94,100–102). For fibroblasts in vitro, proliferation and adhesion increased as the micropore size decreased from 8 to 0.2  $\mu\text{m}$  (102). This result is consistent with other reports of cell interactions with microscale surface topographical phenomena (91), suggesting that the scale, or size, of architectural features has a greater influence than the actual geometrical structure or shape in governing cell–biomaterial interactions.

##### 2. Surface Roughness

Surface roughness, though difficult to define and quantify, has been used to influence cellular functions on biomaterials. Roughness can be characterized by using a scanning mechanical microscope or profilometer to quantify surface topological aspects including the average surface height, distance between highest and lowest points, and increase in total surface area made possible by the roughness (as compared to a smooth surface of equal cross-sectional area) (103). Using corneal and vascular tissue from 14-day chick embryos, Lampin et al. showed a positive correlation between surface roughness of poly(methyl methacrylate) and cell adhesion. This increase was attributed to increased surface hydrophobicity and subsequent serum protein adhesion rather than directly to specific topological parameters of the surfaces (103). Compared to satin-polished titanium surfaces, roughened titanium surfaces enhanced osteoblast adhesion as well as production of extracellular matrix and subsequent mineralization (95). Surface roughness has been shown to be inversely correlated with MG63 osteoblast-like cell proliferation (104,105). However, MG63 osteoblast-like cell alkaline phosphatase activity and matrix production (indicators of cell differentiation) were positively correlated with increased surface roughness (104,105). These results suggest that in vitro

topographical parameters of surface roughness (or secondary effects of surface roughness) may be used to direct cell–material interactions.

### 3. In Vivo Evaluations of Microtextured Biomaterials

In vivo studies concerning microtextured material–cell interactions have had mixed results. Studies of microgrooved silicone substrates implanted subcutaneously in the guinea pig (97) and of microgrooved polystyrene implants in the goat (106) both concluded that the microgrooved surfaces produced the same cellular and tissue response as smooth surfaces: fibrous capsules separated from the implant by a layer of inflammatory cells. The microtextures did not aid the subcutaneous wound healing response, perhaps as a result of differences between the material properties of the implant and the subcutaneous soft tissue surrounding the implant (106). It has also been suggested that these results were due to the influence of inflammatory cells present at the implant surface, which formed an amorphous layer between the surface architecture and the connective tissue. Because inflammatory cells do not respond to the contact guidance phenomenon (107), the cells in the connective tissue may have been unable to sense and respond to the microtopography (97).

However, in other areas or applications, microtextures may prove to be beneficial. Roughened surfaces have been reported to yield better integration of breast and subcutaneous implants as well as enhanced osteointegration and less fibrous encapsulation when compared to the performance of smooth surfaces (108). As previously described, the addition of micropores to a cardiovascular stent has been reported to aid tissue ingrowth, reduce thrombus thickness, and yield a thinner neointimal layer (100). Moreover, it is possible that the architecture of a surface could be planned to maximize the addition of bioactive proteins or ligands (97), creating a biomaterial which uses dual (both chemical and structural/topological) strategies for controlling cell–biomaterial interactions.

### B. Special Application: Scaffolds for Tissue Engineering

Biomaterials used for tissue engineering present special challenges to materials scientists and engineers. On the macroscopic scale, a material scaffold for tissue engineering must have an appropriate shape and sufficient bulk mechanical properties for the intended application. On the microscopic scale, the scaffold must have microstructural and surface characteristics which are conducive to cell growth. Many tissue engineering efforts currently utilize

biodegradable, porous matrices as scaffolds; these materials provide a temporary three-dimensional structure to which cells can adhere and, ideally, maintain their normal differentiated function. Over time, the scaffold can be broken down in vivo, either by hydrolysis or enzymatic activity, and replaced by the extracellular matrix (or tissue) deposited by the cells. A variety of scaffold microstructures have been developed for tissue engineering applications, including fiber-based scaffolds and sponge scaffolds with interconnected pores. Benefits of fiber-based scaffolds include extremely high porosity, up to 97% (109), and a high surface-to-volume ratio. One drawback to fiber-based scaffolds are a potential inability to withstand compressive loads (109), which could cause the scaffold structure to collapse in vivo. Fiber bonding techniques can strengthen scaffolds with respect to compressive loading (110), but may make it difficult to independently control porosity and pore size within the scaffolds (111).

To overcome some of the drawbacks associated with fiber-based scaffolds, a solvent-casting particulate leaching technique has been developed which produces sponge scaffolds, also referred to as foams (112). This technique allows control of porosity, pore size, surface-to-volume ratio, and crystallinity. The highly controllable nature of these foams makes them desirable scaffolds for tissue engineering applications.

### 1. Composition

Poly(L-lactic acid) (PLA), poly(glycolic acid) (PGA), and poly(D, L-lactic-co-glycolic acid) (PLGA) belong to the family of poly( $\alpha$ -hydroxy esters) and are commonly used polymers for the production of synthetic foam scaffolds for a number of reasons. First, these polymers seem to provide a good substrate for cell adhesion and proliferation. Second, because poly( $\alpha$ -hydroxy ester) polymers are degraded primarily via hydrolysis of the polyester bond, the degradation rate in vivo should not vary significantly from one individual to another. Moreover, the degradation rate can be modified via the selection of molecular weight during the fabrication process. In the case of PLGA, the degradation rate can also be controlled by varying the relative composition of the two polymers. Third, the degradation products of these polymers (lactic acid or glycolic acid) can be removed through naturally occurring metabolic pathways, primarily respiration. Finally, PLA, PGA, and PLGA have demonstrated biocompatibility, and the FDA has approved their use for a variety of different applications (113).

One drawback to the use of the poly( $\alpha$ -hydroxy ester) polymers is that the lactic and glycolic acid degradation products may lower the pH in the immediate vicinity of

the polymer (111). In the worst case, the microenvironment may become nonviable for the cells, creating necrosis. This is especially likely in the event that the implant undergoes autocatalysis (111). Since degradation increases with increasing acidity, the release of lactic and glycolic acid could positively feed back and cause the breakdown and release of even more acid products. In addition to cellular and tissue damage, a buildup of degradation products also has the potential to shorten the expected functional life of the scaffold matrix (114,115).

## 2. Porosity

Porosity and pore size are key factors for tissue engineering scaffolds since these parameters help determine a number of performance aspects of the scaffold. Depending on the fabrication technique used, the porosity can range from 0 to 95% (116–118), while pore sizes typically range from ~10 to ~700  $\mu\text{m}$  in diameter (114,117). Porosity can affect the overall initial mechanical strength of the polymer foam. Poly(L-lactic acid) and PLGA have been shown capable of supporting compressional forces of up to 10 kPa when fabricated with a porosity ranging from 80 to 93% (116). Porosity may also affect the rate of foam degradation. An increase in the polymer surface area exposed to the biological environment increases the rate of hydrolysis of the polymer units. Additionally, pore number and size delineate the surface area available for cell attachment, usually maximized as much as possible in tissue engineering constructs (but limited by the mechanical strength required for the specific application and the fabrication techniques). Finally, highly porous constructs can possess thinner pore walls and highly interconnected pore spaces. Interconnection of the pore spaces is important as this allows cells to penetrate deeper into the foam.

## 3. Design for Mechanical Properties

Historically, materials have been selected for implantation applications because they possessed adequate mechanical properties. The mechanical properties of polymer scaffolds vary widely depending on the foam fabrication technique used (112,117,119), even while the biomaterial is kept constant. Additionally, the same degradative properties which make these materials desirable for tissue engineering applications cause changes in the mechanical properties over time (118). The mechanical properties and structure of a tissue engineering scaffold mediate how mechanical stimuli from the biological environment will be transferred to cells within the scaffold. It is well-known that mechanical stimuli have an important role in governing the phenotype and functions of many cell types. Therefore, it is becoming increasingly important to be able to characterize scaffold

mechanical properties to determine if they are appropriate for use in engineered tissues. It is also important to look closely at points of cellular adhesion on the scaffold surfaces to see how and to what degree the macroscopically induced mechanical stimuli are being transferred to the microscopic environment of the cell. An increased fundamental understanding of how cells respond to mechanical influences may provide impetus to design polymeric biomaterials such that a desired micromechanical environment is provided to cells as another means of controlling cell–biomaterial interactions.

## V. CONCLUSIONS

Even the most basic cellular functions, such as adhesion, are the result of complex interactions between a cell and the extracellular environment. Controlling cellular functions on a biomaterial surface is a nontrivial undertaking. First, the correct type and amount of extracellular chemical ligand (or, potentially, mechanical stimuli) must be identified and reproducibly supplied at the biomaterial surface for communication with the cell. This could be accomplished by chemically modifying the biomaterial surface in a number of ways, by creating surface architecture, or by designing the biomaterial to transduce macroscopically applied mechanical loads into an appropriate mechanical microenvironment. Second, the necessary cell membrane receptors need to be identified and strategically targeted to suitably interact with the signal(s) at the biomaterial surface. The receptors must perform adequately, meaning that issues including but not limited to receptor conformation, activation, and ligation need to be addressed. Once a “link” is established between the intracellular and the extracellular environment via receptor ligation, the subsequent intracellular processes—often complex and overlapping chemical signaling cascades—must predictably cause desirable cellular functions. Enough beneficial cellular interactions with the biomaterial must occur to sum to a beneficial tissue interaction with the biomaterial.

Many of the scientific and engineering issues outlined herein can and should be modeled and tested under the controlled conditions possible with *in vitro* cell culture experiments. Computational models and analytical methodologies can help quantitatively characterize and confirm the interactions of cells and proteins with biomaterial surfaces, as well as the influences of mechanical stimuli on cell functions. Carefully designed *in vivo* studies can then follow to perform tests in the presence of conditions that cannot be replicated *in vitro* (e.g., stages of the wound healing process), but which are crucial to establishing the potential of a biomaterial for clinical use. Fundamental

studies in a number of research areas can contribute to the development of strategies for controlling cell and, ultimately, tissue interactions with biomaterials in a clinically desirable manner.

### I. INTRODUCTION

The main routes of administration for ocular therapeutics include topical, periocular, and intraocular routes (Fig. 1) (1). In addition, some ocular diseases may be treated by systemic dosage forms, either by oral ingestion or parenteral injection (2). However, the systemic route presents the great disadvantage of exposing all the organs of the body to the action of the drug, thus leading to unwanted side effects. Since such oral and parenteral systems are largely beyond the scope of this review, the systemic route will not be treated in this chapter.

For evident convenience reasons, the administration of medications to the eye by topical instillation of eyedrops into the lower cul-de-sac is undoubtedly the most popular method. The local instillation of drugs may be used to treat both surface and intraocular pathological conditions (1). However, efficient protective mechanisms such as solution drainage, lachrymation, and diversion of exogenous substances into the systemic circulation via the conjunctiva reduce considerably the availability of the applied drugs. Hence, the success of the therapy is based on frequent instillations for most of the pathological states encountered, leading to poor patient compliance. One of the most common methods to improve this parameter is to increase the

precorneal residence time of topical formulations by using polymers for the preparation of delivery systems such as hydrogels, micro- and nanoparticles, and inserts. The use of such systems for ocular applications has been recently reviewed by Baeyens et al. (3) and by Felt et al. (4). Though some of these systems provided interesting results for local diseases when compared with classical solutions, they remain unsatisfactory in most cases for the treatment of pathologies affecting the posterior segment of the eye. This is mainly due to the structure of the cornea, which is relatively impermeable to most drugs, and to the tight junctional complexes (*zonulae occludentes*) of the retinal pigment epithelium and retinal capillaries, a barrier which inhibits the penetration of substances from the blood flow into the posterior segment of the eye. To circumvent these barriers, different routes of intraocular drug delivery have been investigated.

The first part of this chapter is devoted to the description of some ocular diseases, describing briefly disorders that may be treated by local applications and those which necessitate intraocular interventions. The different polymeric systems (hydrogels, microparticulate systems, and solid dosage forms) allowing ocular drug delivery after local or intraocular administration are discussed in the second and third part of this chapter, respectively.

**Figure 15.1** Routes for the administration of ophthalmic therapeutics.

## II. PATHOLOGIES

### A. Topically Treated Pathologies

#### 1. Inflammation

Inflammation is one of the most common ocular disorders and can have several etiologic causes including trauma, viral or bacterial infections, immunorelated phenomena, or corneal ulceration (3). Blepharitis and conjunctivitis represent common cases of inflammation. Blepharitis describes a variety of inflammatory conditions of the eyelid margins, where usual symptoms are redness, thickening with scales and crusts, and shallow ulcers (5). It may be caused by bacteria, local allergic reactions, or sebaceous secretions from the skin (5). The inflammation of the conjunctiva can be the consequence of bacterial, fungal, or viral infections or of an allergic reaction. In the case of bacterial conjunctivitis, the main causative agents include *Staphylococcus aureus*, *Pneumococcus* species, and *Haemophilus aegyptius* (5).

Treatments of inflammation vary with the etiologic agent and may be based on the use of a topical steroidal active compound associated with nonsteroidal anti-inflammatory drugs such as diclofenac and flurbiprofen, immunosuppressive agent (azathioprine), antimicrobial

agents (tobramycin, ofloxacin), and mydriatic-cycloplegic drugs (pilocarpine) (3).

#### 2. Keratoconjunctivitis Sicca

The terms dry eye and keratoconjunctivitis sicca (KCS) refer to a group of disorders of the ocular surface connected with reduction or instability of the precorneal tear film (6). The symptoms usually identified in such diseases include itchy and burning sensations, photophobia, reflex tearing, redness, blurred vision, mucous strands, and intolerance to contact lenses (7). Diagnosis of dry eye may be based on physical examination as well as on laboratory tests (Table 1). The treatment of KCS relies mainly on the

**Table 15.1** Diagnosis Tools for the Investigation of KCS

Physical examination	Laboratory tests

Fluorescein staining	Goblet cell count
Tear film breakup time	Tear osmolarity
Schirmer test	Tear mucin measurement

Source: Ref. 6.

use of artificial tears to fulfill the physiological role of normal tears, e.g., lowering the surface tension of the tear film, forming a hydrophilic layer, and enhancing the tear volume. Others possible treating agents include Vitamin A derivatives, mucolytic (N-acetylcysteine) and tear stimulating products (bromhexine) (8).

### 3. Glaucoma

Glaucoma is a consequence of the impairment of the aqueous humor outflow. An increased intraocular pressure, progressive optic neuropathy, visual impairment, and in severe cases blindness are common characteristics of this disease (3). The therapy of glaucoma aims either to reduce the rate of aqueous humor secretion or to increase the aqueous humor outflow. The first approach is achieved by using beta-adrenergic agonists (epinephrine) and antagonists (timolol) or carbonic anhydrase inhibitors (acetazolamide), whereas the second approach is based on the use of parasympathomimetic agents (pilocarpine) (9). However, when such medical therapy is unsuccessful argon laser trabeculoplasty or surgical actions are required (see Section II. B) (9).

## B. Intraocular Pathologies

### 1. Glaucoma Filtering Surgery Failure

Glaucoma filtration surgery entails the construction of a fistula between the anterior chamber and the subconjunctival space as an alternative or enhanced passage for the drainage of the aqueous humor from the eye in order to reduce the intraocular pressure and preserve vision in severe cases of glaucoma. The outcomes of filtration surgery are affected by wound healing, a normal event. The healing response is initiated at the moment of injury, when the tissue architecture is disrupted. A complex cascade of events characterized by coagulation, inflammation, angiogenesis, extracellular matrix deposition, and epithelialization occur and fibroblasts proliferate, leading to the obstruction of the filtration site (10). Pharmacological agents have been used to control certain stages of the wound healing response; these include anti-inflammatory agents, antimetabolites or antiproliferative agents, and collagen crosslinking inhibitory agents (10).

### 2. Proliferative Vitreoretinopathy

Proliferative vitreoretinopathy (PVR) is a pathologic condition occurring in part as a complication of retinal detachment, in which cells originating from the retina and transdifferentiating into fibroblasts proliferate, inducing the formation of retractile membranes on both surfaces of the

detached retina (11). The aim of the pharmacological treatment of PVR is to intervene at different stages of disease progression (12), that is, inflammation and cellular proliferation. In the inflammatory phase, long-effect steroids are more suitable, while antifibroblastic drugs can be used in the proliferative phase. Proliferative vitreoretinopathy is a recurrent disease; even if surgical removal of the contractile membranes enables flattening of the detached retina, the proliferation process can reappear (13). The controlled release of anti-inflammatory and antiproliferative drugs can both prevent the development of PVR in high risk eyes and hinder PVR recurrence while minimizing toxic side effects and improving patient comfort.

### 3. Cytomegalovirus Retinitis

Cytomegalovirus (CMV) retinitis is an opportunistic infection frequently seen in patients with acquired immune deficiency syndrome (AIDS), occurring in 15–40% of patients (14), and those with other forms of immune suppression. Ganciclovir was the first virustatic agent that showed an activity against CMV in patients with AIDS (15). Another drug used in the treatment of CMV retinitis is foscarnet, an alternative to ganciclovir if resistant strains of cytomegalovirus develop (16). Both drugs are administered systemically or, if an intolerance develops, intravitreally.

A promising new treatment of CMV retinitis consists of the intravitreal administration of a phosphorothioate oligonucleotide, fomivirsen (17). Its activity is very selective against the virus; its half-life of elimination from the vitreous is long; and it triggers no relevant toxicity.

### 4. Endophthalmitis

Endophthalmitis is an inflammatory response to the invasion of the internal structures of the eye by replicating microorganisms, i.e., bacteria, fungi, or parasites (18). This disease is most often a complication of ocular surgical procedures such as cataract extraction, corneal transplantation, glaucoma filtering surgery, or retinal detachment surgery. Another cause is a penetrating ocular trauma, which can occur in up to 20–30% of the cases. The vitreous body and the retina are generally involved, and depending on the virulence of the infectious agent this disease can lead to retinal necrosis and blindness within a very short period of time.

The current therapeutic strategy for presumed endophthalmitis includes the intravitreal injection of an antibiotic or more frequently a combination of broad-spectrum antibiotics (19). Besides antibiotics, intravitreal corticosteroids such as dexamethasone play an important role in the man-

agement of bacterial endophthalmitis because of their beneficial effect in reducing the inflammation that accompanies the infection. Therapy for fungal endophthalmitis is similar to that for bacterial endophthalmitis except that antifungals, rather than antibacterials, are administered.

### 5. Posterior Uveitis

Posterior uveitis, whether it is endogenous and chronic or associated with systemic diseases such as Behçet's disease, is a pathology characterized by a vitreal inflammation and a retinal vasculitis. In the majority of patients, the etiologic agent is not known. It has been postulated that in many cases uveitis may be autoimmune in origin. Uveitis usually has a low response to treatments with steroids or cytotoxic drugs, and it may require long-term chronic treatment. If untreated, the outcome is generally severe, eventually leading to progressive blindness. The immunomodulating drug cyclosporine was investigated and found effective in treating experimental autoimmune uveitis and acute inflammation unresponsive to the usual treatment (20).

### 6. Posterior Capsule Opacification

Cataract extraction with the implantation of a posterior chamber intraocular lens has become the most popular technique for cataract surgery. However, one of its most frequent complications is posterior capsule opacification (PCO), which appears in 50% of the cases between the third and fifth year postoperatively (21). It is caused by migration, proliferation, and metaplasia to fibroblasts of the epithelial cells of the anterior capsule on the posterior capsule surface. The prevention of PCO, other than by surgical procedures such as cryocoagulation, consists of the administration of antiproliferative drugs in the intraocular infusion fluids during surgery (21).

### 7. Retinal Degenerative Diseases

Age-related macular degeneration (AMD) is the leading cause of irreversible visual loss in the United States in the elderly people (22). Blindness associated with AMD is caused by degeneration of visual cells, a result of degenerative changes in the retinal pigment epithelium (RPE). Whether the disease takes the form of localized degeneration without the complications of vascular invasion or whether cells are destroyed by the disruptive effects of neovascularization, degeneration of the RPE precedes or accompanies death of the associated rods and cones. Laser photocoagulation of choroidal neovascular membranes (CNVM) is currently the only well-studied and widely accepted treatment modality. However, it is beneficial for only a small minority of patients and is associated with an

unacceptably high CNVM persistence and recurrence rate. Consequently, investigators have attempted to develop new modalities for treatment of CNVM: subretinal surgery, radiation therapy, photodynamic therapy, and pharmacological inhibition of CNVM formation (23). Pharmacological therapy has focused on interfering with inflammation, oxidative stress, and angiogenesis. Inflammation is often associated with neovascular membranes, and steroids have been shown to have a direct antiangiogenic activity, in addition to their anti-inflammatory effects. Free radical production is partly the result of the high oxygen consumption by the retina. Antioxidants have been proposed as a preventative measure to reduce lipid peroxidation. Antiangiogenic drugs are the latest addition to the list of suggested pharmacological treatments for AMD. These drugs may be useful in treating and preventing the neovascular phase of this disorder. Local administration would be possible with the advent of slow-release technologies for chronic drug delivery.

## III. TOPICAL DELIVERY SYSTEMS

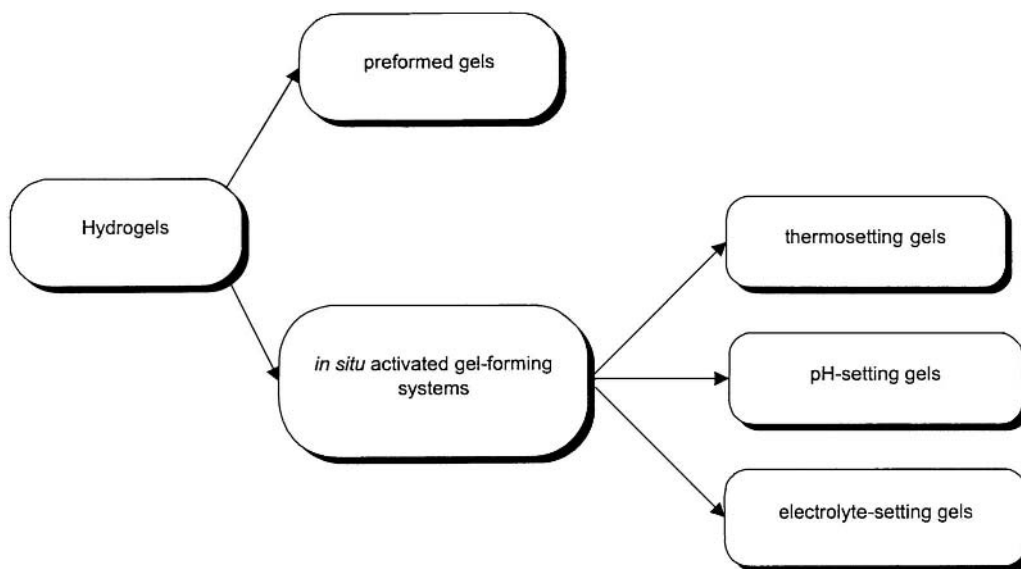

### A. Polymeric Gels

Hydrogels, also called aqueous gels, are defined as colloidal dispersions of high molecular weight polymers which have the ability to swell, but not dissolve, in water or aqueous solvent systems (24–26). Macromolecules in the hydrogels form a swollen, crosslinked network of twisted matted strands bound together by various electrochemical interactions like covalent bonds or somewhat weaker intermolecular forces (van der Waals forces and hydrogen bonds, electrostatic forces, ion bridging interactions, or hydrophobic interactions). The network contains crystalline and amorphous regions throughout the entire system (27,28).

The desired properties of polymers used in ophthalmic hydrogels as drug delivery systems are the following (29):

- Chemical compatibility with the other excipients and the drug
- Stability after prolonged storage and, if possible, heat stability permitting sterilization by autoclaving
- Absence of ocular irritation or toxicity
- Little or no problem for vision
- Promotion of precorneal retention due to viscosity or bioadhesive properties
- Physicochemical properties (pH, osmolality) compatible with the ocular use

Polymeric hydrogels used in ophthalmology are generally classified in two distinct groups (Fig. 2). The first category includes systems which are administered as viscous

**Figure 15.2** Classification of hydrogels as sustained ocular drug delivery systems.

preparations which do not undergo any other transformation on the eye such as an eventual dilution by lachrymation or gradual elimination by lachrymal drainage. These hydrogels are called preformed gels, i.e., they are structured before ocular application. The second group refers to polymeric systems that are topically applied on the ocular surface as solutions or suspensions and which shift from a sol to a gel phase as they are exposed to ocular physiological conditions like pH, temperature, or the presence of ions. This second group of hydrogels is called in situ activated gel-forming systems. Both polymeric gels—preformed as well as in situ forming gels—are used for the ocular route to improve drug bioavailability by extending drug residence on the eye (30). The main advantage of in situ activated gels over preformed hydrogels is that they facilitate the administration of the ophthalmic preparation, since the preparation is conveniently delivered in a drop form and undergoes a transition from a solution to a gel on the ocular surface, thus permitting an administration of accurate and reproducible quantities in contrast to already gelled preparations (31).

The mechanism of drug release from hydrogels involves a combination of diffusion and erosion of the gel surface (30). Due to the hydrophilic nature of the gels, tears readily diffuse into the gel interior thereby rapidly leaching out water-soluble drugs such as pilocarpine salts.

There are two general methods for the loading of hydrogels as drug carriers (25). In the first method, the hydrogel monomer is polymerized in the presence of the drug by addition of chemicals—initiator and crosslinker—so

that the drug remains trapped in the polymeric matrix. This method has the disadvantage that some polymerization conditions may have deleterious effects on the drug and that some chemicals are toxic and difficult to extract from the polymeric device. In the second method, a polymer is allowed to swell in a suitable drug solution or the drug is added to a preformed hydrogel and diffuses through the polymeric network.

It should be noted that in the ophthalmic field, hydrogels are not all loaded with drug, for example, in the case of artificial tears, where the polymeric hydrogels are themselves used as a treatment of tear film disorders (32). This point is further developed subsequently.

From a medical point of view, ophthalmic hydrogels aim to optimize ocular drug delivery of an active ingredient by prolonging the corneal contact time of the drug and decreasing its drainage rate, thus increasing its ocular bioavailability. Furthermore, the hydrogels may also lower the frictional resistance between the cornea and the eyelids which occurs with each blink, thereby exerting a lubricating effect beneficial in tear film disorders (33).

## 1. Preformed Hydrogels

### a. Cellulose Derivatives

Semisynthetic water-soluble cellulosic polymers have been widely used in ophthalmic preparations such as eye drops, artificial tears, and contact lens solutions as viscosity-increasing agents. The first cellulosic derivative used in ophthalmology was methylcellulose (MC), a topically

inert material able to provide gels of high viscosity (34,35). Other cellulosic compounds used in ocular preparations include hydroxyethylcellulose (HEC), hydroxypropylcellulose (HPC), hydroxypropylmethylcellulose (HPMC), and sodium carboxymethylcellulose (CMC Na). These viscolysers differ with respect to their degree of substitution and the nature of the chemical substituents, but present common properties include (36)

- Wide range of viscosity (400 to 15,000 mPas)
- Compatibility with many topically applied drugs
- Stability to autoclaving (120°C)
- Good ocular tolerance

The viscosity of cellulose derivative-based hydrogels depends on the molecular weight grade and on the substitution (nature, degree of substitution) of the derivative (37).

Methylcellulose and HPMC hydrogels are prepared by addition of hot (80–90°C) water to the polymer powder under strong agitation, followed by cooling for 24 h in the refrigerator and swelling of the polymer. Afterward, the final volume is adjusted. The preparation of HEC can be made with cold water. Carboxymethylcellulose and HPC hydrogels are obtained by sprinkling the polymer on the water surface and mixing and boiling the solution.

Cellulosic polymers have been extensively used for ocular drug delivery as viscous solutions in low concentrations rather than as hydrogels in higher concentrations. Some representative examples of clinical and pharmacological studies with these polymers are listed in Table 2. Several investigations have shown the efficacy of cellulosic derivatives in increasing ocular drug availability, by extending the corneal residence time, with respect to simple saline solutions (38–40). Ludwig and Van Ooteghem (41) used slit lamp fluorophotometry to compare the effect

of different cellulosic viscolysers, namely, HEC, HPC, and HPMC, on the ocular retention of a fluorescent tracer in human subjects. They concluded that HEC is more comfortable and thus is superior to the two other polymers in reducing the ocular elimination rate of the viscous eye drops. Other authors have compared the performance of cellulosic derivatives with more recently developed polymers in the field of ocular drug delivery. Generally these polymers, such as polyacrylic acid, sodium hyaluronate, and poly(vinyl alcohol), give better results than cellulose (40,42–45).

Currently, a large number of hydrogels on the market are formulated with cellulosic viscolysers, among them CMC Na (Celluvisc® from Allergan, Irvine, CA), HEC (AdSORBOTEAR® from Alcon, Fort Worth, TX), HPC (LACRISERT® from Merck Sharp & Dohme, West Point, PA), HPMC (LUBRITEAR® Solution from Bausch & Lomb, Tampa, FL), MC (Methocel® from Ciba Vision, Niederwangen, Switzerland).

#### b. Polyacrylic Acid

Polyacrylic acids, also called carbomers or carboxyvinyl polymers, are acrylic acid-based polymers which are available in different molecular weights and different structures (linear, branched, or crosslinked). Carbopol® resins (BFGoodrich Specialty Chemical, Cleveland, OH) are high molecular weight, crosslinked carbomers. Carbopol was introduced in the mid- to late-1950s as a group of synthetic, hydrophilic colloidal gums with improved and constant thickening properties at relatively low concentrations compared with natural gums (51).

Rheograms of carbomers exhibit non-Newtonian flow behavior. A pseudoplastic (decrease of the viscosity with increasing shear rates) or plastic (rheogram with a yield

**Table 15.2** Examples of Ocular Hydrogels Based on Cellulosic Derivatives

Cellulose derivative	Concentration (%)	Species	Drug	Ref.
Methylcellulose	NS	R	Tritiated pilocarpine	38
	1.0	R + H	Nonmedicated hydrogel	45
Hydroxyethylcellulose	1.1, 1.5, 3.4	H	Sodium fluorescein	46
	0.325, 0.5	R + H	Pilocarpine nitrate	39
Hydroxypropylcellulose	0.35–3.4	H	Sodium fluorescein	41
	1.2, 5.0	R + H	Pilocarpine nitrate	47
Hydroxypropylmethylcellulose	0.5	H	Nonmedicated hydrogel	48

	1.63	R + H	Tropicamide	40

Notes: NS, not specified; H, human; R, rabbit.

value) nonthixotropic (none or negligible hysteresis loop in the rheological curves) flow has been described (44,51–55). Carbopol gels have shown elastic properties (56).

Several mechanisms have been suggested to account for the formation of Carbopol hydrogels. Carbomer molecules in their dry state are tightly coiled, thus limiting their thickening capability (Fig. 3). When dispersed in water, the molecules begin to hydrate and partially uncoil. A cloudy acidic dispersion of low consistency is formed (51). Neutralizing the carbomer resin with a suitable base generates negative charges along the polymer backbone. Repulsion of these negative charges causes the polymer to completely uncoil in an extended rigid structure of high viscosity. Neutralization increases consistency and reduces turbidity. Another method for the thickening of Carbopol gels without neutralization involves hydrogen bonding of solvent molecules along the polymer chain to produce a rigid chain (57). The pH of such systems tends to be acidic. A third mechanism explaining the hydrogel formation involves the absorption of water by the crosslinked polymer to form a gel consisting of macroscopic, swollen particles (58,59). There is no evidence for any one mechanism, and it seems likely that gelation occurs by a combination of these processes (51).

The simplest way to prepare Carbopol hydrogels is to disperse the resin in water at room temperature and to neutralize the polymer with bases such as triethanolamine, sodium hydroxide, or even an active alkaline compound. The other method to form carbomer hydrogels is to add hydroxyl donors such as polyols (e.g., glycerine, propylene glycol), sugar alcohols (e.g., mannitol), or polyethylene oxide to carbomer dispersions.

Carbomers present many advantages for the ocular drug therapy, including (54,55,60):

- Good flow and good thickening properties at low concentration
- Relatively good patient compliance

- Excellent appearance
- Compatibility with many active ingredients
- Possibility to neutralize the polymer with a drug
- Bioadhesive properties

The bioadhesive properties are very useful for a controlled drug delivery to the eye because they enable a prolonged contact time between the eye and the drug and because they delay drug elimination (61). The mucoadhesion of carbomer involves several mechanisms such as chain interpenetration of the polymer in the mucus (since both carbomer and mucin are macromolecular expanded networks and both exhibit a significant hydration in aqueous media), hydrogen bonds (both have carboxyl groups), electrostatic interactions (both are ionic polymers), and hydrophobic interaction (both polymer have various hydrophobic functional groups) (62,63). Besides carbomer, other polymers having good mucoadhesive properties include hydroxypropylcellulose, carboxymethylcellulose, carbophil, gelatin, and hyaluronic acid (54,64). Davies and coworkers (65) have emphasized the importance of mucoadhesion for improving the ocular bioavailability of pilocarpine in rabbits and shown the superiority of bioadhesive Carbopol 934P over the nonbioadhesive poly(vinyl alcohol) (PVAL). Dittgen et al. (66) also found Carbopol to be superior to PVAL.

Several authors have examined the stability of carboxyvinyl polymers at various storage conditions and demonstrated the good stability of Carbopol 940 and 941, whose viscosity decreased the least (67,68). Comparing various Carbopol types (910,934,940,941), Unlü et al. (54) concluded that Carbopol 934 had the worst thickening properties and that Carbopol 940 had an excellent appearance and clarity when compared with the other types.

Many studies have explored the potential of carbomer in extending the corneal residence time and increasing the bioavailability of active compounds such as pilocarpine (43,44,69); some representative examples are listed in Table 3.

Figure 15.3 Schematic representation of the mechanism of the sol–gel transition of carbomers (From Ref. 51.)

**Table 15.3** Examples of Topical Hydrogels Based on Carbopol

Carbopol type	Concentration (%)	Drug	Species	Effects	Ref.
940	0.05, 0.1, 0.2	Tropicamide	H	Increased bioavailability	70
940	0.3	Tropicamide	R	Increased bioavailability compared to an ointment and a HPC hydrogel	52
940 and 910	0.6 1.5	Pilocarpine	R + H	2–3 × increase of the drug bioavailability; effects more pronounced in humans than in rabbits	69
940	NS <sup>c</sup>	Prednisolone (acetate)	R	4.5× increase of the aqueous humor levels; 4× increase of the concentration in the cornea	71
934	NS <sup>c</sup>	Prednisolone (sodium phosphate)	R	5.5× increase of the aqueous humor levels; 10.6× increase of the concentration in the cornea	71
940	1; 2; 4; 6	Pilocarpine	R	Extended duration of miosis	43
941	6	Pilocarpine	R	Extended duration of miosis	43
940	1.0–4.0	Flurbiprofen	R	More increased bioavailability than with pluronic F 127 hydrogels	72
934	0.49	Pilocarpine	R	Increased bioavailability as compared to a 6% PVAL hydrogel	65
940	0.1, 0.2	Fluorescein	H	Increased corneal retention	53
940	0.9–5.0	Pilocarpine	R	Extended duration of miosis	44

Notes: H, human; R, rabbit; HPC, hydroxypropylcellulose, 0.7% w/v; NS, not specified.

A large number of commercial products are based on carbomer, including tears substitutes like Lacrinorm<sup>®</sup> with carbomer 940 (Chauvin, Montpellier, France) and eye drops with active compounds such as Pilopine<sup>®</sup> (Alcon).

### c. Sodium Hyaluronate

Hyaluronic acid (HA) is a high molecular weight linear unbranched polysaccharide consisting of repeating disaccharide units of glucuronic acid and N-acetylglucosamine (73). It is a glycosaminoglycan and has a flexible open coil double helix conformation (74). The carboxyl groups of HA are dissociated at physiological pH, thus conferring a polyanionic character to the polymer. In the human body, HA plays an important role in retaining water in the intercellular matrix of connective tissues. It is present in diverse tissues including skin, tendons, cartilage, synovial fluid, and umbilical cords, but also in ocular fluids, particularly in the vitreous and the aqueous humor. Thus, it has been suggested that HA might be used in eye surgery as a substitute for aqueous humor or vitreous either to maintain the shape of the anterior chamber during cataract surgery or to protect corneal endothelium during lens implantation (75).

Until recently, HA had been produced by tissue extraction from umbilical cord of rooster comb, which made its ophthalmic solutions very expensive. However, HA can now be produced by microbial fermentation (76). A highly

purified sterile form can be produced in bulk with a variety of molecular weight ranges and at a cost considerably less than the tissue-extracted material. Healon<sup>®</sup> (Kabi Pharmacia, Sweden) is a patented ultrapurified fraction of the sodium salt of HA (77).

The use of hyaluronic acid in ocular therapy has been reviewed by Bernatchez et al. (78). The concentration of HA commonly used in eye drops varies between 0.1 to 0.3%.

Sodium hyaluronate solutions exhibit a typical pseudoplastic rheological behavior with a low viscosity at high shear rate (46). Its viscosity is shear dependent, and the hydrogel exhibits a drop in viscosity at high shear rates such as during blinking (shear thinning). This rheological property is particularly advantageous in ophthalmic applications because the high viscosity hydrogel can be administered with the advantage of longer ocular surface retention times but without the associated sensation of a foreign body, blurred vision, and patient discomfort as encountered with high viscosity Newtonian solutions (79). Furthermore, the low viscosity of HA hydrogels favors a homogeneous distribution on the whole corneal surface after each blink.

The performance of HA in extending the precorneal residence time of several ophthalmic drugs such as pilocarpine, gentamicin, and tropicamide is summarized in Table 4. The HA 0.25% vehicle led to a twofold increase of the bioavailability of topically administered gentamicin in

**Table 15.4** Ophthalmic Formulations Based on Sodium Hyaluronate

Concentration (% w/v)	Drug	Species	Effects	Ref.
0.25	Gentamicin sulfate	H	Increased bioavailability for at least 10 min	80
0.125, 0.2, 0.75	Pilocarpine HCl	R	Extended duration of miosis; increased corneal residence time and intraocular absorption	81, 82
5.0, 15.0	Pilocarpine nitrate	R	Prolonged miosis	83
	Tropicamide		Prolonged mydriasis	
	Sodium fluorescein		Extended corneal residence	
	Nonmedicated gel		Good mucoadhesion	
0.125, 0.25	Nonmedicated gel	H	No effect of the 0.125% gel on the ocular clearance; extended corneal residence with 0.25%	84
0.125	Nonmedicated gel	R	Extended corneal residence	85
0.125, 0.25	Nonmedicated gel	H	Extended corneal residence	84
0.1, 0.19, 0.25	Sodium fluorescein	H	Extended corneal residence	46

Notes: H, human; R, rabbit; HA; hyaluronic acid (sodium salt).

the human eye for at least 10 min after instillation compared to a saline isotonic buffered solution (80). Gamma-scintigraphic studies of a nonmedicated HA hydrogel also showed an extended corneal residence time at the surface of the eye (84,85).

#### d. Poly(Vinyl Alcohol)

Poly(vinyl alcohol) is a synthetic long-chain polymer obtained by condensation of vinylacetate and partial or full hydrolysis of the resulting poly(vinyl acetate) (86). It is available in various grades that differ in the degree of polymerization and residual acetate content, thus providing different solubilities (87). The molecular weight average has a significant influence on the viscosity: very high molecular weight grades show a very marked change in viscosity for a small change in concentration, whereas low molecular weight grades have little influence on the viscosity of the solution (76). Aqueous solutions of PVAL approximate a Newtonian rheological behavior (47,88).

Since PVAL was first introduced for ophthalmic use in the early 1960s (89) a lot of time and effort have been expended on exploring the influence on ocular bioavailability of various PVAL hydrogels compared mostly to other hydrogels such as cellulose preparations. Some representative examples of ophthalmic formulations based on PVAL and their subsequent effects on ocular bioavailability are presented in Table 5. There have been many contradictory results about the superiority of PVAL in prolonging the corneal contact time. On one hand, PVAL (1.4%) was reported to be superior to MC (0.5%) based on rabbit studies (89). On the other hand, PVAL (1.4%)

has exhibited a significantly shorter elimination time than HPMC (0.25–2.5%) (90). Other authors concluded that cellulose derivatives were superior to 1.4% PVAL (48,91,92). The rationale for these conflicting findings is explained by differences in flow properties and in the viscosity of the tested hydrogel. Indeed, when comparing hydrogels of different polymers, it is important to take into account not the concentration used of the polymers, but rather their viscosity. The importance of the viscosity was pointed out by Patton and Robinson (88), who demonstrated that two nonmucoadhesive hydrogels based on PVAL and MC with Newtonian rheological behavior and with the same viscosity range show comparable effects on the ocular residence time.

Attempts have been made to find the optimal concentration of PVAL in terms of decreased drainage of the hydrogel from the precorneal area. Patton and Robinson (88), testing PVAL concentration range between 0 and 5.0%, concluded that a 3% PVAL solution was the optimum because beyond this concentration large increase in viscosity resulted in only minor decreases in drainage rate and also resulted in a blockage of the drainage duct. However, the concentration of PVAL commonly used commercially is 1.4%, the rationale for this choice of concentration is the visual comfort, concentrated solutions leading to the sensation of foreign body and blurred vision (88). Kassem et al. (96) have reported that PVAL was the most effective vehicle, compared to other cellulosic derivatives, for increasing the ocular bioavailability of phenylephrine, a drug lowering the intraocular pressure (IOP) and added to a beta-methasone preparation in order to balance the side effect of the steroid (elevation of the IOP).

**Table 15.5** Effects of Polyvinyl Alcohol on the Precorneal Residence Time of Hydrogel Loaded or Not with Drugs Compared to Saline Solution

Concentration (%)	Type of PVAL	Drug	Species	Effects	Ref.
0–10.0	Various grades (20–90)	Pilocarpine nitrate	R	Delayed corneal drainage rate; prolonged aqueous humor levels	88
1.0–5.0	Polyviol W40/140	Nonmedicated (tracer $^{99m}\text{Tc}$ )	R	Prolonged residence time	93
1.2	High molecular weight (90 000)	Pilocarpine nitrate	R + H	Extended miosis time	47
1.4	NS	Nonmedicated (tracer $^{99m}\text{Tc}$ )	R + H	Diminution of the drainage rate	45
1.4, 2.8, 4.2		Sodium fluorescein	H	Prolonged residence time; 4.2%: discomfort, blurred vision	94
3.0–6.5	Polyviol W40/140	Nonmedicated (tracer $^{99m}\text{Tc}$ )	R + H	Prolonged residence time (more pronounced in rabbit than in man)	95
6.0	Fully hydrolyzed (MW 86 000)	Pilocarpine nitrate	R	Delayed corneal drainage rate; increased bioavailability	65
4	NS	Sodium fluorescein	H	Delayed corneal drainage rate	42

Notes: PVAL, polyvinylalcohol; R, rabbit; H, human; NS, not specified.

Poly(vinyl alcohol) is a common viscolyser used in many marketed eye drops such as Tears Plus® (Allergan), and Hypotears® (Ciba Vision).

#### e. Other Polymers

Various natural and synthetic polymers have been investigated as potential vehicles for ocular drug delivery and are still in development. These polymers include poly(vinyl pyrrolidone) (PVP), chondroitin sulfate, carrageenans, dextrans, xanthan gum, and chitosan. The synthetic polymer PVP has found interesting applications in ophthalmic solutions, eye drops, and contact lens solutions (40,97,98). They will be briefly described. Chondroitin sulfate is a natural mucopolysaccharide (glycosaminoglycan) acting as a flexible connecting matrix in cartilage and connective tissues (99). It has been examined as a potential polymeric vehicle, but the results were not conclusive in that chondroitin hydrogels failed to enhance the bioavailability of pilocarpine and cyclopentolate (100). Carrageenans are a group of water-soluble sulfated galactans extracted from red seaweed. The main gel-forming carrageenans fractions are the kappa and iota, while the lambda is known as non-gelling, because of its higher level of ester sulfate. Carrageenan hydrogels exhibit pseudoplastic rheological behavior and viscoelastic properties (101). Verschueren et al. (101) have reported the good acceptability of carrageenan hydrogels in human volunteers. Xanthan gum is an anionic

branched polysaccharide composed of glucose, mannose, and glucuronic acid. The polymer is obtained by fermentation of the bacterium *Xanthomonas campestris*. It has been examined for use in eye products and has shown interesting properties: Meseguer et al. (102–104) showed by gamma-scintigraphy that xanthan hydrogels are able to delay corneal clearance by tear flow in the human eye. Xanthan gum has been proposed as a polymer in artificial tears (105). Chitosan is a polycationic natural polymer which exhibits favorable properties for ocular administration such as biodegradability, nontoxicity, biocompatibility, and bioadhesion (106–108). Gamma-scintigraphic evaluation has shown the superior efficiency of chitosan for prolonging precorneal residence time of tobramycin with respect to a commercial collyrium containing the same antibiotic at a concentration of 0.3% (Tobrex®) (Fig. 4) (109).

## 2. In Situ Forming Gels

Gelling systems, also called phase transition systems, consist of a mixture of the drug with a polymeric material that has low viscosity in the dispensing bottle but changes to a very viscous solution or a gel once in contact with the eye (110). The sol–gel transition of in situ activated gel-forming systems occurs as a result of a chemical/physical change induced by the physiological ocular environment. The transition can be triggered by a shift in the pH, by changing the temperature, or by the presence of cations in

**Figure 15.4** Precorneal drainage of  $^{99m}\text{Tc}$ -DTPA in formulations containing 0.3% tobramycin and 0.5% of high molecular weight chitosan (□) as well as Tobrex® (—) (From Ref. 109.)

tears (Fig. 5). It is assumed that the formation of the gel in the conjunctival cul-de-sac could lead to a prolonged release system for the drug (111).

#### a. Gelling Activated by pH Change

The concept of using hydrogels based on pH-sensitive polymers for the ocular route began in the 1980s (112). These hydrogels are based on latex. The term latex defines a low viscosity, stable polymeric dispersion of particles, generally in an aqueous solvent (113). According to the manufacturing method, latexes are globally classified in three categories: natural latexes like rubber, synthetic latexes obtained by polymerization of insoluble monomers emulsified in water, and artificial latexes, also called pseudolatexes, which are prepared by dispersion of a pre-existing polymer in an aqueous medium (114). In situ gelling pseudolatexes are pH-sensitive aqueous colloidal dispersions which undergo spontaneous coagulation and gelation

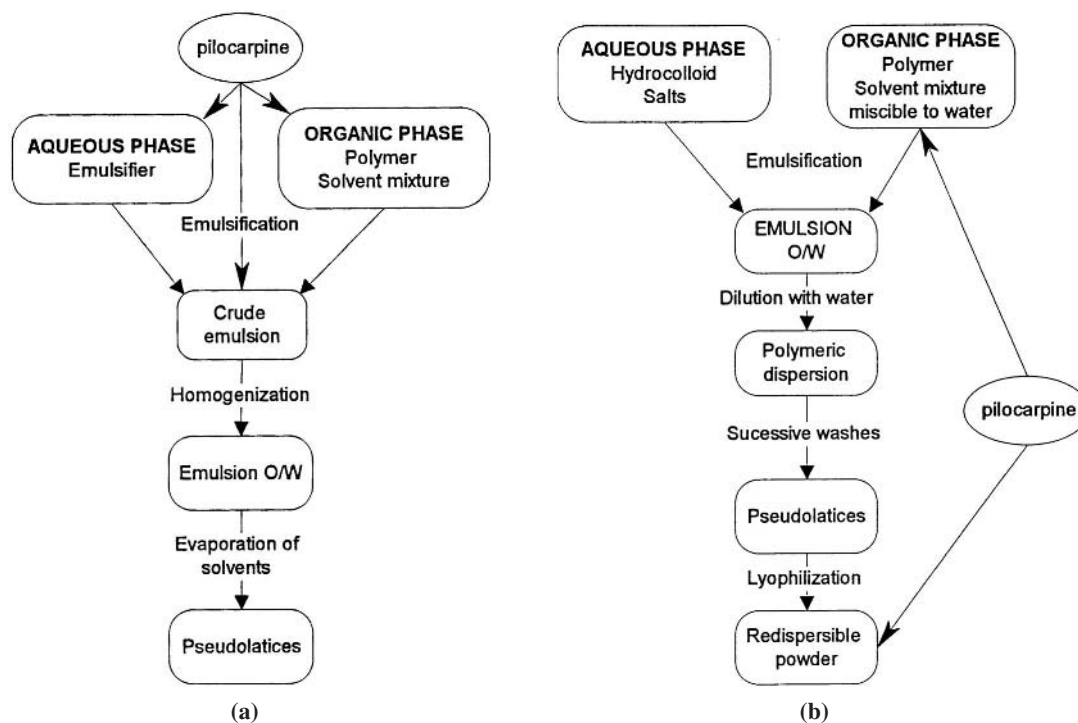

**Figure 15.5** Schematic viscosity behavior of in situ activated gel forming systems: thermosetting gels, pH-setting gels and electrolyte-setting gels (From Ref. 112.)

after instillation in the conjunctival cul-de-sac because of the pH increase (85,115).

The preparation of ophthalmic pseudolatexes involves an emulsification of an organic solvent containing the polymer with an aqueous solution leading to an oil-in-water (O/W) emulsion (112). There are two general methods of preparation (Fig. 6) (116,117). In the first method, the pseudolatexes result from an evaporation of solvents (removal of all organic solvent and a fraction of water). The internal phase of the emulsion contains a mixture of organic solvents not miscible with water and the polymer. The external phase is composed of an aqueous solution with an emulsifier. The bioactive material, e.g., pilocarpine, is added to the dispersion, where it is partially adsorbed onto the polymer. The drug can also be introduced at the beginning of the preparation, in one or other phase before emulsification. In the second method, the dispersion is prepared by a salting out process: the gradual addition of water breaks the equilibrium between the internal phase of the emulsion based on polymer in organic solvent miscible with water and the external phase containing salts in high concentration and hydrocolloids, so that polymeric particles are formed. In this second case, the bioactive material, e.g., pilocarpine, is blended either to the organic phase before emulsification or to the dry powder obtained after lyophilization of the particles (118).

The gel-forming polymers have to be carefully selected with respect to their physicochemical properties and biocompatibility. Cellulose acetate phthalate (CAP) has been shown to be suitable for pseudolatexes containing pilocarpine for several reasons: the compatibility of the polymer with the drug, the stabilizing effect of the polymer at relatively low pH avoiding hydrolysis of pilocarpine, and the relatively low buffer capacity of the polymeric system in the conjunctival cul-de-sac (112). The latex formulation described has a total polymer content (CAP) of 30% w/v and an average particle size of 250 nm. The CAP pseudolatexes form a free-running dispersion of acidic pH (pH = 4.4) and coagulate within a few seconds when in contact with the lachrymal fluid (pH = 7.2). Gamma-scintigraphy was used to monitor formulations based on pilocarpine-CAP pseudolatexes and showed a tenfold increase in precorneal residence time (residence half-life = 400 s) compared to a solution of pilocarpine (residence half-life = 40 s) (110,119). The pharmacological response of pilocarpine pseudolatexes has also been evaluated in terms of miosis (diminution of the pupil diameter), and it has been concluded that the bioavailability of the drug was substantially increased, the pseudolatexes maintaining a constant miosis in the rabbit for up to 10 h compared to 4 h with pilocarpine eye drops (120).

**Figure 15.6** Methods for the preparation of pseudolatexes for the ocular route: (a) evaporation of organic solvent in the internal phase of an O/W emulsion; (b) dilution of the external phase of an O/W emulsion. (From Ref. 112.)

It should be underlined that the long-acting latex, once coagulated, has no impact on vision (112), although a sensation of discomfort seems to be unavoidable immediately after administration as in the case of any preparation of suspension type.

#### *b. Gelling Activated by Temperature Change*

Another method for causing phase transitions of the ophthalmic polymeric preparations on the ocular surface is based on thermogelation. Temperature-sensitive polymeric gels, also called thermoreversible hydrogels, are liquid at room temperature (20–25°C) and undergo gelation when at body temperature. This thermosensitive property makes these hydrogels useful in controlled drug delivery either in topical administration on the skin or mucosa (nasal, ocular, or rectal route) or in parenteral administration (121). Miller and Donovan (122) first mentioned this in situ gel formation for the ocular route. The most common thermosensitive polymers suitable for ophthalmic preparations are poloxamers.

Poloxamers are synthetic nonionic surfactants and are water-soluble triblock copolymers made of poly(oxy ethyl-

ene) (PEO) and poly(oxy propylene) (POP) (123,124). These polymers consist of a central hydrophobic nucleus of POP surrounded by hydrophilic sequences of PEO, conferring surface active properties to the copolymer. Chemically, poloxamers can be classified as polyethers of alcohol ethers, but generically they are referred to copolymer polyols. Different types of poloxamers exhibit different gelation properties and vary over a wide range of molecular weights and the relative proportions of the two constituents (125). Poloxamers are defined by a number, the first two digits of which, when multiplied by 100, correspond to the approximate average molecular weight of the POP portion of the molecule. The last digit, times 10, gives the percentage by weight of the PEO portion.

The series of poloxamers is commercially available as Pluronic® (BASF-Wyandotte) (124). The most commonly used poloxamer, not only in ophthalmology but also in dermatology and cosmetics, is poloxamer 407, also known as Lutrol F127 (BASF, Ludwigshafen, Germany). This is explained by several reasons: first, poloxamer 407 gives colorless and transparent gels, an important parameter for the ocular route; second, it has a very low toxicity and it is also inert toward mucosa; third, the polymer has a high

solubilizing capacity, and, finally, poloxamer 407 requires the lowest concentration for gel formation (123,126,127).

The concentration at which poloxamer solutions exhibit reversible gelation depends on the type of polymer: poloxamers 184 to 188 form gels from concentrations of 50–60% w/v; poloxamers 234 to 288 form gels from concentrations of 40%; poloxamers 333 to 338 give hydrogels by a concentration of 25%; whereas poloxamer 407 forms a gel at only 20% concentration in water at 25°C. For a given type of polymer, as the concentration is increased, the gel becomes harder and harder, and the sol–gel transition temperature decreases (126,128). An increasing concentration of the polymer also results in an increased corneal contact time (128).

Several mechanisms have been proposed to explain the thermogelification, including micellar aggregation forming an intermicellar network and gradual desolvation of the polymer breaking the hydrogen bonds between water molecules and polymer oxygen atoms. But the most recognized mechanism is that thermogelification results from the interaction between the different molecules of poloxamer (124,129–131). The increase in temperature modifies the hydration spheres around the hydrophobic units of POP, which in turn induces greater interactions between these different units, leading to an increased entanglement of the polymeric network (130,132). A schematic representation of the gelation process proposed by Waring and Harris (133) is shown in Fig. 7.

The phenomenon of thermogelling is perfectly reversible: the viscosity of poloxamer solutions increases when the temperature is raised to the eye temperature (33–34°C) from a critical temperature (23–26°C) (130,134). The hydrogel reverts to a solution by placing the preparation at refrigerator temperature and gels again at ambient temperature. The gel can be cooled down and/or warmed up innumerable times with no change in properties (126). The rheological behavior of a poloxamer thermoreversible hydrogel at 20% was shown to be Newtonian below the transition temperature and non-Newtonian above this temperature. Furthermore, the viscosity of the poloxamer hydrogel is affected by the presence of additives: for example, preservatives such as benzoic acid and parabens produce a decrease in the poloxamer gelation temperature (126,135).

Hydrogels of poloxamer can be prepared by two methods. In the cold water process, the polymer is stirred into water at 5–10°C; gelling sets in on heating to room temperature. In the hot water process, the required amount of polymer is dissolved in water under gentle shaking at about 90°C. By this hot method, it takes about 4 h for the polymer to go completely into solution (126). Both methods yield gels with the same properties.

Saettone et al. (136) demonstrated that poloxamers are

**Figure 15.7** Scheme of sol–gel transition of poloxamer hydrogels (From Ref. 133.)

useful not only for modified ocular drug delivery, but are also outstanding ophthalmic solubilizing vehicles for poorly water-soluble drugs such as tropicamide. Miller and Donovan (122) have evaluated the pharmacological activity of pilocarpine nitrate–poloxamer 407 gels in rabbits and reported an enhanced activity of the hydrogel compared to a simple solution. This increased therapeutic effect was explained by the longer permanence and contact of the drug with the ocular surface. Conflicting results were obtained by Dumortier et al. (137), who showed that a thermoreversible poloxamer 407 hydrogel did not prolong the release kinetics of morphine over a simple morphine salt solution in rabbits. Comparing the anti-inflammatory effect of flurbiprofen hydrogel formulated in Carbopol 940 2% and Pluronic F127 20% of the same viscosity, Mengi and Deshpande (72) reported that Carbopol provided a more sustained action than hydrogel with poloxamer. They suggested that bioadhesion of carbopol could play an important role in prolonging the contact of the drug with the

ocular surface. Some commercial products, particularly for contact lenses, are based on poloxamers including Clerz<sup>®</sup> and Miraflow<sup>®</sup> (Ciba Vision).

Some other ophthalmic applications of thermoreversible hydrogels have recourse to other polymers such as the poloxamine marketed as Tetronic<sup>®</sup> (138,139). These are copolymers derived from an ethylene diamine derivative (125).

Despite their undeniable qualities, thermoreversible gels are associated with an important disadvantage, namely, the risk of gelling before use by an increased ambient temperature due to improper packing or storage conditions.

### c. *Gelling Activated by Electrolyte Composition Change*

A possible way to overcome the drawback of critical storage conditions of thermosensitive hydrogels is to use a more specific physiological parameter to trigger gelation, for example, the chemical composition of tears. Gellan gum shows interesting gelling properties in that it forms a gel in the presence of certain mono- or divalent cations present in tears, such as sodium, calcium, and potassium ions (140,141).

Gellan gum is a natural anionic extracellular polysaccharide obtained by fermentation of the bacteria *Pseudomonas elodea*. The anaerobic fermentation conditions are controlled to produce a high yield, the isolation of the polymer from the fermentation liquor is followed by a deacetylation step and a subsequent purification (142). Chemically, this heteropolysaccharide is a linear polymer with a tetrasaccharide repeating unit of L-rhamnose, D-glucose, and D-glucuronate partially O-acetylated in the molar ratios 1:2:1 (143–145).

Deacetylated gellan gum is available commercially under the tradename of Gelrite<sup>®</sup> (Kelco Division of Merck and Co), also called low-acetyl gellan gum. Gelrite is obtained by saponification and clarified by filtration (146).

The gelling mechanism of the deacetylated gellan gum is based on the formation of double-helical segments, which leads to a three-dimensional network and which is induced to form by cations (147–149). Divalent cations, in particular divalent metallic ions such as calcium and magnesium, can coordinate to carboxylate groups to stabilize the gel formed.

Gelrite is capable of forming an optically clear dispersion in water at low concentrations (<2% w/v), whose apparent viscosity can be easily increased by increasing the pH or the polysaccharide concentration (150,151). Another parameter that influences the phase transition is the nature

and the concentration of cations. Mono- as well as divalent cations promote the gelation of the gellan gum. Sodium, a monocation whose concentration in tears approximates 113 mmol/L, causes the gelation of the material when topically instilled into the conjunctival sac (152). However, divalent ions such as magnesium (0.45 mmol/L in tears) or calcium (1.35 mmol/L) are superior in promoting the gelation of the polymer (153,154).

Osmolality is another critical parameter that governs the salt uptake of gellan gum and hence the rate of gelling (155). Owing to an osmotic gradient between the hydrogel and the surrounding environment, hypotonic hydrogel undergoes a rapid gelling and prolongs ocular contact time longer than isotonic or hypertonic gels.

Finally, the presence of ionic additives in gellan gum hydrogel may affect the rheological behavior. For instance, benzalkonium chloride, a common cationic preservative for ophthalmic preparations, increases the elasticity, probably by forming micellar aggregates at the oppositely charged carboxylic groups of the polysaccharide which participate in the intermolecular network of the gel (155).

Heat treatment including autoclaving for sterilization enables the full dispersion of the polymer without loss of apparent viscosity: the hydrogel then has a good thermal stability (150). Thus, the usual method to prepare gellan gum hydrogel (containing generally 0.6% of polymer) consists of dispersing the polymer in deionized water and autoclaving the mixture at 120°C for 10 min to obtain a sterile optically clear hydrogel (152). Additives such as the buffer system (e.g., maleate buffer), tonicity adjusting agent (e.g., mannitol) or preservatives, (e.g., benzalkonium chloride) can be dissolved in water before autoclaving.

Gellan gum hydrogels show pseudoplastic flow properties devoid of a static yield value and little thixotropy (150).

Comparing the methylprednisolone (MP) ester of gellan gum with MP suspension in gellan gum hydrogel, Sanzgeri et al. (156) made the assumption that the release mechanism of the drug is influenced by three factors, namely, the dissolution of the drug, its diffusion through the polymeric network, and the possible erosion of the matrix.

The suitability of gellan gum hydrogel as an ophthalmic vehicle has been investigated in different randomized clinical trials. Levy and Alsbury (157) demonstrated that gellan gum prolonged the pharmacological action of timolol so that a single daily instillation of the hydrogel was comparable to a solution used twice a day to lower the intraocular pressure of glaucomatous patients. This finding is consistent with two other studies. Gunning et al. (158) reported that a Gelrite hydrogel slightly prolonged the duration of action of two new antiglaucoma drugs, and Vogel et al.

(159) observed a twofold decrease of the intraocular pressure in patients who were given a Gelrite-based hydrogel of timolol compared to simple eye drops.

The performance of formulations based on gellan gum, in terms of improved residence time or in terms of enhanced bioavailability, has been assessed either by noninvasive techniques such as fluorometry (155,160) and gamma-scintigraphy (102,161) or by invasive methods involving the dosage of drugs in different parts of the eye (154,162). All techniques showed the prolonged contact time and improved bioavailability of the drug formulated in gellan gum hydrogel when compared with other solutions containing the same drug. Meseguer (102) has demonstrated the performance of Gelrite in delaying the ocular clearance of pilocarpine hydrogel. Despite the extended ocular residence and enhanced ocular bioavailability, gellan gum preparations do not have pronounced side effects caused by systemic absorption.

Dickstein and Aarsaland (163) demonstrated that timolol formulated in gellan gum was significantly less absorbed than a timolol solution and caused less heart rate response.

Ophthalmic preparations containing Gelrite are marketed under the tradename of TimopticXE® (Merck Sharp & Dohme, France).

### 3. Artificial Tears

Besides their use in ocular drug delivery systems, polymers are also commonly employed as wetting agents for contact lens solutions to avoid friction between the eye and the contact lens and as tear substitutes, also called artificial tears, to replace natural lachrymal secretions in cases of dry eye syndrome or KCS. One of the important criteria for selecting a polymer for artificial tears is an extended residence time on the cornea that enables reduction in the instillation frequency of artificial tears. Sodium hyaluronate (SH) exhibits specific properties that makes it an interesting vehicle for the preparation of artificial tears. Indeed, SH has chemical, structural, and rheological similarities with mucin (164). Furthermore, SH has been shown to protect against corneal damage by benzalkonium chloride, a preservative often added in tear substitutes and well known for its potential cytotoxicity (165–169). Thus, SH has been proposed as a vehicle of choice in the preparation of artificial tears (99,170–172). Snibson et al. (173) demonstrated that the corneal residence times of 0.2 and 0.3% SH hydrogels were significantly prolonged for patients with dry eye syndrome compared to healthy volunteers, probably because the tear mucin in dry eyes is altered and binds more strongly to the SH.

Poloxamer 407 hydrogel, with its protective and mucomimetic properties, as well as its optical transparency, can also be used for the treatment of dry eye (133,174). Flow Base®, a preparation containing 18% of poloxamer 407 and sodium chloride together with potassium chloride, has been shown to provide clinical advantages as a tear substitute (133). Poly(vinyl alcohol) can lower the surface tension of water, reduce interfacial tension at an oil–water interface, and enhance tear film stability. These interfacial properties have led to the widespread use of PVAL in artificial tear preparation (42,89). It is, for example, contained in the artificial tears Tears Plus and Liquifilm Forte® (Allergan). Cellulosic derivatives are also used in medication for dry eye: Ultra Tears® (Alcon) contains HPMC; Murocel® (Bausch & Lomb, Rochester, NY) contains MC; and Celluvisc® (Allergan) is based on CMC Na.

### 4. Ocular Tolerance of Hydrogels

Ocular tolerance is an essential parameter in the development of ophthalmic preparations, which have to be safe, i.e., they neither cause any irritation nor lead to any toxicity. The assessment of ocular tolerance involves either *in vitro* methods or *in vivo* tests (175–177). The acceptability of ocular hydrogels in human volunteers can be evaluated on the basis of a subjective evaluation: the volunteers are asked to answer a standard questionnaire with a grading scale (41,46,178). The pain sensation, lacrymation, blurring of vision, irritation, blinking rate, and crusting around the eye are the main evaluated parameters. Visual acuity and reading speed are also indicative of discomfort (178).

Tolerance tests have shown that generally hydrogels are better tolerated than ointments by patients (155,179). Indeed, blurring of vision is common with ointments, whereas hydrogels cause a blurring of short duration even with hydrogels designed for prolonged drug delivery (158). For instance, Gelrite was reported to form an opaque material immediately after administration into the eye (156). However, it does not seem to cause undue irritation. Nelson et al. (180) investigated the ocular tolerance of gellan gum hydrogel in a double-masked, randomized, crossover study where the patient rated the medication using a visual analog scale at different time intervals. The gellan gum hydrogel was found to impair visual function more than the saline solution, but these effects were brief and transitory.

Ludwig and coworkers (53) reported that some human volunteers complained of blurred vision after administration of Carbopol hydrogels. These findings are consistent with a study on human volunteers that reported irritation

with artificial tears based on a carbomer 940 gel (105). Despite these negative results based on a subjective appreciation, carbomer hydrogels do not induce evidence of irritation in rabbits (68).

The ocular tolerance of hydrogels can be related to their rheological behavior. Polymer solutions generally exhibit either a Newtonian behavior or a non-Newtonian behavior (36). Hydrogels with Newtonian flow properties, where the viscosity is independent of the shear rate, are poorly tolerated in the eye because of the transmitted shearing forces associated with blinking and rapid eye movements. Hydrogels displaying non-Newtonian properties, in which the viscosity decreases with increasing shear rate, show much better acceptance because they offer less resistance to the movement of the lid over the ocular globe than viscous Newtonian formulations (76,181).

### B. Dispersed Systems

Nano- and microparticles are polymeric drug carriers in the submicron and micron size range. The only difference between these particles is based on their size. Particles in the micrometer size range ( $>1 \mu\text{m}$ ) are called microparticles or microspheres, whereas those in the nanometer range ( $<1 \mu\text{m}$ ) are called nanoparticles (182). These systems were first developed to resolve solubility problems of poorly soluble drugs, as well as for long-acting injectable formulations and for improved drug targeting (182). An important potential use for these systems was to improve classical aqueous eye drop formulations, which have several disadvantages such as a rapid elimination of the drug from the precorneal site (183). Consequently, colloidal suspensions were designed to combine ophthalmic sustained action with the ease of application of eye drop solutions. Upon topical instillation, these particles are expected to be retained in the cul-de-sac and the drug to be slowly released from the particles through diffusion, chemical reaction, or polymer degradation or by an ion exchange mechanism (184). When using particulate systems for topical ocular purposes, an upper size limit of  $10 \mu\text{m}$  is generally respected in order to prevent patient discomfort (185). The instillation of larger particles could increase lacrymation rate and hence accelerate their elimination from the precorneal area with the consequence of dramatically reducing drug bioavailability. However, Sieg and Triplett (186) demonstrated in the early 1980s that a smaller size limit should also be considered. In fact, comparing the performances of polystyrene microspheres of different sizes by scintigraphy they found that the precorneal elimination of small particles ( $3 \mu\text{m}$ ) (1) was dependent on the volume instilled and (2) had an accelerated washout phase when compared to larger particles ( $25 \mu\text{m}$ ) (Fig. 8) (186).

**Figure 15.8** Precorneal retention of topically instilled particles: (●) 25  $\mu\text{L}$  dose of a  $3 \mu\text{m}$  suspension; (○) 50  $\mu\text{L}$  dose of a  $3 \mu\text{m}$  suspension; (▲) 25 and 50  $\mu\text{L}$  doses of a  $25 \mu\text{m}$  suspension (From Ref. 186.)

Among the several manufacturing techniques generally used for preparing particulate systems (e.g., emulsion polymerization, desolvation of proteins, heat denaturation, electrocapillary emulsification, and interfacial polymerization), emulsion polymerization is the most common for producing nanoparticles for ophthalmic drug delivery (183). The active principles are dissolved, entrapped, encapsulated, or linked to these colloidal carriers (187).

To date synthetic polymers such as poly(alkyl cyanoacrylates) (PACA), polyacrylamides, and polymethylmethacrylates (PMMA) have been most frequently used for the preparation of colloidal formulations for ocular applications (188). The polymer PACA has been the most extensively studied since it has certain advantages over the other two: it is well tolerated, biodegradable, and mucoadhesive (185,188), and it is not histotoxic (189). Poly(alkyl cyanoacrylate) nanoparticles are rapidly biodegrade with a degradation rate depending on the chain length of their ester side chain (182). Two metabolism pathways may take place, depending on the environmental conditions of the nanoparticles. The first possible mechanism corresponds to an erosion of the polymer leading to the formation of formaldehyde (190). The second way of metabolism is the hydrolysis of the ester bonds resulting in a water-soluble polymer backbone and a corresponding alcohol (191) (Fig. 9). The latter mechanism is predominant *in vivo* due to the presence of esterases, which is quite convenient considering the toxicity of formaldehyde produced during the first degradation process.

**Figure 15.9** Poly(isobutyl cyanoacrylate) degradation mechanisms (From Ref. 191.)

Besides acute and subacute tests of toxicity, acrylic polymers have also been evaluated regarding their tolerability after topical application to the eye. It was concluded that empty poly(butylcyanoacrylate) nanoparticles in saline did not cause any adverse reactions to human volunteers (185). Some other acrylic derivatives, i.e., poly(isobutylcyanoacrylate) and poly(hexylcyanoacrylate), have also been shown to be nontoxic after topical iterative application into rabbit eyes (185).

As shown in Table 6, the main field of application of colloidal systems is in glaucoma therapy, studying *in vitro* or *in vivo* drugs such as betaxolol, metipranolol, and especially pilocarpine. Evaluating the release of pilocarpine *in vivo*, Harmia et al. (192) pointed out the importance of the manufacturing method for the pharmacological efficacy of the drug. In fact, they compared the behavior of two particulate systems differing by the localization of pilocarpine, which was either adsorbed or incorporated into poly(butylcyanoacrylate) nanoparticles. Their results showed that the miotic activity was prolonged from about 200 to 270 min when compared with a simple solution for the nanoparticles with adsorbed pilocarpine unlikely for nanoparticles with the incorporated drug. Such an improvement of the miotic response using nanoparticles instead of conventional collyrium was confirmed some years later (Fig. 10) (193). However, regarding the performance of the same

formulations in terms of bioavailability of the drug, it appeared that this parameter was only slightly increased, by a factor 1.2 (193).

So far, two nanoparticulate systems have been developed for ophthalmic drug delivery under the trade names of Piloplex® and GlaupeX®, both containing pilocarpine (185). In the Piloplex delivery system, pilocarpine is bound to charged poly(methylmethacrylate–acrylic acid) copolymer particles, whereas GlaupeX is based on PACA nanoparticles.

In conclusion, most of the results subsequent to the use of colloidal systems for topical ocular application have been promising. However, the commercial development of these products remains limited for various reasons, including (1) stability problems after sterilization, (2) only slight improvement of the pharmacological and pharmacokinetic performances respective of the long manufacturing processes involved when compared to classical solutions.

### C. Inserts

Ophthalmic inserts are defined as preparations with a solid or semisolid consistency, whose size and shape are especially designed for ophthalmic application (i.e., rods or shields) (221). Historically, the first solid medication, precursors of the present insoluble inserts, consisted of squares of dry filter paper, previously impregnated with drug solutions (e.g., atropine sulfate, pilocarpine hydrochloride) (222). Small sections were cut and applied under the eyelid. Later, lamellae, the precursors of the present soluble inserts, were developed. They consisted of glycerinated gelatin containing different ophthalmic drugs (222). However, the use of lamellae ended when more stringent requirements for sterility of ophthalmic preparations were enforced. Nowadays, growing interest is observed for ophthalmic inserts as demonstrated by the increasing number of publications in this field in recent years. The uses of ocular inserts have been extensively reviewed by Felt et al. (4), Bawa (223), Saettone et al. (222,224,225), Khan et al. (226), and Shell (227,228). The patent literature on ophthalmic inserts has been reviewed by Gurtler and Gurny (221), while Baeyens et al. (3) have described the use of inserts as ocular drug delivery devices in veterinary medicine.

Inserts are placed in the lower fornix and, less frequently, in the upper fornix or on the cornea. They are usually composed of a polymeric vehicle containing the drug and are mainly used for topical therapy. Despite several advantages (3) such as accurate dosing, absence of preservatives, and increased shelf-life, they have one significant disadvantage, their solid consistency, which means that they are perceived by patients as a foreign body in the

eye (224). Besides the initial discomfort, other potential disadvantages arising from their solid state are possible movement around the eye, occasional inadvertent loss during sleep or while rubbing the eyes, and interference with vision and difficult placement (and removal in the case of insoluble inserts) (224). Most of the ongoing research is therefore dedicated to improving ocular retention and to ensure an easy placement by the patient, while reducing the foreign body sensation in the eye.

Ophthalmic inserts are generally classified according to their solubility behavior and their possible bioerodibility, depending on the polymer(s) incorporated in the device.

### 1. Soluble Inserts

Inserts described in the literature are most frequently based on soluble polymers (Table 7). Their main advantage relies on their complete solubility compared with their insoluble counterparts, so that they do not need to be removed from the eye after therapy. They are usually divided into two categories according to the origin of the polymer. The first type is based on natural polymers, and the second is derived from synthetic or semisynthetic polymers. Drug release from soluble inserts is generally characterized by a

**Table 15.7** Currently Investigated Polymers for Soluble Ocular Inserts

Carrier	Drugs	Main conclusions	Species	Ref.
Alginate, MC	Pilocarpine	Increased duration of the miotic activity as compared to solutions in the presence of MC.	R	230
Collagen	Gentamicin	3 h after administration, collagen insert gives the highest tear film and tissue concentration compared to topical ointment, aqueous solution, as well as subconjunctival application.	R	231
Collagen	Gentamicin	Concentrations in the precorneal tear film approximate the MIC during the 24 h after insertion.	B	232
Collagen	Gentamicin + dexamethasone	Collagen shields are comparable to the subconjunctival delivery of the same drugs over a 10-h period.	R	233
Collagen	Tobramycin	No significant difference between collagen and aqueous solution in the treatment of induced keratitis.	R	234
Copolymers of N-vinylpyrrolidone	Erythromycin	Complete suppression of a <i>Chlamydia trachomatis</i> infection. Inserts remain in the eye for 7 days.	M	235, 236
HA, HAE	Pilocarpine	Increased bioavailability of pilocarpine compared to a standard aqueous vehicle.	R	83
HPC	Pilocarpine	Delayed and decreased peak concentration in general circulation compared to aqueous solution.	R	237
HPC/D-lactose/glyceryl palmitostearate/Eudragit® RS	Pilocarpine	Increased lipophilicity as well as coating result in an increased pilocarpine bioavailability.	R	238
HPC/EC/Carbopol® 934P (BODI®)	Gentamicin	Concentrations in the precorneal tear film approximate the MIC during the 72 h after insertion.	R, D	239
HPC/EC/Carbopol 934P (Chrono-Logic®)	Gentamicin + dexamethasone	Release of dexamethasone and gentamicin over 24 and 48 h, respectively. Increased lacrimal availability for both drugs when compared to commercial solution.	R, D	240–242
HPC/Eudragit RS	Timolol	Coated inserts antagonized isoproterenol-induced ocular hypotension significantly more than Timolol eyedrops and uncoated inserts; sustained release of Timolol in tear fluid and decreased systemic peak concentration with coated and uncoated inserts compared to the aqueous solution.	R	243
HPC, PVAL, PVAL/Carbopol 940	Timolol	Drug release from the insert decreases in the order PVAL > HPC > PVAL/C940. Reduction in peak plasma Timolol concentration 2–5 times compared to the aqueous solution.	R	244
HPM	Tilisolol	Release by a non-Fickian mechanism.	R	245
PVAL (NODS®)	Chloramphenicol	Increased bioavailability with respect to standard eyedrop formulations.	R	246
PVAL (NODS)	Pilocarpine	Increased bioavailability with respect to standard eyedrop formulations.	R	246
PVAL/XG/HPMC/HA/GB/Eudragit RS 30 D	Pilocarpine	Coated inserts show a sustained release over 9 to 10 h; shift of the peak time to 120–240 min; over 3-fold increased AUC over the standard aqueous solution.	R	247
PVAL, HPC, EC, CAP, Eudragit	Dexamethasone	Increased concentration in eye tissues compared to suspension.	R	248
PVAL, HPC, PVAL/Carbopol 940	Timolol and prodrugs of Timolol	Release from the insert decreased in the order PVAL > HPC > PVAL/C940. Release rate much slower for Timolol prodrugs compared to the Timolol-containing inserts.	R	249
PVP	Pilocarpine	2.5-fold increased AUC over the aqueous solution.	R	250

diffusion process occurring in two steps (221,229). The first corresponds to the penetration of tear fluid into the insert, which induces a rapid diffusion of the drug and forms a gel layer around the core of the insert. This external gelification induces the second phase corresponding to a decreased release rate, again controlled by diffusion. The major problems of these soluble inserts are the rapid penetration of the lachrymal fluid into the device, the blurred vision caused by the solubilization of insert components, and the glassy constitution of the insert increasing the risk of expulsion.

#### a. Natural Polymers

Natural polymers include collagen, which was the first ophthalmic insert excipient described in the literature. Collagen-based inserts were first developed by Fyodorov (223,251) as a corneal bandage used after surgical operations and various eye diseases. Collagen shields were later suggested also as potential drug carriers (231). The therapeutic agent is generally absorbed by soaking the collagen shield in a solution containing the drug. Once placed in the eye, the drug is gradually released from the interstices between the collagen molecules, as the collagen dissolves. Accordingly, the residence time of drugs (252) such as antibacterials (253,254), anti-inflammatory agents (255,256), antivirals (257,258), or combination drugs (233) was increased when compared to traditional eye drops. For example, Bloomfield et al. (231) compared the levels of gentamicin in tears, cornea, and sclera of the rabbit eye after application of a collagen insert, drops, an ointment or by subconjunctival administration. After 3 h, they found that the collagen insert gave the highest concentration of gentamicin in the tear film and in the tissues when compared with the other types of formulations. The corneal shields, currently available for clinical use, do not contain drugs and are designed specifically as disposable therapeutic corneal bandages (224). For example, Bio-Cor® (Bausch and Lomb, Clearwater, FL) is made of porcine scleral collagen, while Medilens® (Chiron Ophthalmics, Irvine, CA) and ProShield® (Alcon) are prepared from bovine corium tissue (258–260). The main problem arising from the use of collagen is that it may cause an inflammatory reaction in the ocular tissues. Also, if shields are not used in association with antibacterials, a secondary infection may occur (257). Nowadays, the use of such devices is controversial due to possible prion-based infection.

#### b. Synthetic and Semisynthetic Polymers

Ophthalmic inserts containing synthetic [i.e., poly(vinyl) alcohol (247,248)] and semisynthetic [i.e., cellulosic derivatives (230,237–239,243,247,248)] polymers are fre-

quently described in the literature. This stems in part from their advantage of being based on products well adapted for ophthalmic use and their ease of manufacture by conventional methods, including extrusion (239), compression (238), and compression molding (261). Ethylcellulose, a hydrophobic polymer, can be incorporated in the formulation to decrease insert deformation and therefore prevent blurred vision (239,241,248). Regarding the risk of expulsion, several authors (239,241,242,244,249) have incorporated a carbomer (Carbopol) which is, at low concentrations, a strong and rather well-tolerated bioadhesive polymer. Recently, Baeyens et al. (240–242) and Gurtler et al. (239,262) have used cellulose acetate phthalate in combination with gentamicin sulfate to decrease drug solubility. Prolonged release of the drug above the minimum inhibitory concentration (MIC) was obtained for more than 50 h, while gentamicin incorporated without CAP was released over less than 24 h. Subsequently, a new insert (ChronoLogic®), providing release of gentamicin and dexamethasone at different rates was developed. The prolonged release of gentamicin—an antibacterial agent—is combined with the immediate release of dexamethasone—an anti-inflammatory agent—against structural damage that can be caused by the inflammatory reaction (Fig. 11).

The release rate can also be decreased by using a copolymer of methacrylic acid (Eudragit®) as coating agent (238,243,247). Saettone et al. (238) have observed in rabbits that Eudragit®RS-coated inserts containing pilocarpine induced a miotic effect of longer duration compared to the corresponding uncoated products (Fig. 12).

Lacrisert® is a soluble insert that was commercialized by Merck Sharp and Dohme in 1981 (223). The device

**Figure 15.11** Combined release of gentamicin sulfate (■) and dexamethasone phosphate (□) at different release rates from a single insert containing 5.0 mg of gentamicin sulfate and 1.0 mg of dexamethasone phosphate (tested in rabbit, mean ± SEM, n = 6). (From Ref. 241.)

**Figure 15.12** Miotic activity profiles of uncoated (○) and coated (●) ophthalmic inserts. (Adapted from Ref. 238.)

weighs 5 mg, measures 1.27 mm in diameter with a length of 3.5 mm, and is composed of hydroxypropylcellulose and is useful in the treatment of dry eye syndrome. The device is placed in the lower fornix where it slowly dissolves over 6–8 h to stabilize and thicken the tear film (263).

New Ophthalmic Delivery System (NODS®), originally patented by Smith & Nephew Pharmaceuticals Ltd. in 1985, consists of a medicated flag (4 mm × 6 mm; thickness, 20 μm; weight, 0.5 g) which is attached to a paper-covered handle by means of a short (0.7 mm) and thin (3–4 μm) membrane (246). All components (flag, membrane, and handle) are made of the same grade water-soluble poly(vinyl) alcohol. For use, the flag is touched onto the surface of the lower conjunctival sac. The membrane dissolves, rapidly releasing the flag which swells and dissolves in the lachrymal fluid to deliver the drug. When evaluated *in vivo*, NODS produced an increase in bioavailability for pilocarpine and chloramphenicol with respect to standard eyedrop formulations (246).

## 2. Insoluble Inserts

Inserts made up of insoluble polymer can be classified into two categories (242): reservoir and matrix systems. Each class of insert shows different drug release profiles. The reservoir systems can release drug either by diffusion or by an osmotic process. It contains, respectively, a liquid, a gel, a colloid, a semisolid, a solid matrix, or a carrier containing drug. Carriers are made of hydrophobic, hydrophilic, organic, natural, or synthetic polymers. The second category, matrix systems, is a particular group of insoluble ophthalmic devices mainly represented by contact lenses.

The main disadvantage of the insoluble devices is their insolubility, since they need to be removed from the eye after treatment.

### a. Reservoir Inserts

Reservoir inserts based on a diffusional release mechanism of the drug consist of a central reservoir of drug enclosed in specially designed semipermeable or microporous membranes allowing the drug to diffuse from the reservoir at a precisely determined rate. Drug release from such a system is controlled by the lacrimal fluid permeating through the membrane until a sufficient internal pressure is reached to drive the drug out of the reservoir. These diffusional systems prevent a continuous decrease in release rate by the use of a barrier membrane of fixed thickness, resulting in a zero order release pattern.

Ocusert® (developed by Alza Corporation, Palo Alto, CA) is undoubtedly the most commonly described insoluble insert in the literature (Fig. 13) (64,224,228,264–269). This flat, flexible elliptical device consists of a pilocarpine reservoir with alginic acid, a mixture surrounded on both sides by a membrane of ethylene vinyl acetate copolymer. The device is encircled by a retaining ring impregnated with titanium dioxide. The dimensions of the elliptical device are as follows: major axis, 13.4 mm; minor axis, 5.7 mm; thickness, 0.3 mm. Two types of Ocusert are available for humans: Pilo-20® and Pilo-40®, providing two different release rates for pilocarpine (20 and 40 μg/h, respectively) over a period of 7 days (264). In rabbits, Sendelbeck et al. (264) have compared the distribution of pilocarpine in ocular tissues after administration by eyedrop or by the Ocusert system. After the administration of eyedrops, pilocarpine levels in ocular tissues rose and fell within each 6-h intervals between eyedrops. On the other hand, pilocar-

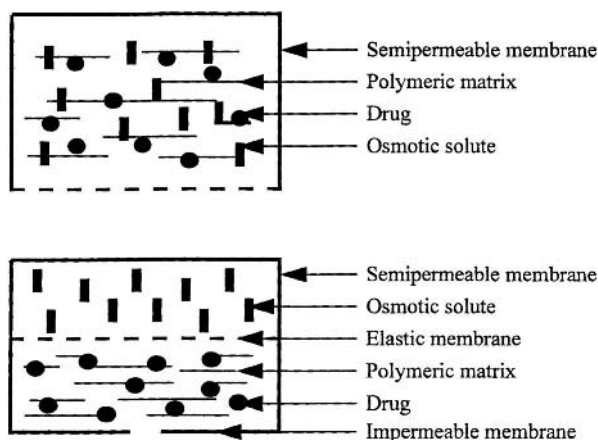

**Figure 15.13** Ocusert® system.

pine levels remained constant over a 2- to 8-day period with the delivery system.

Reservoir inserts based on an osmotic release mechanism of the drug are mostly described in the patent literature, and *in vivo* tests are rarely reported (221). They are generally made up of a central core surrounded by a peripheral component. The central part can consist of a single reservoir or two distinct compartments (Fig. 14). The single reservoir contains the drug, with or without an additional osmotic solute dispersed through a water-permeable polymeric matrix (e.g., ethylene vinyl esters copolymers) so that the drug is surrounded by the polymer as discrete small deposits. If the central part is made up of two compartments, the drug and the osmotic solute are placed in separate chambers, the drug reservoir being surrounded by an elastic impermeable membrane and the osmotic solute reservoir by a semipermeable membrane (e.g., cellulose acetate derivatives). The peripheral part of these osmotic inserts comprises in all cases a covering film made of an insoluble semipermeable polymer.

The majority of patents deals with systems having a unique central reservoir (270,271). The release of drug from these inserts can occur via two release mechanisms, an osmotic and a diffusional release (221). When the insert is placed in the ocular environment, this starts the osmotic release, meaning tear fluid diffuses to the peripheral deposits through the semipermeable polymeric membrane, wets them, and induces their dissolution. The solubilized deposits generate a hydrostatic pressure against the polymer matrix triggering its rupture in the form of pores releasing the drug. This osmotic part of the release is characterized by a zero order release profile. Ideally, the drug is continuously

**Figure 15.14** Schematic representation of two types of osmotic inserts.

released from the osmotic insert by the increasing formation of apertures in the device forming a lattice of composition dispensing paths in the polymer on all sides of the inserts. In fact, these paths are interconnected, forming tortuous microchannels of irregular shapes and size, causing a second drug release corresponding to a diffusional non-constant release.

The release of drug from systems having a central reservoir subdivided into two compartments (272,273) starts as soon as the device is placed in the eye. Tears diffuse into the osmotic compartment, inducing osmotic pressure that stretches the elastic membrane and contracts the compartment containing the drug, so that the active compound is forced through the single drug release aperture. Thus, these systems are characterized by two distinct compartments and a single aperture having a very small diameter.

A constant zero order release can also be reached by using reservoir devices based on silicone polymers. The prolonged release of drugs can be controlled either by a diffusion process (274,275) or by an osmotic mechanism (276,277). Recently, Chetoni and coworkers (277) manufactured bioadhesive polydimethylsiloxane rod-shaped inserts maintaining lacrimal concentrations of oxytetracycline above the MIC for at least 3 days.

#### b. Matrix Inserts

As mentioned previously, the matrix insoluble inserts are mainly represented by contact lenses. The initial use of contact lenses was for vision correction. Their use has been extended as potential drug delivery devices by presoaking them in drug solutions. The main advantage of this system is the possibility of correcting vision and releasing drug simultaneously. Contact lenses are composed of a hydrophilic or hydrophobic polymer which swells by absorbing water. The swelling, caused by the osmotic pressure of the polymer segments, is opposed by the elastic retroactive forces arising along the chains as crosslinks are stretched until a final swelling (equilibrium) is reached.

Refojo (278) has proposed a subdivision in five groups of contact lenses, namely, rigid, semirigid, elastomeric, soft hydrophilic, and biopolymeric. Rigid contact lenses have the disadvantage of being composed of polymers [e.g., poly(methylmethacrylic acid)] hardly permeable to moisture and oxygen, a problem which has been overcome by using gas permeable polymers such as cellulose acetate butyrate. However, these systems are not suitable for prolonged delivery of drug to the eye and their rigidity makes them very uncomfortable to wear. For this reason, soft hydrophilic contact lenses were developed for prolonged release of drugs such as pilocarpine (279), chloramphenicol

and tetracycline (280), and prednisolone sodium phosphate (281). The most commonly used polymer in the composition of these types of lenses is hydroxyethylmethyl methacrylic acid copolymerized with poly(vinylpyrrolidone) or ethylene glycol dimethacrylic acid (EGDM). Poly(vinylpyrrolidone) is used for increasing water of hydration, while EGDM is used to decrease the water of hydration.

Shell et al. (229) and Khan et al. (226) have shown that drug release from presoaked contact lenses was extremely rapid, with an in vivo residence time in general not longer than 24 h. In addition, preservatives, such as benzalkonium chloride, cannot be avoided and they have greater affinity with the hydrophilic contact lens material than for the aqueous drug solution (223). Bawa (282,283) has described other approaches to decrease drug release rate from contact lenses. These include the introduction of the drug into the monomer mixture followed by polymerization of the monomers in the presence of the drug. This procedure removes the need for preservatives and consequent eye sensitization, since the drug is added in the matrix as a solid (282,283). However, the main problem associated with all contact lenses is their high cost of manufacture and the difficulty of incorporating a precise amount of drug into the matrix. Disposable contact lenses have been com-

mercially available for many years, and the continued progress made in polymer chemistry should facilitate the development of this type of insert in the future.

### 3. Bioerodible Inserts

These inserts are formed by bioerodible polymers (e.g., crosslinked gelatin derivatives, polyesters) which undergo hydrolysis of chemical bonds and hence dissolution (Table 8) (237,248,264,284,285). The great advantage of these inserts is the possibility of modulating their erosion rate by modification of their chemical structure during synthesis and by addition of anionic or cationic surfactants. A cross-linked gelatin insert was proposed by Attia et al. (248) in order to increase bioavailability of dexamethasone in the rabbit eye. The dexamethasone levels in the aqueous humor were found to be fourfold greater compared to a dexamethasone suspension. More recently, absorbable gelatin sponges (Gelfoam®) described in *USP XXIII* were used to deliver drugs to the eye (286–289). The device consists of a crosslinked gelatin sponge. The drug is incorporated in this polymeric system by soaking it in a solution containing the active compound. In vivo results showed that the Gelfoam device is more effective than conventional

**Table 15.8** Currently Investigated Polymers for Bioerodible Ocular Inserts

Carrier	Drugs	Effects	Species	Ref.
Gelatin	Dexamethasone	Increased dexamethasone concentration in eye tissues compared to suspension.	R	248
Gelatin	Gentamycin	Ocular irritation.	B	285
Gelatin	Pilocarpine	2-fold increase in duration of effect as compared to pilocarpine administered as a solution of 1.0 and 60 cps viscosity.	R	290
Gelatin (Gelfoam®)	Phenylephrine + tropicamide	Mydriatic response is larger and longer lasting than that produced by eyedrops with an equivalent amount of drugs.	R	289
Gelatin (Gelfoam)	Pilocarpine	Gelfoam device is more effective than conventional pilocarpine dosage forms in prolonging the duration of the pilocarpine.	R	286
Polypeptide	Idoxuridine	Better results than drops and ointment in the treatment of herpes simplex keratitis.	R	284
PVMMA	Pilocarpine	Delayed and decreased peak concentration of pilocarpine in general circulation compared to aqueous solution.	R	237
PVMMA	Timolol	2- to 5-fold reduction of peak plasma Timolol concentration compared to the aqueous solution.	R	244
PVMMA	Timolol and prodrugs of Timolol	Release rate much slower for Timolol prodrugs compared to the Timolol-containing inserts.	R	249

Notes: PVMMA, n-butyl half ester of poly(methyl vinyl ether/maleic anhydride); B, bovine; R, rabbit.

pilocarpine eyedrops and various other gel formulations in prolonging the action of pilocarpine (286), phenylephrine (289), and tropicamide (289).

However, erodible systems can have significantly variable erosion rates based on individual patient physiology and lacrimation patterns, while degradation products and residual solvents used during the polymer preparation can cause inflammatory reaction.

In conclusion, a wide range of polymers can be used to manufacture ocular inserts. Inserts are a promising alternative administration route because of their various advantages compared to classical dosage forms. However, only a few of these formulations have been commercialized. This can be attributed to the reluctance of ophthalmologists and patients to replace traditional ophthalmic solutions as well as the cost and the need to train both the prescribers and the patients to place the inserts correctly in the eyes. In the future, the use of ophthalmic inserts will certainly increase because of the development of new polymers, the emergence of new drugs having short biological half-lives or systemic side effects, and the need to improve the efficacy of ophthalmic treatments by ensuring an effective drug concentration in the eye for several days.

#### IV. INTRAOCULAR DELIVERY SYSTEMS

Different routes of intraocular drug delivery have been investigated. Periocular injections may either be subconjunctival or sub-Tenon's. Subconjunctival injections are made underneath the conjunctiva, whereas sub-Tenon's injections are made beneath the Tenon's capsule. Following periocular injection, the administered drug passes through the sclera and into the eye by diffusion. Penetration of drugs into the vitreous following periocular injection is generally negligible. This route of administration is often employed to treat severe infections of the anterior portion of the eye or to administer drugs as an adjunctive treatment to glaucoma filtering surgery (2). Intraocular injections may be intracameral, intravitreal, intracapsular, or subretinal (see Fig. 1). The intracameral injection, i.e., in the anterior chamber, may be sought for intraocular antibiotic therapy as a last resort in case of severe infections of the eye. Injections within the posterior chamber might be beneficial after cataract surgery to prevent complications. Intravitreal injection of drugs represents a direct way of attaining effective drug concentrations in the vitreous cavity (291). The vitreous humor is a hydrophilic gel, containing 99% water and 1% of organic substances such as collagen and hyaluronic acid, through which drugs diffuse freely as they would in water (292). After injection into the vitreous body, drugs may be eliminated through the retina or by

diffusion into the aqueous humor of the posterior chamber with subsequent removal by the normal egress of fluid from the anterior chamber. The intravitreal dosage route was initially reserved primarily for the treatment of endophthalmitis; nowadays this route is also used for the treatment of other sight-threatening intraocular diseases.

Intracapsular administration is achieved by dissolving drugs into the intraocular infusion fluids used during surgery. This route allows the treatment of afflictions of the capsular bag such as posterior capsular opacification, a frequent complication of cataract surgery (21).

Subretinal injections allow drug delivery directly to the retina, or more precisely to the retinal pigment epithelium cells. Conventional delivery routes cannot achieve adequate intracellular concentrations of drugs or other substances such as oligonucleotides or genes to modulate functions of RPE cells effectively. Subretinal injections are performed by a transvitreal approach (293) or by creating a tunnel in the sclera.

Successful treatment of most intraocular diseases requires multiple injections to maintain therapeutically effective drug concentrations for a desired period of time. Additionally, repeated intraocular injections can cause several complications, such as increasing risk of ocular infection, vitreal hemorrhage, retinal detachment, and cataract. Moreover, the initial peak level of drug achieved immediately after a bolus injection may result in direct toxicity to ocular tissues. Because of the rapid clearance of drugs from the eye and the variable toxicity encountered in various studies, researchers have been encouraged to develop new systems of intraocular drug delivery that would sustain a therapeutic level of the drug over an extended period of time. Thus, the "peak and valley" effects could be minimized and drug concentrations could be maintained at an effective therapeutic level for a prolonged period of time.

#### A. Intraocular Implants

##### 1. Bioerodible Polymers

Bioerodible polymers are particularly suitable in the case of intraocular implants since their use eliminates the step of removing the implant after the drug has been released, which in some applications can represent a significant advantage over other systems.

##### a. *Poly(Lactic Acid), Poly(Glycolic Acid) and Their Copolymers*

Polymers and copolymers of lactic and glycolic acids are poly( $\alpha$ -hydroxy acids) (PLA and PLGA) that are generally synthesized by a condensation reaction at high temperature via ring-opening polymerization of the corresponding lac-

tide and glycolide (294). The mechanism of degradation of these polymers is a simple chemical hydrolysis predominantly occurring in the core of the matrix (295). The polymeric chains are first cleaved by hydrolysis, thereby releasing acidic monomers which are rapidly eliminated by a physiological pathway. The degradation rate can be varied by many factors: the composition of the polymer used, its conformation, and also the physicochemical characteristics of the incorporated drugs (296).

Intraocular biodegradable poly( $\alpha$ -hydroxy acid)-based implants have been developed as new drug delivery systems for the treatment of glaucoma filtering surgery failure

or vitreoretinal pathologies. These implants are generally in the form of small cylinders which can be implanted in the eye by means of a syringe with a conventional needle (19- or 20-gauge). Table 9 summarizes the different experiments using these polymers.

Various experiments were carried out concerning implantation of PLGA-based drug delivery systems containing 5-fluorouracil (5-FU) for the management of glaucoma filtering surgery outcome. In the first studies in 1994 (298,299), efficacy and biocompatibility of such implants were assessed. After subconjunctival implantation, filtration fistulae survival time was significantly lengthened. A

mild host response inflammatory reaction was triggered in both guinea pig and rabbit eyes 1 week after implantation, and slight inflammation persisted for at least 6 weeks. Steady-state concentrations of 5-FU were achieved in the conjunctiva and the sclera 24 h after implantation and continued for about 200 h (300,301). The advantage of such a system is its reversibility during the first 14 days in case a contraindication to the use of 5-FU appears postoperatively.

Rubsamen et al. (302) investigated PLGA-based cylinders containing 5-FU to treat experimental PVR in rabbit eyes. The devices could deliver therapeutic levels of 5-FU for almost 3 weeks and reduce the incidence of tractional retinal detachment. No adverse mechanical or toxic effects were apparent during the time of the study. However, because these devices were not fixed in the vitreous cavity, they might move and come into contact with the retina. Consequently, a stable localization of the device in the vitreous base through a suture fixation or an alternative mode of fixation at the site of implantation might be desirable. In 1994, Hashizoe et al. designed a new device that is implanted at the pars plana and releases drugs directly into the vitreous (303). These scleral plugs, made of PLGA, gradually released doxorubicin in a concentration maintained within the therapeutic levels for 1 month, without any notable toxicity to the retina. In another study with PLA-based scleral plugs with doxorubicin, drug release was still prolonged and showed less initial burst (304).

Sustained release of ganciclovir for the treatment of cytomegalovirus retinitis was also investigated (Fig. 15) (306,307). The concentration of ganciclovir was maintained within the therapeutic range for over 3 months in the vitreous and for over 5 months in the retina and the

**Figure 15.15** Concentrations of ganciclovir in the vitreous and the retina/choroid after implantation of ganciclovir-loaded PLGA scleral implant (From Ref. 306.)

choroid. Concerning retinal toxicity, the authors concluded that the biocompatibility of the device might be clinically acceptable. A promising study was carried out by Yamakawa concerning the *in vitro* release of phosphorothioate oligonucleotide from PLGA matrices (308). Pseudo-zero order release of oligonucleotide lasted more than 20 days.

Treatment of endophthalmitis was investigated with antibiotics (309), antifungals (310), and anti-inflammatory agents (311). In all cases, the intravitreal sustained delivery device showed great promise as a means of delivering therapeutic intravitreal levels of drugs over an extended period of time.

In order to prevent posterior capsule opacification (PCO) after cataract surgery, several investigations have been made to inhibit proliferation of lens epithelial cells. Poly(lactic and glycolic acid) with indomethacin, implanted in the capsular bag, significantly decreased intraocular inflammation, but did not reduce PCO (317). On the other hand, the implantation of PLA implants containing indomethacin and daunorubicin reduced PCO formation by approximately 50%. The administration of EDTA, which complexes with calcium, disrupted the interaction between the posterior capsule and migrating lens epithelial cells by inactivating the adhesion molecule integrin, significantly reducing cell migration onto the posterior capsule (312). Implants with fluorometholone (314) as well as a new dexamethasone delivery system (Surodex®) (315,316) were found to be a safe and effective treatment method to reduce intraocular inflammation after cataract surgery.

#### b. Polycaprolactones

Other polymers from the polyesters family have been evaluated as drug delivery systems. Poly- $\epsilon$ -caprolactone (PCL) is synthesized by a ring-opening polymerization of the monomer  $\epsilon$ -caprolactone at high temperature. It is semicrystalline and rather hydrophobic compared to poly( $\alpha$ -hydroxy acids) (318).

As with PLA and PLGA, degradation of PCL produces  $\epsilon$ -hydroxycaproic acid by cleavage of the polymeric chains at the ester linkage, leading to an initial decrease of the molecular weight without any significant weight loss. When the molecular weight reaches about 5000, small polymeric fragments begin to diffuse from the matrix and weight loss occurs; subsequently, fragments undergo phagocytosis (318).

Intraocular application of polycaprolactone-based delivery systems has been investigated by Borhani et al. (319). Devices of PCL loaded with 5-FU and implanted intravitreally exhibited a slow release and thus proved to

be efficient against PVR by providing a constant concentration of drug during the active period of the disease. An inflammatory cell reaction was found in the sclera near the implant site; however, no implant-related inflammation was observed (319).

Peyman et al. (320) developed a PCL-based biodegradable porous implant. Nontoxic water-soluble inorganic salts such as sodium or potassium chloride were used as pore-forming agents and incorporated into PCL by a melting process. Biodegradable porous reservoir devices were prepared and loaded with different substances, i.e., 5-FU, ganciclovir, foscarnet, and the dye carboxyfluorescein. When the implants are immersed in water, the inorganic salts dissolve, leaving pores in the PCL devices. A concentration gradient across the wall of the polymer is created that forces the flow of the drug from the inner reservoir system to the surrounding aqueous medium. The release pattern followed zero order kinetics without any initial burst and lasted more than 6 months (320).

### c. Polyanhydrides

Polyanhydrides can be synthesized by melt-polycondensation, dehydrochlorination, or dehydrative coupling (321). The first method leads to the formation of high molecular weight polymers, and the two last methods to polymers of lower molecular weight. The most frequently investigated polyanhydride is a copolymer of 1,3-bis(carboxyphenoxy)propane (PCPP) with sebacic acid (SA), a more hydrophilic monomer. Pure PCPP has an extremely long lifetime (over 3 years), whereas after copolymerization with 80% SA, this is reduced to a few days (322). The ratio of the two monomers plays an important role in the rate of hydrolysis of the resulting polymer: when the proportion of sebacic acid increases, the hydrophobicity of the polymer decreases, resulting in a faster rate of hydrolysis of the polymeric chains at the surface. It should also be noted that polyanhydrides are pH sensitive: they undergo faster breakdown at high pH and are more stable in acidic media (322).

Due to their surface erosion and excellent biocompatibility (323), polyanhydrides have been particularly useful for the controlled delivery of drugs for the prevention of glaucoma filtering surgery failure (Table 10).

Implants made of bis(p-carboxyphenoxy)hexane and sebacic acid, loaded with 5-FU, were implanted intraoperatively at the site of filtration surgery in rabbits (324). Intraocular pressures were lower in the experimental groups during the second postoperative week, but eventually both experimental and control eyes returned to preoperative levels. Filtration blebs lasted longer in experimental eyes; im-

plant disappearance occurred after intraocular pressure and bleb failure. Experimental eyes showed more postoperative complications, such as hyphema, implant extrusion, corneal pigmentation, and haze. Eventually, the filtration surgery failed in both the experimental and control rabbit eyes (324). When using bis(p-carboxyphenoxy)propane instead of PCPH (325), the filtration surgery also failed in both experimental and control rabbit eyes. These negative results are probably due to the fact that the polymer becomes depleted of drug before its erosion is complete. To prolong the duration of drug release, a more hydrophobic polymeric carrier may be required to slow down the diffusion of the hydrophilic 5-FU. Jampel et al. implanted PCPP-SA devices containing 5-fluorouridine in monkeys (326). The duration of success of the filtration surgery was significantly longer in the eyes that received the implant than in the controls. Since the anatomy and physiology of the monkey eye resemble closely the human eye, the assessment of the implants efficacy has much clinical relevance.

The intraoperative use of mitomycin C (MMC) is common among ophthalmic surgeons; however, it is associated with multiple complications such as loss of the tissue vascularization, which leads to leaky filtering blebs that have thinner epithelium, bleb-associated endophthalmitis, and scleritis (332). A localized and sustained delivery of this agent would allow reduction of side effects. Incorporation of MMC into polyanhydrides enhanced efficacy and reduced toxicity (327).

Polyanhydrides containing taxol and etoposide, which are hydrophobic drugs, showed favorable release kinetics (328,330) and were thus implanted in monkey eyes (329). Use of disks containing taxol, but not etoposide, had a marked beneficial effect on intraocular pressure and bleb appearance after filtration surgery. The difference between

the two drugs may result from the greater antiproliferative potency of taxol and its greater duration of release from the polymer (329).

## 2. Nonbiodegradable Polymers

### a. Ethylene Vinyl Acetate

The ethylene vinyl acetate (EVA) copolymers are a family of materials with a number of promising advantages. This thermoplastic lipophilic polymer is mainly used as a membrane in reservoir systems. Ethylene vinyl acetate is permeable to certain lipophilic substances such as pilocarpine but sufficiently hydrophobic to be relatively impermeable to hydrophilic drugs as well as water. In 1992, Ashton and coworkers developed an implantable sustained release device to treat chronic disorders of the eye (333). This device consists of a central core of drug entirely coated in polyvinyl alcohol, a permeable polymer. The surface area available for release, and consequently the release rate, is then controlled by additional layers of ethylene EVA, which is impermeable to the drugs used, and PVAL. Water diffuses into the device and dissolves part of the pellet, forming a saturated drug solution. The drug diffuses then out of the device, and as long as the solution inside the device is saturated, the release rate is constant (334).

This device has been implanted subconjunctivally and intravitreally in animal and human eyes for the treatment of various vitreoretinal disorders (Table 11). As it is non-

degradable, this system is almost devoid of any intraocular inflammatory response. However, it has to be removed or replaced to prevent any risk of fibrous encapsulation.

The first devices were developed to prevent glaucoma filtering surgery failure. Blandford et al. (336) implanted subconjunctival implants containing 5-FU. Devices prolonged the reduction of intraocular pressure. Although 5-FU was released from the devices for 2 weeks, intraocular pressure remained low for 3 months. These implants have also been implanted in patients undergoing filtering surgery (337); the mean follow-up was 2.5 years. In three of the four patients, intraocular pressure was controlled with stabilization of the visual field. The other patient had early failure. No untoward events were linked to the placement of the implant.

Treatment of intraocular inflammation and posterior uveitis with EVA/PVAL devices was also investigated. Implants were prepared, containing dexamethasone (342,343). Dexamethasone was released continuously for 3.5 months at an effective concentration. Furthermore, the devices were well tolerated with no indication of toxicity or inflammation. Cyclosporine devices were implanted by Pearson et al. (344). Data suggest that due to the high potency of cyclosporine and the very slow release rate from the device, these implants would provide sustained intravitreal levels of the drug for up to 10 years. However, cyclosporine levels produced by these implants appeared to be toxic in the rabbit, resulting in focal lens opacification. This toxicity was reversible and resolved after the device was removed. In a rabbit model of uveitis (346), cyclosporine implants appeared to effectively suppress ocular inflammation. Intravitreal cyclosporine remained at therapeutic levels for at least 6 months, and histopathologic examination showed that cyclosporine-treated eyes had preserved architecture and greatly reduced inflammatory cells. Devices containing both cyclosporine and dexamethasone were also prepared (345). Based on the fact that cyclosporine and corticosteroids reduce inflammation by different mechanisms, a device which contains both drugs in combination would be more effective than a device containing either agent alone. These implants maintained therapeutic levels of both drugs in the vitreous over 10 weeks, and the presence of dexamethasone did not seem to change the release characteristics for cyclosporine (345).

However, the main application of EVA/PVAL devices is the treatment of CMV retinitis with ganciclovir. First developed by Smith et al. in 1992 (334), this system has been widely experimented in both animal and human eyes (338–340,347–352). The ganciclovir device was approved by the Food and Drug Administration in 1996 and is commercially available under the name Vitrasert™ (Bausch and Lomb Surgical), each implant containing a minimum

of 4.5 mg of ganciclovir and being designed to release the drug over a 5- to 8-month period of time. The international AIDS Society has promulgated recommendations concerning Vitrasert (341), which offers a number of advantages over systemic ganciclovir therapy, including the longest median time of control of retinitis reported to date (Fig. 16) (340,353). Better control of retinitis from higher intraocular drug levels may reduce the risk of emergence of viral resistance. The disadvantages include pain and discomfort from surgery, a transient decrease in visual acuity, and the risk of complications inherent in the surgical procedure, which may increase with multiple operations. Because of the lack of systemic anti-CMV effect of the ganciclovir implant, patients remain at risk for developing CMV disease elsewhere (340). Thus, concomitant oral ganciclovir therapy is usually recommended.

*b. Polysulfone*

Polysulfone is a water-impermeable polymer. A polysulfone capillary fiber (PCF) has been investigated as a slow-release delivery system. It is an anisotropic ultrafiltration fiber mainly developed for cell culture purposes. Polysulfone capillary fibers have the following important features: they have deep macrovoids in its outer membrane, which increase the surface area for drug diffusion and release; they are permeable to lipophilic as well as hydrophilic compounds; the PCF-drug device can be readily sterilized; the device prevents dispersion of drug formulations, such as liposomes or microspheres, in the vitreous; and most important the bioactivity of the drug is unchanged by utilizing the PCF device since the fabrication process does not require chemical reaction, heat, or solvent exposure. The obvious disadvantage of this device is the need for

surgical removal of the drug-depleted device since it is not a biodegradable system.

Rahimy et al. (354) found that the PCF system is capable of maintaining a constant intravitreal level of the hydrophilic dye carboxyfluorescein (CF) for up to 45 days. Investigation of the in vitro release suggests that the PCF device is a reservoir diffusion-controlled system. Carboxyfluorescein diffusion through the PCF membrane is mainly driven by the concentration gradient between the PCF core and the incubation medium. The transport of CF molecules across the PCF membrane remains constant if the core is maintained in a saturated state, such as a solid or suspension form. However, such a state is difficult to maintain in this case since CF is highly water soluble. Intravitreal implantation of this device into rabbit eyes showed sustained-release kinetics for up to 45 days in the vitreous cavity. Furthermore, both clinical and histopathological data demonstrated that the PCF device is well tolerated by the rabbit eye (354).

Promising results have been obtained with daunomycin-charged PCF for the treatment of PVR (355). Devices were implanted intravitreally in rabbit eyes and results showed that the release of daunomycin was maintained at a therapeutic concentration in the vitreous for at least 21 days. The devices prevented tractional retinal detachment in an experimental model of PVR and were well tolerated without causing toxicity to ocular tissues (355).

**B. Viscous Nonaqueous Injectable Preparations**

1. Third Generation Poly(Ortho Esters)

Poly(ortho esters) (POE) are hydrophobic and bioerodible polymers whose main characteristics are a release of the drug by surface erosion, following zero order kinetics. Since the late 1970s, four generations of POE have been synthesized to produce bioerodible carriers for drug delivery. Among them, the third generation has been recently described (356) and characterized by Merkli et al. (357).

This viscous, ointmentlike, material is prepared by a transesterification between trimethyl orthoacetate and 1,2,6-hexanetriol (357). Drugs can be incorporated by simple mixing at room temperature, without the use of a solvent. This characteristic is of considerable interest with respect to peptide and protein delivery, as well as for other thermolabile drugs. Poly(ortho esters) can be injected using a syringe with an appropriate hypodermic needle without any other surgical intervention, which is a significant advantage when compared with solid devices that must be placed either with a trocar or through a surgical procedure.

The release of drugs from semisolid POE occurs via a combined erosion and diffusion mechanism. Because POE contains pH-sensitive linkages in the polymeric backbone,

the erosion rate can be controlled by incorporating acidic substances into the polymer matrix to accelerate the erosion rates or basic ones to stabilize the polymer backbone (358,359).

Degradation occurs in two steps: the first reaction is a rapid hydrolysis of the labile ortho ester bonds. This initial reaction is followed by a slower hydrolysis which produces a carboxylic acid and a triol (357). Degradation rate is also influenced by the physicochemical properties of the incorporated substances (359).

POE has been investigated as an injectable bioerodible polymeric implant for controlled subconjunctival release of antimetabolites such as 5-fluorouracil and mitomycin C as an adjunctive treatment to glaucoma filtering surgery (360). The biotolerance of the semisolid biodegradable POE was investigated subcutaneously and with the cage-implant system (361): the biocompatibility appeared to be acceptable. The subconjunctival biocompatibility in rabbits was studied by Bernatchez et al. (362). The acute inflammation resolved rapidly and no chronic inflammation developed. After further purification of the polymer and using an aseptic preparation method instead of  $\gamma$ -sterilization, Zignani et al. (363,364) further improved the biocompatibility of the polymer. Extended biocompatibility investigations have also been carried out both in the anterior and posterior parts of the rabbit eye (365). After intracameral injection, polymer biocompatibility appeared to be dependent on the amount injected in the anterior chamber. When a small quantity (typically 50  $\mu$ L) was administered, the polymer degraded within 2 weeks with a good biocompatibility, without harming any ocular tissues nor increasing the intraocular pressure. After intravitreal administration, POE was well tolerated and no inflammatory reaction developed during the study. The polymer degraded slowly, appearing as a round and whitish bubble in the vitreous cavity (Fig. 17).

Since POE appears to be a biocompatible material, the efficacy of a system containing 5-FU has been tested in a rabbit model of glaucoma filtering surgery. Results appear encouraging because POE systems lowered intraocular pressure and maintained filtration blebs for more than 4 weeks (unpublished results).

## 2. Fourth Generation Poly(Ortho Esters)

A fourth generation of POE has been very recently developed (366,367). These POE are said to be self-catalyzed since they possess short dimers of glycolic or lactic acid within the polymeric chain, allowing an excellent control of the polymer degradation rate.

The exact mechanism of hydrolysis of self-catalyzed POE has recently been elucidated (369). It proceeds in three consecutive steps: in the first step, the lactic acid di-

**Figure 15.17** External photograph of rabbit eye 5 days after intracameral injection of 50  $\mu$ L POE (From Ref. 365.)

mer segment hydrolyzes to generate a polymer fragment containing a carboxylic acid end group which will catalyze the ortho ester hydrolysis. A second cleavage produces free lactic acid which also catalyzes hydrolysis of the ortho ester links (369).

The biocompatibility of this last generation of POE has been assessed subconjunctivally (unpublished results). These polymers are far more hydrophobic than the third generation, which means that polymer lifetime under the conjunctiva was much longer. Almost no hyperemia and chemosis was triggered, which suggests that POE are promising candidates for ophthalmic applications (unpublished data).

## C. Dispersed Systems

### 1. Nanoparticles and Microspheres

#### a. Nanoparticles

Concerning the ophthalmic potential applications of nanoparticles, they are mainly used as a topical treatment for glaucoma, inflammation, or external infections of the eye since they are administered as drops and provide a sustained action (see Section III.B). A few studies have been conducted concerning the intraocular application of nanoparticles. El-Samaly and coworkers (370) described the intravitreal injection of acyclovir and ganciclovir nanoparticles made of biodegradable polymers, i.e., bovine serum albumin (BSA), polyethylcyanoacrylate, and chitosan. All of these polymers exhibited interesting characteristics during in vitro evaluation (drug loading capacity, particle size, homogeneity of nanosphere formation, drug release). Polyethylcyanoacrylate was chosen for in vivo studies in rabbits because it demonstrated the best drug loading and the

smallest particle size. Therapeutic levels of ganciclovir were detected in the vitreous for up to 10 days following injection of the PECA nanospheres. Lens opacification and vitreous turbidity appeared after the injection of this colloidal opaque dispersion, certainly due to the drug formulation.

### b. Microspheres

The polymers used for the preparation of microspheres are mainly based on lactic and glycolic acids. These bioerodible systems present the advantage that they do not have to be removed after degradation of the microspheres and delivery of the drug. Following administration of the suspension in the eye, the particles remain at the delivery site and the drug is released from the polymeric matrix through diffusion, polymer degradation, erosion, or a combination of these processes.

Besides topical ophthalmic application, which have been widely studied (184) (see Section III.B), some authors have investigated microspheres for intraocular injections to provide sustained release of drugs (Table 12).

Subconjunctival injection of microspheres for the prevention of glaucoma filtering surgery failure was investigated by incorporating adriamycin (372). This delivery

system using PLA microspheres was found to reduce significantly intraocular pressure as well as prolong filtering bleb persistence. When injecting fluorescein-loaded microspheres, transient conjunctival inflammation was found 6 to 7 days after injection. Clinically, a granulomatouslike reaction appeared, and one eye showed necrosis at the site of injection. The conjunctival reaction disappeared in a few days with no further complication (371).

In 1991, Khoobehi et al. (373) investigated the intravitreal injection of microspheres containing fluorescein as a drug model. High concentrations of the dye were detected within 24 h and gradually decreased after 5 days; lower concentrations were still measurable for 16 days. Moritera et al. (374) entrapped 5-FU in PLA and PLGA microspheres and injected them intravitreally in rabbits. The drug was released over a period up to 7 days. The microspheres were observed as a white mass in the vitreous cavity and were completely cleared out after 48 days. Administration of microspheres had no adverse effects on the ocular tissues, even though the degradation products of PLA and PLGA are acidic. Peyman et al. (375) demonstrated the efficacy of microspheres in increasing the half-life of encapsulated antimetabolites when injected intravitreally in primate eyes. Both cytarabine and 5-FU were entrapped in PLGA microspheres; both were still detect-

Notes: POPOP, 1,4-bis[2-(5-phenyloxazolyl)]-benzene; bFGF, basic fibroblast growth factor.

able in the eye 11 days after injection and the clearance kinetics were similar for both drugs. Moritera injected PLA microspheres with adriamycin in rabbits (376). This drug, 50 times more potent than 5-FU, was released at a continuous rate for over 14 days and was effective in preventing the rate of retinal detachment after 4 weeks in an experimental model of PVR and showed no toxicity to the retina even at a relatively high dose. Giordano et al. (377) entrapped retinoic acid, a highly hydrophobic drug, in PLGA microspheres and obtained a constant release of the drug. This system could provide therapeutic levels of retinoic acid for 40 days. Giordano et al. assessed biodegradation and tissue reaction to intravitreal PLGA microspheres (378). A mild localized, nonprogressive foreign body reaction was observed. The cell reaction was composed mostly of glial cells and fibroblasts. The choroid and retina were normal. No clinical inflammatory signs were observed 4 days postoperatively and thereafter (378).

Antiviral drugs such as acyclovir and ganciclovir were also encapsulated into microspheres and administered intravitreally (379,380). In both cases, drugs were released at a sustained rate and appeared to be promising for the treatment of viral retinitis.

As mentioned, there is no effective therapy available for achieving sufficient intracellular drug concentrations to modulate functions of retinal pigment epithelium cells. Since RPE cells have phagocytic activity, drug delivery could be targeted with the use of microspheres. A first study by Moritera et al. (381) showed that gelatin-coated PLA microspheres containing a fluorescent dye, 1,4-bis[2-(5-phenyloxazolyl)]-benzene (POPOP), were phagocytosed by RPE cells *in vitro*. In further work by Kimura et al. (382), PLA microspheres were loaded with a fluorescent dye, rhodamine. Ogura et al. (293) injected these rhodamine-loaded microspheres subretinally via a transvitreal approach with a glass micropipette in the rabbit. Microspheres were degraded in the cytoplasm of the RPE cells, but fragments were observed for up to 4 weeks. The retinal architecture overlying the delivery site was well preserved, which suggests that direct delivery of substances to the RPE cells is feasible, without damaging the neural retinal structure (Fig. 18) (293).

Another application of subretinal administration of microspheres is the creation of a model of choroidal neovascularization. By administering gelatin microspheres im-Rev 16.01egated with basic fibroblast growth factor (bFGF), a reproducible subretinal neovascularization was triggered, which represents a useful model for testing drugs against retinal diseases such as age-related macular degeneration (383,384).

In conclusion, most intraocular diseases, including sight-threatening endophthalmitis, devastating CMV reti-

**Figure 15.18** A glass micropipette is inserted transvitreally to administer the microspheres subretinally. (From Ref. 293.)

nitis, proliferative vitreoretinopathy and uveitis, as well as glaucoma filtering surgery failure and degenerative diseases of the retina, were treated by systemic and topical administration of drugs in the past. These routes of treatment led, in the majority of cases, to the loss of the eye due to the poor penetration of the various drugs into the vitreous cavity. The means of bypassing physiological and anatomical barriers and achieving high concentrations of drugs within the eye is through direct intraocular administration. The use of intraocular drugs has formerly been restricted to the treatment of endophthalmitis. Nowadays, it is also considered for the disorders described in this chapter. As all these clinical conditions require frequent and repeated intraocular injections of drugs, this may cause severe complications such as retinal detachment, vitreous hemorrhage, or intraocular infections. That is why sustained delivery systems have been developed, in order to prolong the therapeutic intraocular levels of drugs and thus diminish the frequency of the injections.

Biodegradable polymers have an advantage over other controlled release systems in obviating the need to surgically remove the drug depleted device. Potentially, biodegradable matrix systems also enjoy a number of other advantages in terms of simplicity of design and predictability of release if this is controlled solely by the erosion of the matrix. In many cases, however, the release occurs also by diffusion through the matrix, making the process more difficult to control, particularly if the matrix is hydrophilic and thereby absorbs water, promoting degradation in the interior of the matrix. To maximize control over the release process, it is desirable to have a polymeric system which degrades only from the surface and delays the permeation of drug molecules. Achieving such a heterogeneous degradation requires the rate of hydrolytic degradation on the

surface to be much faster than the rate of water penetration into the bulk. The ideal polymer would have a hydrophobic backbone, but with a water-labile linkage. Many classes of polymers have been designed with these considerations in mind. Among them, polyanhydrides and poly(ortho esters) erode from the surface. Taking advantage of the pH dependence of the rate of ortho ester cleavage, preferential hydrolysis at the surface is obtained by either addition of basic substances to suppress degradation in the bulk or incorporation of acidic catalysts to promote degradation on the surface.

Devices that are not biodegradable such as the EVA-PVAL implants are of clinical utility for chronic, sight-threatening diseases such as CMV retinitis and uveitis. These conditions are likely to require long-term drug therapy; therefore any device may need to be replaced once depleted of drug. On the other hand, in diseases such as glaucoma filtering surgery failure or PVR, which require relatively short-term therapy (weeks or months), a biodegradable system is clearly more desirable.

Microspheres have been shown to increase the efficacy, reduce the toxicity, prolong the activity, and provide site-specific delivery for many drugs when administered to the eye. Microspheres are very stable; their production is reproducible; and the release rate is controllable. Yet, the injection of microspheres in the vitreous is always followed by an impairment of the visual acuity.

## V. CONCLUSION

The ideal ophthalmic drug-release system should fulfill criteria which are identical for local as well as intraocular application: the systems should provide a sustained therapeutic concentration of drug in a reliable and predictable way over an adequate period to obtain the desired clinical response; the concentration of drug administered should be uniform over the administration period with no early or late excessive release of the drug; the formulation should be easily handled and administered either by the patient or by medical personnel; the device should have a long shelf-life and be easily sterilized; and there should be no toxic effect from sustained exposure to the drug or degradation products of the device.

None of the sustained delivery systems introduced to date and discussed in this chapter fulfill all these criteria, though they represent great strides when compared with classical solutions. Viscous formulations of the hydrogel type provide an increased bioavailability, but do not allow a significant sustained and controlled release of the incorporated drugs. Colloidal systems are often associated with stability problems and are difficult to sterilize. Solid systems are not always well tolerated by the patients.

Some new approaches, such as the use of lectins or cyclodextrins for topical formulations and iontophoresis to allow enhanced penetration of drugs to the posterior segment of the eye, may be promising alternatives to the various polymeric systems discussed in this chapter.

## ACKNOWLEDGMENTS

The authors wish to express their thanks to Annette Meier-Nabholz (Galenica Distribution AG, Schöubühl, Switzerland) for providing information on marketed hydrogels.

### I. INTRODUCTION

The oral cavity is an external environment where a wide range of conditions are in constant change (i.e., pH, temperature, abrasion forces, presence of bacteria, etc.). However, under physiological conditions, the oral cavity is very tolerant and resistant to external challenges. In order to achieve this goal, the teeth and their associated structures, such as the jaws and gums, must display harmonious behavior and interrelationships. The anatomical design of teeth and associated tissues provides resistance to this hostile environment. However, several factors (diseases, physiologically unacceptable conditions, trauma, etc.) may alter the function and structure of the oral cavity elements. Clinical treatments directed to restore and maintain the normal functions of the oral structures (teeth and supporting tissues) are grouped in what is known as dentistry.

Dentistry involves the repair and/or removal of decayed teeth, malocclusion correction, straightening of the teeth, and the design and manufacture of false teeth or other prosthetic devices. Studies within the dental biomaterial field are focused on the clinical functionality and longevity of dental implant devices in order to improve human dentition health, esthetics, and quality of life.

There are four main groups of widely used materials in dentistry: metals and alloys, ceramics, synthetic organic polymers and biopolymers (derived from natural tissues), and composites (an organic matrix of different kinds of polymers filled with inorganic fine particles). Although several metallic biomaterials are widely used due to their

good properties, they show a slow and progressive decrease in specific applications which is concomitant to an increase in the use of polymers, composites, and inorganic materials. This might have different explanations: (1) non-precious metal alloys can be chemically unstable in the oral environment (etching, oxidation, pigmentation); (2) a general negative feeling against visible alloys in dentistry has appeared in recent years based on esthetic criteria; (3) many of the nonprecious metal alloys frequently show biological complications (allergenicity, cytotoxicity, carcinogenicity); (4) complex equipment is required for metal processing, which usually makes its dental application too expensive; (5) the price of many metals is not balanced and depends on economic or political crisis. For these and other reasons, the materials used for dentistry have been modified in recent years. These changes in use tendency are characterized by (1) increased use of polymers, composites, and ceramics; (2) development of new techniques for covering metal surfaces with polymer or ceramic materials; (3) development of composites for specific dental applications; and (4) improvement of adhesiveness of all these materials to dental structures. However, the use of polymers in dentistry has to be combined with the use of other types of biomaterials due to the special characteristics of the oral biological environment where different soft and hard tissues are found. Thus, for example, endosteal or endosseous devices placed into the bone tissue are mainly metals and alloys (1).

In a short historical overview, it must be mentioned that oral disease treatment and tooth replacement can be found

in ancient civilizations. Dead animal parts or minerals were used to replace damaged structures. In the 17th century, the implants used for oral treatment became more similar to the missing or damaged part: teeth extracted from cadavers or from living persons were used. In the 18th and 19th centuries, increasing attention was given to the basic properties of the implanted materials. A systematic investigation of the physical, mechanical, and biological properties of dental implant devices was carried out. The technological and scientific advances in the 20th century provided the basis for the design of new biomaterials with a better behavior and an adequate durability for dental applications.

The use of polymers for dentistry was initiated in the 19th century. Thus, gutta-percha (leathery material derived from the latex of certain trees) was used as a material for dental impressions in 1848 (it is still an important material for root canal filling); vulcanized caoutchouc was employed in 1854 for denture bases; and celluloid (developed in 1869 from a homogeneous colloidal dispersion of cellulose nitrate and camphor) was used around 1870 for dental prosthetics. Figure 1 shows an old dental prosthetic device (a caoutchouc base with porcelain teeth) that has been in continuous use for 45 years (from 1940) and finally substituted by another polymethyl methacrylate (PMMA) device. However, the modern age of polymers began in 1909 with bakelite (a phenol–formaldehyde resin), a material scarcely used in dentistry. The first rigid polymer employed in odontology was PMMA, which has been used from 1930 for different purposes (denture bases, artificial teeth, removable orthodontics, surgical splinting, and even for esthetic filling in anterior teeth). In the 1930s many other polymers appeared for dental and surgical uses (poly-

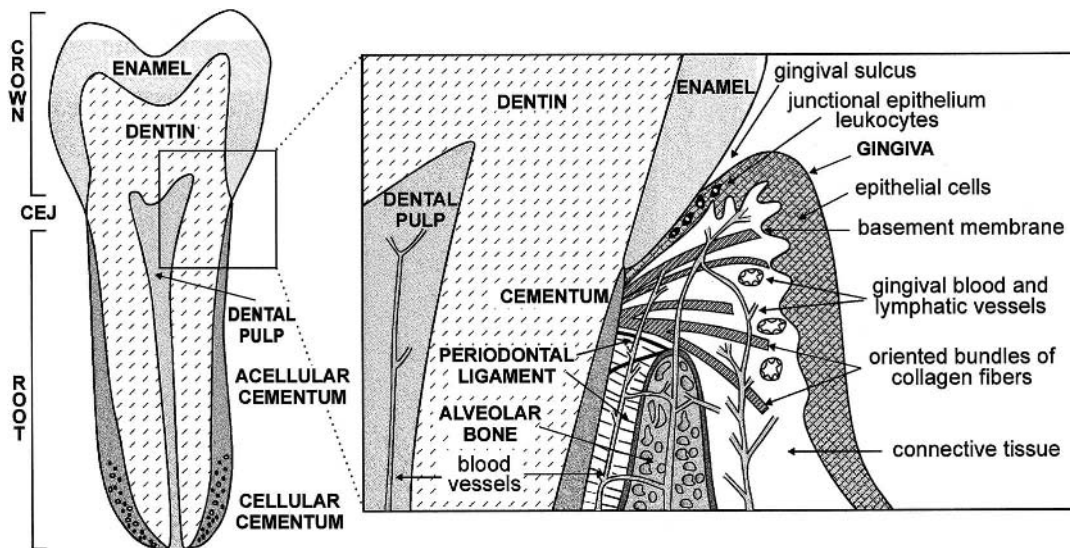

**Figure 16.1** Old caoutchouc (prepared around 1940) complete dental lower prosthesis with porcelain teeth.

amide, polyester, polyethylene, etc.), prepared in different forms (rigids, softs, fibers, adhesives, etc.), and exhibiting several applications (dentures, veneering of crowns and bridges, fillings, mouth protectors, sutures, implants, etc.). Bis-GMA, a combination of bis-phenol and glycidyl methacrylate, appeared in 1956 as an important innovation in the field of rigid polymers for dental uses. From that time on, there has been continuous and important research concerning the use of polymers and composite materials for dentistry.

## II. ORAL BIOLOGY AND BIOCHEMISTRY

When a material is used for any surgical purpose (implant, suture, etc.), the organism reacts in order to restore the integrity of the affected tissues. There are many general processes following any kind of injury, such as inflammation and development of inflammatory tissue, cell proliferation, and necrosis of damaged cells. But the specific response depends on the biology of the particular affected regions. Thus, the use of restorative materials for biomedical applications requires a good knowledge of the biology and biochemistry of the specific location considered. Oral surgery repair treatments move into a highly specialized biological environment. A significant part of the functions performed at the maxillofacial level shows a mechanical component that exhibits high stress. The specific properties of the biological components at this location must accomplish such requirements. Most treatments involve the use of nonnatural materials that must be able to perform specifically designed functions in that particular biological theater. Therefore, the characteristics of the biology and physical chemistry of this neighborhood must be analyzed when considering the use of biomaterials at the maxillofacial level. Human dentition consists of 32 teeth (candidates to implant sites); there are four incisors, two canines, four premolars, and six molars in each jaw (mandible and maxilla). The anatomical shape of these teeth is heterogeneous reflecting their specific functions; the incisors and canines are used for cutting and tearing, while premolars are used for crushing, and the molars for grinding. Three different zones can be distinguished in each tooth: the root, attached to the tooth-bearing bone of the jaws by a fibrous ligament (periodontal membrane), the neck, embraced by the fleshy gum tissue, and the crown, that projects into the mouth. Figure 2 shows a longitudinal section of a tooth with its major structures.

After an oral surgical operation, in most cases the picture is characterized by the presence of a hard material surrounded by soft tissues. All of these components must be adequately interfaced in order to function properly, and

**Figure 16.2** Schematic diagram of the major tooth compartments, connective tissues, and cells in the periodontal unit. CEJ: cemento–enamel junction.

this requires the cooperation of many different tissue cells and biopolymers. The main role corresponds to connective tissues forming the periodontium, which is responsible for the support and attachment of the tooth in the bones of the jaw. Many different connective tissues (ranging from mineralized to fibrous) can be distinguished in the oral cavity (Fig. 2; Table 1): alveolar bone, enamel, dentin, cementum, periodontal ligament, and gingiva (2–18).

The basic constituents of human enamel and dentin, their composition, and several other parameters (mechanical properties, elastic modulus, and viscoelastic properties) have been reported (18–20). The enamel is the very hard, dense, and brittle cover of the tooth’s crown that is located above the gumline. Enamel is highly mineralized and contains prismlike structures comprised of hydroxyapatite crystallites and very little organic material. Its properties make dental enamel a good material for cutting and masticating food, processes that involve friction and wear. Mature enamel is an acellular nonliving structure that cannot be renewed after damage.

The bulk of the tooth is made up by dentin, which defines its shape. Dentin, a continuous nonuniform mineralized tissue, is similar in composition to bone but is tougher and less hard than enamel (9,10). It is formed by a highly mineralized matrix (peritubular dentin) that surrounds the dentinal tubules. These tubules are distributed throughout the dentin matrix in a more or less uniform manner. In contrast to enamel, dentin is a living tissue. A layer of dentin producing cells, the odontoblasts, surrounds the pulp cavity of the tooth sending projections into the den-

tinal tubules. Secondary dentin, a less organized form of tubular dentin, is produced throughout life. Tertiary, or reparative, dentin is formed when the enamel of the crown is damaged. The dentin is nourished by the pulp in which cells, tiny blood vessels, and a nerve are enclosed in the pulp chamber. Below the gumline, from the cervix to the apex of the root, dentin is covered by the cementum to which the periodontal ligaments bind attaching the tooth to the alveolar bone (17). Cementum is less hard than dentin, showing properties very similar to those of bone.

The connective tissues of the oral cavity are involved in several specific and diverse functions, including speech, mastication, and the maintenance of face esthetics. Moreover, the periodontium represents one of the biological barriers against the external environment (21). Thus, it can be affected by a variety of diseases producing alterations of its connective tissues and requiring frequent clinical treatments (22–28).

From a general point of view, the connective tissues can be considered as composed of cells and extracellular matrix (ECM). In such tissues there are many types of cells performing different functions, e.g., biosynthesis of the ECM components, lipid storage, biological protection, etc. Table 1 shows some of the different tissues and cell types from the periodontal unit. Fibroblasts, one of the principal cells of the periodontal connective tissues, are involved in maintaining the connective tissue matrix (29). After an alteration of the periodontal connective tissues, following injury, fibroblasts migrate into the wound site. Also epithelial cells appear to be related to the formation of epithelial

**Table 16.1** Tooth Compartments and Associated Tissues

Tissue and cells	Characteristics and function	Ref.
<i>Mineralized</i>		
Enamel		
Ameloblasts	Enamel-producing cells; differentiated and polarized epithelial cells. Secretion of amelogenins (proline-rich proteins; 5–28 kDa) and enamelins (more acidic and lower proline content than amelogenins; 42, 56, and 72 kDa). Noncollagenous fibrils. Mineral content: 95–98%. Mature enamel: nonliving tissue.	2
Dentin		
Odontoblasts	Dentin-producing cells; differentiation of mesenchymal cells. Single layer of fully differentiated and polarized cells; located at the boundary between the dentin and pulp chamber. Mineral content: 65%. Secretion of extracellular matrix components, uncalcified matrix: predentin and control of its mineralization. Synthesis of noncollagenous proteins.	2–10
Cementum		
Cementoblasts	Secretion of collagen and noncollagenous proteins. Type I (>90%) and type III (<5%) collagen.	2–4,8–17
Alveolar bone		
Osteoblasts	Matrix-producing cells. Formation of mineral bone tissue. Synthesis of type I collagen (100%) and noncollagenous proteins. High levels of alkaline phosphatase. Synthesis of collagenolytic enzymes and their inhibitors.	2,3
Osteoclasts	Specialized resorptive cells. Role in remodeling processes. Resorption of the degraded organic matrix by osteoblasts.	2,3,18
Osteocytes	Embedded in the mineralized matrix in the lacunae space. Derived from osteoblasts. Role in the calcium exchange between mineralized tissue and blood. Matrix-producing cells; resorptive properties but to a lower extent than osteoclasts and osteoblasts.	2,3
<i>Nonmineralized</i>		
Dental pulp		
Dental pulp cells	Loose connective tissue enclosed in the dentin. Nerves and vascular elements permeate the tissue and provide nutrients entry, supporting metabolic activity via the blood vessels and capillaries.	2,3,5,11,13
Periodontal ligament		
Fibroblasts	Collagen-producing cells. Dense collagenous structure. Synthesis of type I (>90%), type III (<18%), and type V (<1%) collagens. Presence of other cells from blood and lymphatic vessels.	2–4,11
Gingiva		
Fibroblasts, epithelial cells	Collagen-producing cells. Type I and type III collagens represent 60% of the total tissue protein. Synthesis of type IV and type V collagens (<1%).	2–4,10,13
Mast cells, leukocytes, plasma cells	Primary defense against invading microorganisms. They are present in gingiva and periodontal ligament.	2,4

attachments during wound healing after periodontal therapy. On the other hand, the ECMs can be divided into two groups: those forming interstitial connective tissue and those from the basement membrane (30–36). However, both types of ECM comprise many different macromolecular structures, which can be grouped into collagens, glyco-

proteins, and proteoglycans, attending to their major components (37–45).

Collagens and glycosaminoglycans (one of the components of proteoglycans) are discussed elsewhere in this book since these molecules are used as natural biopolymers in the biomaterials field. The periodontal tissues are

highly collagenous. The family of collagens accounts for more than 50% of the total tissular protein. Collagens are well-known proteins whose chemical and tridimensional structures are clearly elucidated (37–42). The fibrillar type I collagen is the one present in the largest amount. However, this type of collagen is only the representative molecule of a broad family of proteins which mainly have a structural function in connective tissues. But in spite of such a structural role, the relative proportions of the different collagen types are important factors in determining biological functions at the ECM. In particular, the periodontal structures contain high proportions of type I collagen, about 90% of the collagen present in the periodontium, whereas type III collagen only accounts for about 10%, and other minor collagen types are only present in about 1% (4).

Based on this information, it is perfectly comprehensible that a significant part of the diseases and misfunctions at a maxillofacial location will be related to collagens. For instance, a destruction of collagen bundles occurs during gingivitis (22), and extensive degradation of connective tissues with a concomitant reduction in the amount of collagen appears in chronic periodontitis (4), considering only two of the most common diseases at the periodontal level. Also physical trauma-induced lesions, which are frequent at the oral cavity, may affect collagen deposition and fibroblasts migration, although cellular and biochemical studies concerning this topic are scarce.

The ECM is a structurally stable association of biopolymers surrounding the connective tissue cells. But this matrix is not a simple inert supporting material (46–48). It exhibits close functional relationships with the tissue cells; specific cell receptors interact with ECM components modulating cell behavior (43,49). These functional components have been grouped into a heterogeneous family of adhesion glycoproteins that include some types of collagens and several noncollagenous ECM proteins (43,49,50). Particular matrix components can associate in a diversity of macromolecular structures defining specific ECMs with whom different types of cells can interact. Noncollagenous proteins present in oral cavity tissues are involved in several processes, as the initiation and formation of apatite crystals (mineralized tissues) and the regulation of cell proliferation and tissue growth and development (16,17,51). In the dentin matrix, a mineralized tissue, there are several noncollagenous ECM proteins (Table 2) (52,53). The main characteristic of these proteins is their acidic nature, some of them presenting the capacity of being phosphorylated. Several of these proteins are also found in the bone matrix (osteonectin, osteopontin, osteocalcin, matrix Gla protein, proteoglycans, etc.) (53–65). However, some of them ap-

pear to be dentin specific such as dentin phosphophoryn, dentin sialoprotein, and dentin matrix protein-1. Some characteristics of these proteins from the mineralized tissues are summarized in Table 2. Bone morphogenetic proteins (BMPs), which are present in dentin, deserve special attention since they can induce bone formation (66–68).

As already mentioned, some natural polymers such as collagen are used in different applications in biomaterials science (69). Other noncollagenous glycoproteins from the ECM that also play important roles in the control of cell behavior should be taken into consideration in dentistry. A brief description of some of these proteins is shown in Table 3 (70–85). In this way, fibronectin has been used in the treatment of periodontal disease (27,28), and laminin-5 is used to promote cell attachment of gingival epithelial cells to titanium alloy implants (86).

When studying biomaterials, one should never forget that they are going to be in close contact with the surrounding tissue cells. Cells are in constant communication with their external environment. Several cell surface receptors are involved in cell-to-cell association and cell-ECM interactions (87–89). These receptors are grouped into different families based on similarity of structure and function, such as integrins, selectins, cadherins, etc. Integrins are heterodimers comprised by two different transmembrane subunits ( $\alpha$  and  $\beta$ ) that play a critical role in cell-to-cell and cell-ECM association. They are capable of transducing information from the external environment to the inside of the cell (90–92). The maintenance of a normal cell phenotype is dependent on the signals received from the ECM. Thus, the possible alteration of the external cell environment is an important aspect to be considered in order to understand host response to biomaterials. The binding site or receptor recognition sequences, among them the arginine-glycine-aspartic acid sequence (RGD), have been described in several adhesive ECM proteins (Tables 2 and 3) (93,94).

However, many other natural molecules are also involved in the complex mechanisms that control cell behavior. Thus, polypeptide growth factors have a determinant role in stimulating migration and growth of cells in wound healing and repair. Interesting studies are still in progress concerning this topic (26).

These brief comments are intended to present the complexity of the biology of the maxillofacial region where cells (fibroblasts, endothelial cells, bone cells and nerve cells, among other cell types), many biopolymers (collagens, proteoglycans, and glycoproteins), and growth factors play specific roles resulting in a highly specialized structure. All of them must be considered when studying the response of a biomaterial after any use at this location.

**Table 16.2** Noncollagenous Proteins in Mineralized Tissues

	Bone	Dentin
Glycoproteins/sialoproteins	<p>Osteonectin (SPARC) Protein of 35 kDa. Acidic secreted protein, cystein rich. Affinity for collagen, gelatin and hydroxyapatite. Calcium binding protein. Role in bone matrix assembly. 13% carbohydrate. (2,10,54)</p> <p>Bone sialoprotein (BSP) 70–80 kDa; 20% sialic acid. (2,55,56)</p> <p>Osteopontin (sialoprotein I) 32 kDa; 5% sialic acid, high content of phosphate. Contains the -GRGDS-sequence (2,18,57,56,58)</p> <p>Bone sialoprotein II 13% sialic acid. (2,9,10)</p> <p>Bone acidic glycoprotein (BPG-75) (2,10,59)</p>	<p>Osteonectin Similar to those from bone.</p> <p>Osteopontin Similar to those from bone.</p> <p>Dentin matrix protein-1 (Dmp-1) Specific of dentin. Aspartic acid and serine rich protein. Expression in odontoblasts and osteoblasts. Binding to collagen. Contains one RGD sequence. Role in matrix calcification. (10,62)</p> <p>Dentin sialoprotein (DSP) Specific of dentin. 53 kDa. Synthesized and secreted by odontoblast cells of the dental papilla. (10,63)</p>
Phosphoproteins	<p>Phosphoserine and phosphothreonine proteins 5–70 kDa. Some are glycoproteins and/or sialoproteins. (2,9,10)</p>	<p>Phosphophoryns 155 kDa. Specific of dentin. More than 50% of noncollagenous dentin proteins. 75% of serine and aspartic acid and 85% of serine residues are phosphorylated. They are able to bind calcium ion with high affinity. Higher phosphorylation and molecular mass than bone phosphophoryns. Heterogeneity between dentin of different species. (7,10,64,65)</p>
$\gamma$ -Carboxy glutamic acid-containing proteins	<p>Osteocalcin (BGP) Major endogenous protein constituent of the bone (5.2–5.9 kDa). It contains three Gla residues; present in mineralized tissues and also found in plasma. Its plasma content is related to metabolic bone disease. Specific role in matrix mineralization. (2,9,10,58,60)</p> <p>Matrix Gla protein (MGP) 10 kDa. Five Gla residues. (2,9,60)</p>	<p>Osteocalcin (BGP) Similar to those from bone.</p> <p>Matrix Gla protein (MGP) Similar to those from bone.</p>
Proteoglycans	<p>Biglycan Core of 38 kDa and two GAG chains of 40 kDa. Containing primarily chondroitin 4-sulfate. (10,61)</p> <p>Decorin Core of 38 kDa and only one GAG chain of 40 kDa. Containing primarily chondroitin 4-sulfate. (10,61)</p>	<p>Biglycan and decorin (major proteoglycans) Proteoglycans represent about 2.5% of the organic matrix. Small core proteins and GAG chains of 35–40 kDa. All the GAG have been detected but they are composed predominantly of chondroitin 4-sulfate. The content in predentin is higher than in dentin and is enriched in chondroitin-6-sulfate. (5,7,44)</p>
Serum-derived proteins	$\alpha_2$ HS-Glycoprotein, serum albumin, fibronectin	$\alpha_2$ HS-Glycoprotein, immunoglobulin, serum albumin, transferrin

*Notes:* Some serum derived proteins trapped or binding to the mineralized tissues are also indicated. Gla:  $\gamma$ -carboxy glutamic acid; GAG: glycosaminoglycans. References in brackets.

**Table 16.3** Main Noncollagenous Proteins (Elastin, Glycoproteins, and Proteoglycans) of the Extracellular Matrix

Component	Characteristics	Ref.
Elastin	Single polypeptide chain of 72 kDa. Glycine rich protein (33%). High alanine, valine, and proline contents; presence of hydroxyproline. Elastin fibers form a network with two different components: amorphous elastin and microfibrils (10–12 nm diameter). Covalent crosslinks. Responsible for tissue elastic properties. Synthesis by fibroblasts, chondrocytes, and endothelial and smooth muscle cells.	70,71
<i>Glycoproteins</i> Fibronectin	Variants of a dimer (440–550 kDa) of two polypeptide chains (230 kDa) disulfide bonded near the C terminus. Each chain is composed of a different number of repeats (type I, type II, and type III repeats). Three regions with alternative splicing; 4–10% carbohydrate. High degree of sequence homology between fibronectin from various species. Interactions with collagen, glycosaminoglycans, fibrin, heparin, cell surface receptors, etc. Cell attachment site of -Arg-Gly-Asp-(Ser)- recognized by cell surface receptors of the integrin family. Functions: control of cell adhesion, cell spreading, cellular motility, differentiation, opsonization, and wound healing. Serum, stroma, and particular basement membrane. Synthesis by fibroblasts and other cell types.	72–74
Laminin	Family of trimeric basement membrane glycoproteins with multiple domains, structures, and functions. Three disulfide-linked polypeptide chains (850–900 kDa) are assembled in a cruciform structure with three short arms containing globular domains and a long arm with a distal globular domain. Different isoforms according with tissues and origins. Major noncollagenous protein of basement membrane. They show different cell biological activities controlling cell adhesion, growth, morphology, differentiation, and migration; have role in matrix assembly. Repeats with similar sequences to the EGF-like domains. Cell laminin receptors are mainly of the integrin family.	75–78
Tenascin	Six-armed structure (1900 kDa). Three arms are assembled forming a trimer (disulfide bonded) and two trimers are bound forming the hexamer molecule through disulfide bonds. Isoforms. The molecule contains three structural domains: a terminal globule at each arm (C terminus), thick distal, and thin proximal segments. Repeats with similar sequences to the EGF-like domains and domains similar to the type III repeats of fibronectin. Tendons, ligaments, bone, cartilage, and smooth muscle. Synthesis by fibroblasts and glial cells.	79,80
Thrombospondin	Three polypeptide chains (180 kDa) crosslinked by interchain disulfide bonds near the N terminal domains (420 kDa). The molecule is organized into globular domains connected by thin regions of polypeptide. Large globular structure at the N terminal (three chains assembled) and three globular domains each corresponding to the C terminal polypeptide chain. Binds to heparin, fibronectin, fibrinogen, type V collagen, and calcium. Thrombin-sensitive protein. Associated to extracellular matrix. Synthesis by platelets.	81,82
<i>Proteoglycans</i>	Family of molecules composed of different core polypeptide chains where one or more types of glycosaminoglycans are attached by O-glycosidic linkages. Widespread distribution on cell surfaces, in basement membranes, and in the extracellular matrix of most tissues. They are involved in cell–cell interactions, cell migration, differentiation, tissue morphogenesis, cell–substrate attachment, and in the ionic control of filtration through basement membranes.	83–85

### III. TESTING AND EVALUATION OF MATERIALS FOR DENTISTRY

Many factors must be considered in the evaluation of the potential use of a material in a biological environment. Every process resulting from the presence of such a material is a consequence of a reciprocal set of reactions, i.e., host response against the material and vice versa. These responses cannot be independently analyzed since both arise from the presence of the material considered and are closely related. The main events occurring related to the material–host reactions are summarized in Fig. 3.

The behavior of a material in a biological environment would first depend on its intrinsic properties related to its physicochemical structure. However, these properties are modulated by the surrounding tissues, with the cellular and biochemical components of that particular site playing a determinant role. Depending on the characteristics of this local double response, the material might be cataloged as biocompatible. However, in spite of these short-range responses, the potential long-range consequences arising from the presence of the material should be also considered. For instance, products liberated from the material may produce significant effects in distant tissues or organs (95). Such possibilities should be taken under consider-

ation when designing assays for testing and evaluating a material for biomedical applications.

A biomaterial behaves as a foreign body in terms of the tissue response it evokes (96). Therefore, there is a sequence of events, ranging from the molecular scale to the cellular and tissue level, that can be expected following any biomaterial application. But the particular characteristics of the whole response are also dependent on the surgeon's skill, the patient's condition, and, more importantly from the present point of view, the material properties. Thus, the chemical, physicochemical, and mechanical properties of the material must be considered. On the other hand, the biodegradability of the biomaterial represents another point of interest. Nonbiodegradable materials constitute a permanent trauma to the adjacent tissues. But absorbable products result in scar tissues whose presence would depend on the material removal rate. In summary, there are many properties of biomaterials to be considered in terms of tissue reactions against their presence. Among these properties, some of the most relevant are surface roughness and porosity, interfacial forces, surface charge, hydrophilicity, chemical composition, leaching of chemicals into the surrounding tissues, shape, size, and permeability (97).

The surface roughness determines the contact area of

Figure 16.3 Summary of the general host–implant reactions.

the material with the surrounding tissue and the extent of the tissue–material interactions at the physicochemical level. The porosity of the material, pore size, and distribution affect the ingrowth, attachment of the adjacent tissues, and protein deposition (98). The interfacial forces arising from the surface properties of the product can also determine to a large extent interactions between the biomaterials and the tissue or physiological fluids. Surface charge must be also considered. This charge may result from the processing of the biomaterial or from either surface defects or adsorbed charged molecules. The hydrophilicity of the material and the distribution of polar and nonpolar groups in its surface are also important since the material will be located in a polar environment, and these factors determine the thermodynamical parameters of the biomaterial–tissue interactions. All the surface properties of the biomaterial may be involved in processes of macromolecules adsorption (98,99).

Most of the nonnatural products to be used as biomaterials can be considered as inert in terms of liberation of component products. However, the biological environment is highly aggressive for any foreign material, and consequently leaching of chemicals into the surrounding tissue may occur during degradation of the used product. This is especially important when the liberated products are monomers from the polymerization process due to their potentially high toxic effect (100). Thus, the chemical composition of the biomaterial is also something to be considered. Size and shape are also important physical factors when considering the material–tissue relationships. In fact, most of the mentioned effects are related to the relative surface of the biomaterial, which correlates with size and shape. But these two factors are also intrinsically important. The size and shape of the device must be compatible with the anatomical and histological characteristics of the implantation site. Moreover, in general, large and sharp devices can induce more reactions in the surrounding tissue than small and flat structures.

On the other hand, any biomaterial is potentially subjected to etching processes. Thus, corrosion would affect metal devices, or dissolution would affect ceramics. Polymers are subjected to degradation. They can be partially or totally destroyed by different causes, e.g., heat, oxidation, mechanical forces, radiation, etc. But biological degradation of polymers is also possible, e.g., enzymic action or phagocytic activity of macrophages (101). This is very important when considering the tissue reaction to an implanted polymer. Sometimes biological degradation is a required characteristic of resorbable implants. However, it can also result in secondary toxic effects produced by the liberated components. Therefore, the synthesis of the poly-

meric biomaterial should tentatively control all of these specific requirements and precautions.

In spite of all the previous considerations concerning the properties that polymeric material should exhibit to be used for biomedical applications, its response against biological environments must be tested prior to human clinical uses. Thus, after manufacture of a polymer according to the structural characteristics required for its desired function, the resulting product must be tested both *in vitro* and *in vivo*.

Most of the *in vitro* tests involve cell culture in the presence of either the potential biomaterial or products resulting from its degradation (97,102,103). The validity of these assays can be extended by using tissue or organ culture, a more reliable test but involving highly specific methodologies. There are many different *in vitro* tests (104–110). They usually deal with the cell morphology, cell adhesion and spreading, cell migration patterns and rates, cell growth kinetics, and DNA and protein synthesis in the presence of the material to be tested (105,106,111–113). These cellular characteristics are representative of the cell response against nonbiological materials. Thus, their analyses give information concerning the potential biological performance of the material.

Results from *in vitro* tests are obtained in relatively short periods of time and normally with a low cost. However, they do not completely mimic the complexity of the potential responses after implantation.

The *in vivo* tests intend to overcome such limitations. But they require a defined standardization in allowing a clear explanation of the obtained data. Sometimes the results appearing in the literature are difficult to interpret because the experiments have been performed under very different conditions. In fact, the *in vivo* tests are mainly related to implantation in animals, and the selected animal species is of crucial importance, as well as the animal age and the dietary and laboratory living conditions, for generalization purposes.

The effects of implanted materials on biological fluids must also be considered. After implantation, the blood and cellular exudates contact the material and many physiological reactions can occur. These are of great importance when related to blood. Among these potential effects, immune response and thrombogenicity are of special significance. Immune responses should be considered under *in vivo* testing conditions of an implant. This assay should be extended to products potentially arising from the degradation of the implanted material. Remote site immune responses, e.g., urticaria or asthma, may also appear after implantation. Concerning thrombogenicity, even chemically inert materials can produce thrombus on contact with

blood (114,115). The surface of the implanted material may adsorb plasma proteins resulting in altered local protein concentrations and modified blood coagulation.

In order to evaluate materials for dentistry, all of the mentioned steps should be considered. First, if the material to be used is a new one, its toxicity must be tested by *in vitro* assays (e.g., Fig. 4; Table 4) (105). Further, implant devices should be tested *in vivo*. Subcutaneous and/or intramuscular implantation in experimentation animals can be the first step since the host response, including cellular and immunological data, can thus be measured for relatively short periods of time (e.g., Fig. 5) (116–120). The bacteriological effects are also very important when materials for dentistry are being considered. First, alterations on the local immune response, modifying the resistance of the oral environment to bacteriological contamination, may result from the presence of the biomaterial. On the other hand, the product would be exposed to bacterial degradation at the maxillofacial unit, which should also be

**Figure 16.4** Sepiolite (clay)–collagen complex has been tested by scanning electron microscopy for biocompatibility. The adhesion and spreading of human skin fibroblasts have been studied as a function of time: (A) 20 min,  $\times 5000$ ; (B) 30 min,  $\times 5000$ ; (C) 60 min,  $\times 2500$ ; (D) 120 min,  $\times 2500$ . Cell-to-sepiolite–collagen complex attachments are indicated by arrows. The clay–type I collagen complex is a suitable substrate for fibroblast attachment (see Ref. 105). According to this analysis fibroblasts exhibit a normal morphogenetic process when sepiolite–collagen complexes are used as substrate. The cell spreading seems to be essential for fundamental biological properties such as mobility, macromolecule biosynthesis, or proliferation. Bars = 1  $\mu\text{m}$ .

taken into account (Fig. 5). The next step is to consider the device implantation at the maxillofacial unit of a suitable animal model. Probably primates are the most preferred experimental animals because their physiological and immunological responses are very similar to those in humans. However, some materials used in maxillofacial surgery are not adequately tested in monkeys. The behavior of this type of animal as well as its anatomy sometimes do not allow these clinical tests. For instance, these animals can remove the devices to be tested with their fingers. Thus, small and calm beagle dogs are sometimes used for these purposes. The *in vivo* analyses require histopathological and radiographic examinations and should be performed for long periods of time, even at the order of years, to evaluate the functional abilities of the implant. When studying the use of a biomaterial as dental implant, its osteoconductive and osteoinductive abilities should also be taken under consideration when bone regeneration is required.

#### IV. OPERATIVE DENTISTRY AND ENDODONTIC TREATMENT

Specific dental surgical treatments using polymer materials are shown in Fig. 6. Some dental defects are shown as well as the division of dentistry dealing with them and the currently used methods of treatment.

##### A. Operative Dentistry

Operative dentistry deals mainly with the removal of tooth caries, a localized disease that begins at the surface of the tooth and may progress through the dentin into the pulp cavity. Caries is one of the most widespread health problems in humans, with a concomitant economic relevance. Nowadays three main topics can be distinguished in operative dentistry: (1) floor and wall protection of the carved cavity after caries removal; (2) filling and restoration of the cavity by using composite materials; and (3) bonding between composites and dental structures.

##### 1. Bases, Liners, and Varnishes for Cavities

There is a large diversity of organic and inorganic materials for these purposes. They can be used as a barrier against other materials with aggressive pH, for thermal or electrical insulation, or to provide hardness and mechanical resistance (121,122). These materials are nowadays under revision since in the last years special attention has been paid to adhesion mechanisms between biomaterials and dental tissues (123). The materials most frequently used are zinc polycarboxylate cement, glass-ionomer cement, and different varnishes.

**Table 16.4** Summary of the Results Obtained from Proliferation Curves of Human Skin Fibroblasts Grown on Sepiolite–Collagen Complex

Substrate	DNA <sup>a</sup> (pg/cell)	Protein <sup>a</sup> (pg/cell)	Saturation cell density <sup>a</sup> (cells/cm <sup>2</sup> )	Doubling time <sup>b</sup> (days)
Plastic	8.81 ± 0.19	454 ± 49	60,000 ± 4,500	1.40 ± 0.08
Sepiolite–collagen	8.88 ± 0.29	451 ± 37	66,000 ± 5,435	1.36 ± 0.05

<sup>a</sup> Values determined for cells at the stationary phase.

<sup>b</sup> Time required to double the cell population determined in the logarithmic phase.

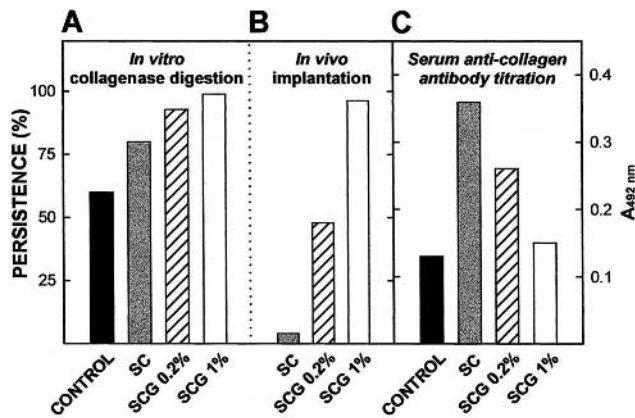

*Notes:* Sepiolite–collagen complex does not modify the extent of DNA and protein contents nor the kinetic parameters of the cell growth when compared to a standard substrate, like culture plastic dishes, under the conditions used in this *in vitro* assay. Normal adhesion and growth of fibroblasts and other so-called anchorage-dependent cell types in culture require suitable substrates. Thus, sepiolite–collagen complex exhibits biocompatibility with regard to cell proliferation. Data are expressed as averages ± SD.

*Source:* Ref. 106.

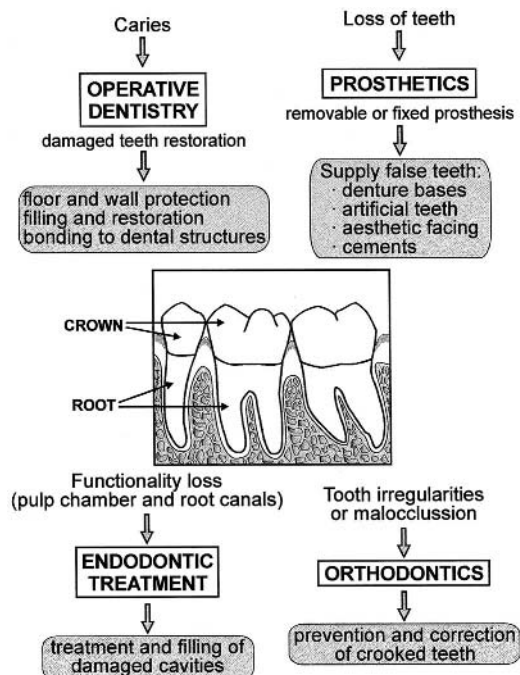

Zinc polycarboxylate (or polyacrylate) cement is prepared by mixing zinc oxide and the polymer solution, a highly viscous water solution of polyacrylic acid (25,000–50,000 molecular weight). Carboxyl groups of the polymer structure are crosslinked by the metal ion or form a com-

plex with the calcium ions in the surface of the calcified tissue. The resulting product is not only highly resistant, with similar properties to dental zinc phosphate cement, and has an excellent biocompatibility, but also shows adhesion to the enamel and dentin layers of the tooth (124).

Glass-ionomer cement also results from a two-component mixture. Instead of zinc oxide, fluorocalcium aluminosilicate glass powder is used and, as the second component, a solution of a variety of acids, mainly homopolymers or copolymers of acrylic acid with different proportions of

**Figure 16.5** (A) Degradation of collagen in type I collagen–sepiolite complex by *Clostridium histolyticum* collagenase (see Ref. 116). The degradation of collagen by the bacterial enzyme decreases when the protein is bound to the clay; the degradation of collagen fibers by collagenase is lower than that produced in collagen solutions (control) (see Ref. 117). This would be in agreement with the longitudinally ordered structure of collagen in the protein–clay complex (see Ref. 118). (B) Evaluation of the subcutaneous implantation of sepiolite–collagen complex. Persistence of the biomaterial determined as percentage of (<sup>14</sup>C)-acetylated collagen remaining at the implantation site after two months. (C) Titration of anti–type I collagen antibodies by ELISA tests (measurements of absorbance at 492 nm, A<sub>492</sub>) in rat sera 2 months after implantation of sepiolite–collagen complex (SC) and sepiolite–collagen complex treated with 0.2% (v/v) and 1% (v/v) glutaraldehyde (SCG).

**Figure 16.6** Scheme of different areas of dentistry.

tartaric, itaconic, or maleic acid. Polyacid groups interact with calcium and aluminum ions from the glass. The resulting product is a more rigid cement, exhibiting a high mechanical resistance and adherence to enamel and dentin as the zinc polycarboxylate cement. It can also release fluoride ions, which induce the formation of fluorapatite in the teeth. Glass-ionomer cement can be also used as restorative material and luting cement (125–130). These materials present some advantages over acrylic bone cements: absence of monomer, lack of exotherm during setting, and improved release of incorporated therapeutic agents. They integrate with the bone influencing its growth and development. They have been used successfully in several biomedical applications; however, adverse effects have been described on neural tissues (131).

The varnishes are constituted by natural (copal, colophony, etc.) or artificial (polystyrene) resins dissolved in conventional organic solvents like chloroform, ether, or some alcohols. A thin (few micrometers) film of the polymer appears after application of these solutions on the dental surface. These products are used as barriers against several irritants. When protection against thermal changes or rigid support are required, a suitable cement is also used (122,124).

## 2. Filling and Restorative Materials

### a. Composite Resins

Composite resins are made up of an organic matrix (polymeric structure) and an inorganic particulate or fibrous (small fibers) filling. They are held together by using a coupling or binding agent. Additionally, some colorants, stabilizers, or primers for the polymerization reaction are added.

Dental amalgam has traditionally been employed as material for cavity filling; but the use of this material is controversial (esthetic problems, eventual toxicity, environmental pollution by mercury, etc.) (132–134). Glass-ionomer is a product also now employed for restorative purposes (129,130). Polymethyl methacrylate resins have also been used as filling materials, but they have several disadvantages such as low molecular weight of the monomer, high polymerization shrinkage, marginal percolation (caries relapse), nonadhesion to dental structures, pulp toxicity, and low color stability.

Bis-GMA represented an improvement over PMMA mainly due to its higher monomer molecular weight (135,136). In order to reduce the viscosity of the original monomer solutions, many others monomers have been considered (bis-phenol dimethacrylate, aromatic or aliphatic urethane dimethacrylates, diethylene glycol dimethacrylate, triethylene glycol dimethacrylate, decamethylene

glycol dimethacrylate) (137–139). Therefore, there are many different products available that result from mixtures of these monomers and exhibit a diversity of properties (rheological, mechanical, polymerization contraction capacity, etc.). The potential risk of the use of bisphenols (used in some industrial sectors) is nowadays being considered since estrogenic effects can be induced as a result of the degradation of the organic matrix (140,141). Recently, some composite resins have appeared for their use as dental filling, bis-GMA being replaced by monomers of polysiloxane containing photopolymerizable methacrylate groups. The addition of small particles of inorganic fillers (silica, aluminum oxide, different kinds of glasses, etc.) has produced the modern dental composite resins which are characterized by high hardness, resistance to wearing, and low polymerization shrinkage. The size and amount of the inorganic particles present in these filling materials are dependent on the required properties. Products composed of large particles (several micrometers) are more resistant, whereas the presence of small particles (average size lower than 1  $\mu\text{m}$ ) results in a lower resistance but an easier polish. The first type is indicated when high load and resistance to wearing are required (molars) and the second one when the esthetic criteria are essential (anterior teeth) (137,138). There are many different commercially available composite resins containing particles of variable size (142): macroparticles from 8 to 25  $\mu\text{m}$ , miniparticles from 1 to 8  $\mu\text{m}$ , microparticles from 0.04 to 0.20  $\mu\text{m}$ , and blends of different sizes, thus covering many different clinical requirements (Fig. 7).

The properties of these materials are improved when the surface of the inorganic particles is covered by an agent that increases the adhesion between the inorganic compo-

**Figure 16.7** Scanning electron microscopy of a contemporary dental composite resin.

nent and the polymeric (organic) matrix of the composite. Silanes (i.e.,  $\gamma$ -methacryloxypropyltrimethoxysilane) have been used for such a purpose (143).

The polymerization of these filling materials can be produced by either chemical (autopolymerization or auto-curing) or photochemical (photopolymerization or light-curing) mechanisms. Auto-cured filling composites are formed by two components—initiator (i.e., benzoyl peroxide) and activator (usually a tertiary amine, i.e., dihydroxyethyl-p-toluidine)—that are mixed prior to their application (139). Light-cured composites are now widely used. They are available in a single-component form (usually a paste-containing syringe). Some of them contain benzoin ether (which absorbs at 365 nm) and are activated by long-wavelength ultraviolet light (from 340 to 380 nm). Others can be cured by visible light (around 470 nm wavelength) and contain diketones and amines (e.g., dimethylaminoethyl methacrylate). Visible light-cured composites allow larger polymerization thickness than the UV light-cured ones (139).

Clinical applications of composite resins have increased significantly in recent years. Their most extended use is in direct plastic restorations (fillers) using them with different strength and densities. Besides, they are also used as rigid restoration (inlays, onlays, laminate veneers); cementing agents (fluids with little inorganic component); fissure and tooth enamel damage sealers (prevention of caries in cases of higher susceptibility); artificial teeth; covering of metal surfaces; etc.

Research is going on as this group of materials is the most dynamic in the dental biomaterials field. Thus, new nomenclature is arising in order to categorize the new composite resins. The new names incorporate either new manufacturing technologies or new properties, such as: *ormocer* (organic modified ceramic), *ceromer* (ceramic optimized polymer), and *Polyglass* (glass polymers); others incorporate buffering capacities (i.e., liberation of fluoride, hydroxyl, or calcium ions if the pH conditions vary during restoration).

### b. Compomers

The term compomer refers to some restorative versatile materials composed by a mixture of composite resins and glass-ionomer cements (144). However, this term is not yet universally accepted, nor defines all the possibilities that this type of material offers. Compomers contain a bifunctional monomer, which is able to react with the methacrylate groups of other monomers as well as with the cations liberated by the glass particles (145). In some cases, they are formed by a composite resin modified by a certain amount of ionomer, while in others glass-ionomer is the

the main component. Compomers combine the most positive attributes of both components with a concomitant decrease in their individual possible inconveniences. Composite resins contribute mainly mechanical and wearing resistance (low in ionomers), while ionomers increase the adhesive capacity to the dental structures (composite resins do not adhere due to their hydrophobic nature) and release fluoride ions.

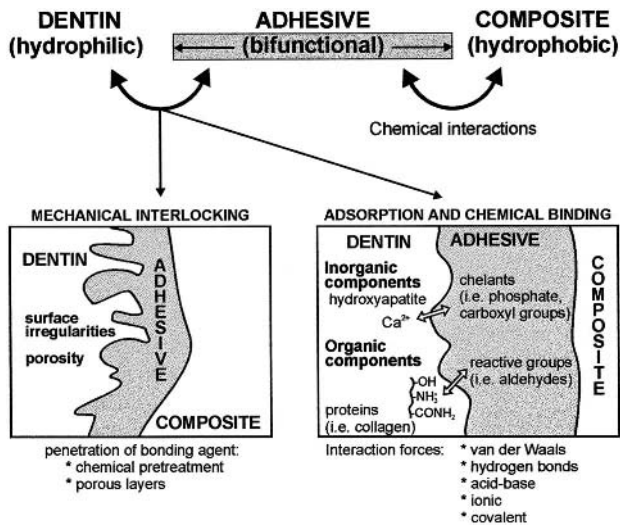

### 3. Bonding to Dental Structures

Composite resins lack adherence to the dental surfaces. Thus, specific attachment treatments are required for the establishment, by physicochemical processes, of a continuity between the tooth mineralized tissues and the implant (123,146). The two main approaches currently in use are bonding to either enamel or dentin, since bonding to cementum is difficult and is under study.

Enamel is mainly an inorganic structure (contains about 95% inorganic material, 1% collagen, and water). To obtain this bonding, the enamel surface is etched by a diluted acid solution (acid-etch technique). The most commonly used is a treatment with 37% orthophosphoric acid for 15–25 s. It causes a partial demineralization at the end of the enamel prisms, either at the central (type I) or interprismatic (type II) zones. Longer periods of treatment increase the depth of the demineralized zone and the resulting adherence is lower (type III). The acid treatment generates a wide irregular surface with plenty of microretention tags that are filled by a fluid resin. Finally, the process is concluded when the composite is applied. After polymerization the resulting product is firmly attached via micro-mechanical bonds (138,147).

Enamel and dentin present significant differences in composition and structure that do not allow similar bonding treatments for both locations. Dentin contains a large amount of collagen making it hydrophilic, whereas most composites are hydrophobic. Moreover, dentin has odontoblastic extensions that project into the dentinal tubules. The smear layer produced during the cavity carving protects the dentinary canals and is sometimes used to form a network with polymers and adhesives which bonds to dentin. In other cases, such a smear layer is partially or completely removed prior to any other treatment. Therefore, there are many different bonding products containing “conditioners,” “cleansers,” or “primers” to be used as required (148).

Normally, complex bifunctional reagents, or adhesives, are required to promote composite-dentin bonding. One molecule end (usually a functional methacrylate group) reacts with the composite, and the other end is able to interact with the inorganic (calcium, hydroxyapatite) or the organic

**Figure 16.8** Scheme of the interactions between dentin and adhesives.

(reactive protein groups) or both components of the dentin (Fig. 8). Those chemicals for the inorganic component would also react with the inorganic part of the enamel. The resulting structures are maintained by different types of interactions, including covalent bonds, ionic interactions, hydrogen bonds, and van der Waals forces. Some of the most widely used agents added to the resins, such as dichlorophosphate, phenylphosphate, glycerolphosphate, etc., interact with dentin calcium through their phosphate groups. A similar interaction in which carboxyl groups are involved is found in polyacrylic acid-containing glass-ionomers (125). These chemicals can also react with the amine and hydroxy collagen groups (137,147). The interaction of the adhesive with the hydrophilic matrix of dentin is also established by the addition of hydrophilic polymers such as hydroxyethyl metacrylate (HEMA) (148). Binding can be also obtained by the presence of isocyanate groups which react with the hydroxy, carboxy, amino, or amide groups of collagen as well as with hydroxyapatite (137,149); in other cases the reagents used are aldehydes and oxalates, e.g., 4-methacryloxyethyl trimellitate anhydride (4-META) (137,150).

The adhesive can penetrate into the dentin surface irregularities or pores, thus achieving a micromechanical interlocking between the adhesive and the dentin surface or dentin canals, as illustrated in Fig. 8 (147,151). In order to increase the roughness of the dentin surface, the use of primers (chemical pretreatments) is normally used. When an acid treatment is used on the dentin surface, a partial demineralization is obtained, making collagen molecules more accessible to the reactive groups of the adhesive.

Thus, a hybrid layer is formed where, in addition to a mechanical interlocking, a more favorable chemical binding is achieved.

In summary, the study of bonding materials to dentin is an active field characterized by widespread research. The apparent clinical success that is sometimes obtained still requires conclusive evaluation (123). The constant progress in this field has introduced the appearance of different generations of adhesive procedures. Briefly, the first adhesives used were hydrophobic liquid resin applied to the etched enamel surface; over this layer, the restorative resin was attached without manipulation of the dentin. In a second generation, dentin begins to be involved and the adhesive is composed by a mixture of hydrophobic and hydrophilic resins that interact with the smear layer. These treatments evolved into the use of hydrophilic resins applied on cleared dentin surfaces. The next step was the use of hybrid layers (partially demineralized dentin in which exposed collagen fibers interact chemically with the adhesive) (152). Nowadays, the trend is to use simpler techniques, reducing the number of involved steps, and trying to apply the different components simultaneously.

## B. Endodontic Treatment

Necrosis of the tissues at the pulp chamber and the root canals of the teeth occur by deep caries or other aggressions (Fig. 6). Treatment of the infection requires the removal of the damaged tissues that cannot be regenerated. Therefore, the resulting pulp cavities, previously enlarged, cleaned, disinfected, and dried, must be filled by using different materials and techniques. These materials should provide an increased tooth stability by improving the mechanical force transfer from the tooth to the underlying bone. The long-term stability of these fillers depends on the proper sealing of the tooth root apex area.

The nature of the materials employed is very important since they contact internal tissues through the root apex. They can be plastics (cements, pastes, etc.) or solid pieces (thin cones). Among those of the first group there is a wide diversity: antiseptic pastes, alkaline pastes (usually containing calcium hydroxyde), medical cements, etc. Many of these cements contain synthetic resins, i.e., polyvinyl, polyethylene, epoxy, polyacrylate, polycarbonate, etc., which contribute to the hardness of the final product and also seal the internal part of the canals (153–155). However, solid or semisolid materials with a small enough diameter to be passed through the tooth root canal and with different shapes (sharp cones, long pins or screws) can be used for filling purposes (Fig. 9). Silver was first used; but gutta-percha (resulting from the polymerization of the trans isomer of the isoprene) mixed with a cement is now

**Figure 16.9** Gutta-percha cones of two different sizes.

the most employed sealing material. In order to improve the properties of this polymer for dental purposes, several different additives have been included—zinc oxide, fillers, plasticizers, radiopaque agents, etc. Nowadays it is also used under the form of soft gutta-percha, prepared by heating the thermoplastic product immediately prior to its use (154,155).

Finally, other polymers used for the endodontic treatment are silicones, hydrophilic polymers (e.g., HEMA), epoxy, and so forth (155).

## V. PROSTHETICS

Dental extraction of teeth considered hopeless because of the extent of their pathology is one of the most frequent surgical procedures performed upon humans. In order to maintain a proper oral functionality, prostheses are required (Fig. 6). Patients can use two types of dental prostheses: removable or fixed. The first group of devices are classified into complete/total (contacting to the oral mucosa) and partial (supported by the teeth and the oral mucosa). Complete prostheses are constituted by a base (a rigid polymer) and the artificial teeth (porcelain or polymers) (Fig. 10). Removable partial prostheses used to be formed by a metal alloy base (cobalt–chromium) and a rigid polymer that simulates the gum, and the artificial teeth (Fig. 11).

Fixed prosthesis requires carving of the natural teeth, either the one to be treated (preparation of a dental crown) or those adjacent to the toothless zone (preparation of a dental bridge). Afterward a metal structure is prepared that is covered by a polymer or ceramic for esthetic purposes. Finally, the fixed prosthesis will be cemented to the natural carved teeth (anchor). Fiber-reinforced composites (i.e.,

**Figure 16.10** Complete dental upper prosthesis prepared with acrylic resin.

based on a light-polymerized bis-GMA matrix) are now under study in order to make metal-free prostheses with better esthetic qualities (156–158).

### A. Removable Dental Prosthetic Bases

The most frequently used removable denture bases are rigid; however, for specific cases resilient ones are recommended.

Rigid bases for complete or partially removable prostheses are normally prepared with PMMA. This polymer is known to be an ideal base material because of its stability in the oral environment although it absorbs some amount of water and is fragile. It can be used in either thermopolymerized systems (by using benzoyl peroxide as

**Figure 16.11** Detail (metal structure and acrylic teeth) of a removable partial prosthesis.

heat activated initiator) or light-cured systems, as those described in the operative dentistry section. The mechanical properties of PMMA, mainly its fragility, are improved by including small amounts of ethyl methacrylate, butyl methacrylate, etc.; or small particles of an artificial rubber (butadiene styrene); or aluminum, magnesium, and zirconium oxide powders; or by forming copolymers with vinyl acetate and vinyl chloride (158–160).

Other polymers used for this sort of base are copolymers of HEMA and methyl methacrylate, which exhibit a good adhesion between the prosthesis and the oral mucosa due to the adsorption and elasticity properties of HEMA. Polystyrene and polycarbonate can also be used, but their processing is difficult and expensive (159).

There are clinical cases related to highly sensible oral tissues where the use of soft and resilient bases is recommended (e.g., after surgery). Some acrylate derivatives mixed with plasticizers (e.g., dibutylphthalate), which are soft materials exhibiting a slow polymerization rate, are used in these cases (161).

### B. Artificial Teeth, Esthetic Facing, and Cements

Porcelain has been used for the construction of artificial teeth since the end of the 18th century. Polymethyl methacrylate has also been used for this purpose. Now PMMA copolymers and certain vinyl or styrene resins are used. Nevertheless, the selection of the material employed for the artificial teeth is influenced by clinical considerations as well as the wearing of the material. The development of new composites, as described in the operative dentistry section, has resulted in new materials for the elaboration of artificial teeth (e.g., dimethacrylate urethane resins with microfilling particles) (159).

Veneering in crown and bridge prosthetics (esthetic facing) present a metal structure (precious or nonprecious alloys attached to the anchor teeth) covered by a PMMA resin or porcelain. Initially, thermocured acrylic derivatives were also used. But vinyl acrylic and acrylate derivatives, thermo- or light-cured composites (such as those described for operative dentistry), are now in wide use due to their improved resistance against wearing (159). However, these compounds have no adhesion to the underlying metal structure. Therefore, some adhesive must be also included (162); 4-META has been used to perform this function. Pyrolytic recovering of the metal surface with a thin glass layer is also employed since the resin can be attached to this layer by a silane treatment (150,163,164).

More recently, the appearance of ceromers has made it possible to introduce metal-free veneers, inlays/onlays, and short bridges in regions without heavy mechanical

stress (165,166). In this way, metallic materials are substituted by fiber-reinforced ceromers forming an inner layer that is then recovered by additional layers of conventional or modified composite resins.

The prosthetic elements are usually fixed to the carved teeth by either an inorganic (e.g., zinc phosphate) or a polymer cement (e.g., zinc polycarboxylate or glass ionomer). In recent years, prosthetics directly attached to the teeth have appeared. They are mainly attached to the dental enamel through composite resins (e.g., Rochette bridge, Maryland bridge, etc.). The device is subjected to physical (perforation, blasting, abrasive treatment, etc.), chemical (acid treatments), or electrolytic procedures which allow a further surface retention of the composite (122,167,168).

## VI. ORAL AND MAXILLOFACIAL SURGERY

There are many oral and maxillofacial surgical treatments where polymers of natural or artificial origin are being tested or used. Some of these applications are shown in Table 5.

### A. Bone Loss Replacement, Fracture Immobilization, and Facial Outward Prostheses

At the end of the 19th century, vulcanized caoutchouc was introduced among jaw fragments to avoid maxillomandible deviations or deformities after surgical resections. Further, PMMA implants were used since they faithfully reproduced the removed mandibular fragment. Silicon or metal alloys have been also employed for bone loss replacement. But now autologous or conserved bone are preferred for these purposes (169).

**Table 16.5** Applications of Polymers in Oral and Maxillofacial Surgery

Bone loss replacement
Dental implants
Facial outward prostheses
Fracture immobilization
Hemostasis
Mouth protectors and habit suppression devices
Obturator prostheses for abnormal communications
Plastic and reconstructive operations
Preprosthetic surgery
Surgical dressing
Sutures
Temporomandibular joint surgery

Regarding fracture immobilization, two different groups of lesions are distinguished: small dentary and/or alveolodentary fractures with luxation of a short dental group and complex maxillomandible fractures with deviation of fragments. Concerning the first group of lesions, composites such as those used in operative dentistry can be employed either to reconstruct a tooth fragment lost or to immobilize the affected dental group by using splints attached to the enamel after acid etching. Auto-cured PMMA can be also used for these splints. In maxillomandible fractures, osteosynthesis via the use of metal mini-plates or steel wires is required (169,170).

Palliative treatments of the lesions resulting from complex fractures, with vast loss of facial soft tissues, were studied and developed after the world wars. Many different materials have been used for these treatments but there is not an ideal product. There are rigid or elastic materials, some of which can admit colorants. Rubbers, polyvinyl chloride, PMMA, vinyl resins with plasticizers, RTV (room temperature–vulcanized) silicone elastomers, polyurethanes, methacrylamide, butylacrylate or methylmethacrylate are some of the products used (159,171).

### **B. Plastic, Reconstructive, Preprosthetic, and Temporomandibular Joint Surgery**

Some facial congenital or acquired deformities (sinking, asymmetries, etc.) as well as rhinoplasty, mentoplasty, ocular displacement due to orbit floor fracture, and eyelide surgery in facial paralysis treatment require corrective procedures involving implanted polymers. Paraffin was used at the beginning of the 20th century for remodeling of small facial defects. But tumor formation and migration of the implant were two main problems. Liquid silicone injections were used, manufactured with differing viscosity degree. However, migration of the implanted material has been observed (microspherical particle deposits in liver, lymph nodes, and kidney have been reported) (169). Elastic solid silicones manufactured under the form of blocks or sheets are preferred. Polyvinyl alcohol, polytetrafluoroethene (PTFE), polyester, and polyurethane have been also tested (169,172).

The aim of preprosthetic surgery is the increase of the maxillar or mandibular alveolar ridge by using an implant. This treatment is mainly recommended for patients exhibiting atrophy where conventional denture base prostheses cannot be used. The most tested materials have been polyvinyl alcohol, acrylate-amide sponge, silicones, silicone polyester, and Proplast (173–176). Further, hydroxylapatite and other ceramic materials have also been tested successfully (177,178).

Relapsing luxation treatment, insertion of materials in

ankylosis treatment, condyle or meniscus replacement, etc., are included among temporomandibular joint (TMJ) surgical operations. Polyethylene, acrylic cups, PTFE, silicone discs, etc., were formerly used for this surgery. Also, Proplast was employed. It is a mixture of PTFE and glass carbon fibers, which can be invaded and covered by connective tissue, thus acting as a remodeling material (173–175). Autologous grafts or lyophilized bone are also used for these treatments.

### **C. Sutures**

Suture threads can be classified taking into account different criteria: according to the type of material from which they are made (natural or synthetic) or considering the permanence of the material (resorbables and nonresorbables) (179). Although metals can be employed, polymers are the most commonly used materials. Depending on the geometry of the thread fibers, they can be considered as monofilamentary or polyfilamentary plaited. This is an interesting difference since the space between fibers of plaited threads can be filled by exudation or oral secretions. Thus, plaited threads must be processed in order to increase their hydrophobic character (e.g., silicone treatment).

Resorbable sutures have many uses in oral and maxillofacial surgery to suture deep tissues. Catgut and collagen are used to elaborate natural resorbable sutures. Collagen is obtained from animal tendons; it is rarely used, although it seems to be less of an irritant than catgut. Submucous and serous layer of bovine intestine are used to elaborate catgut. This traditional material is a monofilamentary thread but exhibits a disadvantage: its diameter increases in only a few hours due to its absorption properties. Catgut can be simple or chromic. The latter is absorbed at a slower rate and is less of an irritant than simple catgut (167,180–182).

Polyglycolic acid is a resorbable synthetic homopolymer. There are also copolymers of glycolic and lactic acids. Polygluconate and polydioxanone are also employed as resorbable suture threads. The tissue reaction produced against these synthetic materials is lower than that appearing for those of a natural origin. This is due to the different degradation processes involved in the resorption mechanism: physicochemical reactions for the polymers and enzymatic degradation for collagen and catgut (101,180,181). New materials for intra- and extraoral applications are appearing combining reduced tissue reaction with fast-absorbing properties (183).

Among the nonresorbable threads, silk is the most used suture in oral and maxillofacial surgery. Capillarity phenomena are its main disadvantage. Polyamides, polyester, polypropylene, polyacrylonitrile, etc., are also used as non-

resorbable threads. All these threads tend to slacken slightly; thus more knots are required in order to tighten and reinforce the sutures (182).

**D. Other Applications**

Obturing prostheses are used for abnormal, temporary or permanent, communication treatments between the oral cavity and other cavities (nasal, sinus, orbit, etc.) due to congenital (cleft palate) or acquired (post-tumoral resections, complex injuries, etc.) lesions. Polymethyl methacrylate is usually employed and is attached to the teeth by metal wires (Fig. 12) (184).

So far polymers have no application as dental implants. Nevertheless, there are some old reports about the use of acrylic intraosseous implants for the immobilization of teeth in periodontal disease.

In several surgical dental procedures, the control of hemorrhage is critical. This is the case of apical sealing in endodontic surgery, which requires a dry root end cavity to insert the filling material. Bovine collagen and bone wax (with oils, wax mixtures, antiseptics, etc.) are used as hemostatic agents for some bone or periosteum hemorrhages. A mixture of surgical wax and fibers of calcium alginate permits an easy placement of a root end filling under sterile and nontoxic conditions (185).

Surgical cement is sometimes required during wound healing following some surgery in gingiva. Most of these cements used for surgical dressing are inorganic substances containing fatty acids and many additives, such as antiseptics, sedatives, etc. Some light-cured materials, containing urethane and acrylate resins are currently under use.

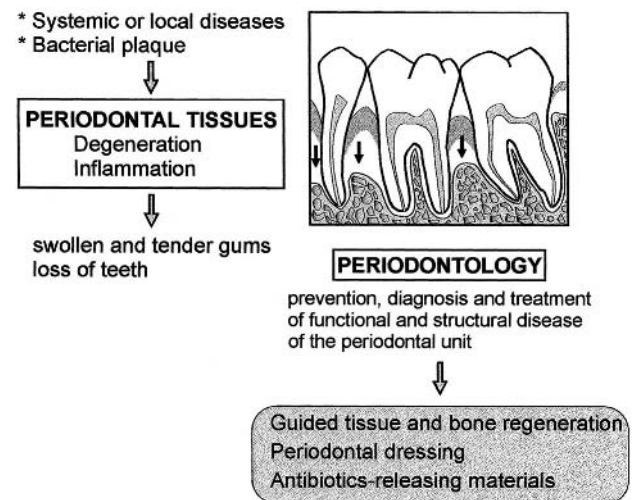

**Figure 16.12** Obturing acrylic device to avoid the communication between oral and nasal cavities after surgical removing of a palatal tumour.

Different kinds of intra- or extraoral mouth protectors and habit suppression devices are frequently used for the prevention of dental or bone fractures and complex facial injuries, TMJ lesions, dental abrasions, etc., which can result from violent activities related to sports, bruxism, or certain habitual behaviors. Polymers are the most used materials: silicones, PMMA, caoutchouc, soft acrylic resins, polyvinyl chloride, vinyl polyacetate, polyethylene copolymers, etc. Many of these are thermoplastics whereas others are prepared by auto- or thermo-cure mechanisms (159,171,184).

**VII. PERIODONTOLOGY**

Periodontal disease is caused by specific hardened bacteria which adhere to the teeth inducing inflammation of the soft tissues surrounding the teeth. A major consequence of periodontal disease is the loss of periodontal support with destruction of the fibrous connective tissue attachment. This is the support of the periodontal ligament which connects tooth root cementum and surrounding alveolar bone. If this process goes on, destruction of cementum and bone may occur, leading eventually to the loss of the teeth. The ultimate goal of periodontology is the development and improvement of therapies for the prevention, diagnosis, and treatment of periodontal disease (Fig. 13). There are many different groups of periodontology treatments using biomaterials, as summarized in the following sections. However, basic research is now focused in periodontal regeneration, trying to induce the formation of new bone, new cementum, and supportive periodontal ligament (68,186).

**Figure 16.13** Origin of periodontal disease and different treatments used in periodontology.

This approach is based on the regenerative wound healing potential of progenitor stem cell populations from the periodontal tissues.

### A. Guided Tissue Regeneration

Guided tissue regeneration (GTR) procedures have been used for regeneration of the attachment apparatus on teeth (187–193). This technique has also been considered as a surgical procedure for either ridge augmentation or implantation of osteointegrated materials to support a prosthesis.

The possibility of periodontal tissue regeneration is of particular importance in the treatment of furcation-involved teeth. It has been demonstrated that GTR therapy accounts for a high rate of success and predictability in the treatment of second-degree furcation involvement of mandibular molars (194). The GTR approach has also been used in the treatment of class II furcation defects in combination with other modalities designed to achieve regeneration, such as bone grafting, root demineralization, attachment proteins, and/or coronally positioned flaps (195).

Prevention of the epithelial migration along the cemental wall of the pocket has been treated by placing barriers of different types covering the bone and the periodontal ligament (Fig. 14), these membranes being removed 5 weeks after the operation. Millipore, Teflon, and Gore-Tex (expanded polytetrafluoroethylene) membranes have been used for these purposes (196). However, there are no ideal universal characteristics for these materials, such as pore size and polymer type, and different criteria must be applied in each particular clinical case (197,198).

Bioresorbable type I collagen barrier membranes have also been used for GTR (69,113,199). The results obtained

have demonstrated that sites treated with a collagen barrier exhibit significantly better healing when compared to control sites over a 1-year period of study. Subgingivally placed membranes of the type used for treatments of defects in monkey may predictably promote the formation of a new connective tissue attachment in recession-type defects (190,191). A combination of the bone inductive protein (osteogenin or bone morphogenetic protein-3) plus type I collagen as well as a combination of osteogenin with coralline hydroxyapatite have been used for treatment of critical size calvaria defects in rats (200). The results from histometric measurements of healing indicate that osteogenin plus collagen has the greatest potential for regenerating calvarial bone defects (190).

One of the new trends in the research involves the development of bioresorbable grafting materials chemically based on synthetic polymers (201). Specific membrane porosities do not seem to be required for bone formation, but optimal pore sizes are advantageous regarding nutrient flow, wound stabilization, and peripheral sealing to prevent ingrowth of soft tissue forming cells. The best known groups of polymers used for medical and dental purposes are collagen, mentioned previously, and aliphatic polyesters. The most frequently used synthetic membranes are homopolymers or copolymers of polyglycolide and/or polylactide (202). Occlusive bioresorbable membranes made of polylactic or polyglycolic acid are equally successful as expanded polytetrafluoroethylene membranes in regenerating bone in transosseous defects in the rabbit mandibular ramus (203). Clinical results using these bioresorbable barrier membranes in the treatment of interproximal intrabony periodontal defects show comparable results to bioresorbable type I collagen membranes (204).

One apparent advantage of poly( $\alpha$ -hydroxy acids) is their degradation by hydrolysis, resulting in decomposition products that are mostly metabolized to carbon dioxide and water. The degradation rate is dependent on the presence of enzymes, bacteria (infection), mechanical strain, and pH. The addition of D-lactide or glycolide results in a faster degradation. However, the hydrolysis of these polymers releases lactic and/or glycolic acids; if the concentration of these monomers goes over a certain threshold they may be toxic to cells and present osteolytic effects.

Guided tissue regeneration has also been considered in relation to osteointegrated implants. Following extraction of the natural tooth, the edentulous ridge begins to resorb palatally, lingually, and toward the apex. Therefore, the implants must be placed immediately into the extraction sites and covered with a membrane. This technique has been reported as valid for preservation of the bone at the site of implantation.

Bone grafts have been used in periodontal and implant

**Figure 16.14** Implantation of expanded polytetrafluoroethylene membrane (Gore-Tex).

surgery with the aim of increasing the bone volume in the defect area. Bone substitute can be classified into two groups: xenogenic and autogenic materials. The second is the most frequently used. Demineralized freeze-dried bone represents an allograft material (from the same species, but not the same individual) (205). Bone substitutes should exhibit biocompatible material properties, being tolerated and integrated by the host tissues and gradually replaced by newly formed bone (206,207). Recently, several synthetic bone grafts have also been used for clinical applications and the obtained results are comparable to those obtained with natural bone (208). Guided bone regeneration (GBR) seems to be more efficient when autogenic bone grafts are used in combination with adequate protection by barrier membranes (209).

The future of GTR and GBR promises to be exciting; new materials or modified ones, especially in combination with biological factors, will become available.

## B. Periodontal Dressings

Periodontal dressings are mainly used to achieve and maintain a close adaptation of the mucosal flaps to the underlying bone, for the comfort of the patient and to protect the wound prepared during surgery. The most commonly used periodontal dressings may be divided into two groups: eugenol-containing and non-eugenol-containing dressings. They are formed by a solid component—zinc oxide, resins, tannic acid, cellulose fibers, and zinc acetate—and a liquid one that may contain eugenol, vegetable oils, thymol, and color additives. Cyanoacrylates have also been used as periodontal dressings with varying success. They are directly applied as a liquid onto the wound or sprayed over the wound surface. Antibacterial agents should be incorporated in periodontal dressings to prevent bacterial growth in the wound area.

## C. Antibiotic-Releasing Materials

Antibiotic-containing implants can be used to suppress or prevent postsurgical infections after biomaterial implantation. The design of these systems must include consideration of the controlled diffusion of the associated drug (antibacterial agent, anti-inflammatory drugs, etc.) (206,210). These drugs could also be mixed with the cement (e.g., polymethyl methacrylate) at the insertion time.

Different materials, such as acrylic strips, monolithic fibers, and dialysis tubings, have been used for sustained local release of antimicrobial agents (192). Bioabsorbable materials can also be used for *in situ* applications. This eliminates the risk of disturbing a healing site after therapy. The most frequently used bioabsorbable materials are Surgical (hemostatic gauze made of oxidized regenerated cel-

lulose), Colla Cote (a collagen wound dressing), and Tisell (a fibrin sealant).

Hydroxypropylcellulose has been used as matrix for degradable films containing chlorhexidine or tetracycline (211). Polycaprolactone, another degradable polymer, and ethylene vinyl acetate copolymers have served as a matrices for monolithic fibers loaded with tetracycline for local treatment of periodontal pockets or subgingival root surfaces (212). Most of the intrapocket controlled release devices are composed of nondegradable matrices.

Treatment of marginal periodontitis may include the use of local antibiotics. Surgical bioabsorbable materials (e.g., Tisell and Colla Cote) and acrylic strips have been reported to be capable of an *in vivo* prolonged release of doxycycline (213). This mode of delivery increases the concentration of antibiotic at the site of action by incorporating the drug into different devices for insertion into periodontal pockets. In contrast to irrigation, these devices may assure an antimicrobial effect for a prolonged period.

## VIII. ORTHODONTICS AND OTHER APPLICATIONS

Removable intraoral devices, composed of PMMA plates and wires (in the form of springs, arches, gibs, screws, elastics, etc.), are used in orthodontics to obtain tooth movement or habit suppression (Fig. 6). These devices tend to give tone to the perioral muscles. Fixed devices are also employed. Orthodontic tooth movement is finally achieved by a remodeling of alveolar bone and the response of the periodontal ligament to a mechanical force (214). The dental movement is obtained by different arches and wires forming bands and brackets. Bands are cemented to the teeth and brackets can be welded to the bands or directly bonded to the enamel. For esthetic reasons, polycarbonate or ceramic bases for the brackets have also been employed; but they exhibit a significant fragility that is sometimes reduced by using plastic-covered metal bases. Attachment of bands is obtained by using zinc phosphate, polycarboxylate, or glass-ionomer cement, whereas slightly fluid composites and enamel acid etching have been used for the bracket attachment. Rubber elastic rings are also elements employed for the orthodontic treatments (215,216).

Other applications of polymers in dentistry should also be mentioned; among them are those in which polymers are used as impression materials or for the construction of work models. Elastic dental impression materials, hydrocolloids and elastomers, are very useful in dentistry. Agar, a linear polymer of D-galactose, was the first hydrocolloid used for these purposes. Later on, alginates (alginic acid salts; polymer of D-mannuronic and L-guluronic acids) were introduced in this field and are nowadays widely

used. Polysulfide rubber materials, polysiloxanes, and polyethers are among the elastomeric impression materials (217). Polyvinyl siloxane is used in different indirect procedures in prosthodontics and restorative dentistry due to its favorable handling properties, good patient acceptance, and physical properties (218).

Calcium sulfate and dental stone gypsum were the first materials used to construct work models, but epoxy resins are also now employed due to their hardness and dimensional stability (219).

Finally, waxes and thermoplastics are also used in dentistry. They are natural and synthetic waxes used in occlusion registration, pattern elaboration, and many other auxiliary applications in dentistry. Complex mixtures, composed of waxes, resins, fillers, and plasticizers are also sometimes employed (220,221).

## IX. NEW PERSPECTIVES

Much research remains to be done concerning oral biology and biochemistry in connection with biomaterial applications in dentistry. Polymers and composites are widely used in this field and their applications are under continuous evolution. Due to the understanding of their structure and properties, these compounds have a bright future in the field of dentistry. Connective tissue adherence to these materials, replacement of hard structures, achievement of proper cell–biomaterial interaction controlling cell proliferation and differentiation after implantation are some of the main biological problems to be treated over the next few years.

Polymers and polymer-containing biomaterials require specific considerations. The chemical composition of a macromolecule determines its conformation, which is further responsible for most of the properties determining its behavior as an implant. An ideal biomaterial must provide not only a scaffolding or three-dimensional architecture for tissue regeneration, but also must modulate specific cell functions. Thus, the goal in the development of a polymeric biomaterial is the synthesis of an adequate chemical structure, designed to be nonresorbable, partially resorbable, or fully resorbable, with specific surface properties in order to promote cell adhesion and to enhance tissue adaptation. In this way, a more stable implant-to-tissue interface, according with the demands of each particular application, could be obtained. New approaches in the synthesis of new biomaterials have been reviewed (222,223).

Besides the traditional chemical methods of polymer synthesis, a combination of biological and chemical synthesis is now being considered in order to improve polymer synthesis (e.g., polyphenylenes) (223). Moreover, an alternative synthesis of polymeric materials has been described

using bacteria and plants in large-scale production of biodegradable plastics. Polyhydroxyalkanoates (polyesters), a family of bacterial biodegradable plastics and elastomers, are polymers that have properties ranging from stiff and brittle plastics to rubberlike materials, and possess inherent biodegradability (224). Another example is the production of poly-3-hydroxybutyrate in *Saccharomyces cerevisiae* transformed with the bacterial polyhydroxybutyrate synthase gene (225).

The great advances in genetic engineering have also contributed to the development of new biopolymers or novel proteins encoded by artificial genes. This promising approach allows the synthesis of new biopolymers (natural or quimeric proteins) with specific sequences, structures, and properties by using recombinant cDNA technology. DNA sequences coding for specific molecular arrangements of proteins have been selected and transfected into bacterial systems, and the protein was produced in large amounts. In this way, different quimeric proteins, containing sequences of natural fibrous proteins (silk, elastin, and collagen) have been prepared using either bacterial or yeast systems. Artificial fibrous proteins containing repetitive sequences have been successfully synthesized including silklike polymers, elastin analogs, polymers containing both silklike and elastinlike blocks, and collagenlike proteins (226,227). Another example is the Pronectin F polymer—a commercially available molecule that is the product of an artificial gene containing sequences of silk and fibronectin. Silk contributes a high tensile strength, even stronger than high tensile steel, and fibronectin apportos the RGD receptor recognition amino acid sequences that enable the attachment of several types of mammalian cells (93,94,228).

It is well known that growth factors and other mitogenic and/or differentiating agents can be used in different systems to modify the response to a material (12,67,186,229). Cellular and molecular biology basic research is studying the specific proteins in the oral cavity presenting mitogenic or differentiation activity that may be useful for periodontal and alveolar bone regeneration. It is well known that bone morphogenetic proteins (BMPs) are excellent molecules for the stimulation of oral bone formation (67,68,230,231). Potential applications of these proteins in the restoration of oral cavity defects have been studied, allowing periodontal ligament regeneration. Other therapeutic candidates are enamel matrix proteins that have been reported to stimulate acellular cementum formation, also allowing functional periodontal ligament formation (232). The therapeutic use of the functionally active proteins requires their large-scale production. This has been achieved by the use of recombinant cDNA technology. As an example, recombinant BMP-2 has been extensively studied in animal models and is currently being tested in

human clinical trials (231). Porous synthetic polymers (e.g., poly-D,L-lactide-co-glycolide particles) are beginning to be used as carriers for BMPs, promoting the induction of new bone formation (233).

## Biomaterials in Burn and Wound Dressings

**Robert L. Sheridan, Jeffrey R. Morgan, and Rashid Mohammad**

*Shriners Burns Hospital, Massachusetts General Hospital, Boston, Massachusetts, and Harvard Medical School, Cambridge, Massachusetts*

### I. INTRODUCTION

In few areas have new biomaterials been incorporated into daily practice as in the management of burns and wounds. Burn management has changed dramatically over the past two or three decades, thanks to a host of critical care and surgical innovations (1), and new biomaterials are playing an increasingly important role as patients with larger and more complex wounds are surviving. The initial improvements in survival were due largely to an understanding of fluid resuscitation that developed in the 1950s and 1960s (2,3). The next major hurdle to overcome was the routine occurrence of wound sepsis. This was eliminated as a common problem by the development and practice of early and accurate identification of deep wounds and prompt and effective excision and closure (4–7). Various biomaterials have materially contributed to the success of this important progress in burn care.

Refinement of the surgical operations for excision of large wounds combined with improvements in critical care techniques have extended our ability to support patients who have suffered serious burns (8). Burn physical and occupational therapy and burn reconstruction have developed in parallel, facilitating our ability to deliver increasingly satisfying long-term outcomes (9). Further progress

is hampered severely by the lack of a durable skin substitute. The successful development of a permanent skin substitute will have an enormous impact on the care of patients with serious burns. Multiple clinical research groups and biomaterials scientists continue to work on this difficult problem.

Conceptually, skin substitutes are temporary or permanent; epidermal, dermal, or composite; and biologic or synthetic. Biologic components are xenogenic, allogenic, or autogenic. From the perspective of the practicing clinician, skin substitutes are either temporary or permanent. The objective of this chapter is to review the current state of skin substitutes and to speculate on future directions in this important area of research. Whenever possible, proprietary product names will not be used; any products not mentioned are not purposefully excluded.

### II. STRUCTURE AND FUNCTION OF THE SKIN

Skin, the body's largest organ, is incredibly complex. Functionally there are two layers with a highly specialized and effective bonding mechanism. The epidermis, consisting of the strata basale, spinosum, granulosum, and cor-

neum, provides a vapor and bacterial barrier. The dermis provides strength and elasticity. The thin epidermal layer is constantly refreshing itself from its basal layer, with new keratinocytes undergoing terminal differentiation over approximately 4 weeks to anuclear keratin-filled cells that make up the stratum corneum, which provides much of the barrier function of the epidermis. The basal layer of the epidermis is firmly attached to the dermis by a complex bonding mechanism containing collagen types IV and VII. When this bond fails, serious morbidity results, as demonstrated by the disease processes of toxic epidermal necrolysis (10) and dystrophic epidermolysis bullosa (11).

### III. TEMPORARY SKIN SUBSTITUTES

Temporary skin substitutes are used to provide a number of potential benefits to healing: transient physiologic wound closure, pain control, absorption of wound exudate, and prevention of wound desiccation. Physiologic wound closure implies a degree of protection from mechanical trauma, vapor transmission characteristics similar to skin, and a physical barrier to bacteria. These membranes attempt to foster a moist wound environment with a low bacterial density. There are four common uses for temporary skin substitutes in burn care: (1) as a dressing on donor sites to facilitate pain control and epithelialization from skin appendages, (2) as a dressing on clean superficial wounds to a similar end, (3) to provide temporary physiologic closure of deep dermal and full thickness wounds after excision while awaiting autografting or healing of underlying widely meshed autografts, and (4) as a "test" graft in questionable wound beds. There are a large number of such membranes in common use.

#### A. Human Allograft

Human allograft, applied as a split thickness graft after procurement from organ donors remains the gold standard of temporary dressings in burns (Fig. 1) (12–14). This material is applied in a viable state after storage in the refrigerated or frozen state. It can be refrigerated for 7 days or less, but can be stored for extended periods when cryopreserved. Viable split thickness allograft will vascularize and will reliably provide durable biologic cover until it is rejected by the host, usually within 3 or 4 weeks. Prolongation of allograft survival, through the use of antirejection drugs, has been done clinically (15), but is not generally practiced for fear that this will result in excessive infection (16). When modern screening techniques are followed, the viral disease transmission risk appears to be vanishingly small.

**Figure 17.1** Human allograft, applied as a split thickness graft after procurement from organ donors, remains the gold standard of temporary dressings in burns.

#### B. Human Amnion

Human amniotic membrane is used in many parts of the world to cover clean superficial wounds, including partial thickness burns, donor sites, and freshly excised burns awaiting donor site availability (17,18). This inexpensive membrane material is generally obtained fresh and used immediately or after brief refrigerated storage (19,20). Like porcine xenograft, it has been combined with silver to facilitate control of bacterial overgrowth (21). Although amnion does not vascularize (22), it can provide coverage that, in optimal circumstances, is nearly as good as that of allograft in some wounds (22). The principal concern with amnion in the developed world has been the difficulty in screening donors for viral diseases. In North America, human skin allografts are placed into frozen storage awaiting the return of numerous laboratory tests allowing one to safely exclude the possibility of viral disease transmission. When using amnion, the risks of disease transmission must be balanced against the clinical need and the known characteristics of the donor in individual circumstances.

#### C. Xenograft

Skin from various animals has been used for many years to provide temporary coverage of wounds (23). The only example of this practice still widely seen is the use of porcine xenograft (Fig. 2) (24). Porcine xenograft is often used as a reconstituted product consisting of homogenized porcine dermis which is fashioned into sheets and meshed (25). It is generally used for temporary coverage of clean wounds such as superficial second degree burns and donor sites (26). Its has been used in patients with toxic epidermal necrolysis (10,27), another superficial but extensive

**Figure 17.2** Skin from various animals has been used for many years to provide temporary coverage of wounds. The only example of this practice still widely seen is the use of porcine xenograft, which remains a very effective and safe temporary dressing.

wound. Porcine xenograft has been combined with silver to suppress wound colonization (28,29). Porcine xenograft does not vascularize, but it will adhere to a clean superficial wound and can provide excellent pain control while the underlying wound heals.

#### D. Synthetic Membranes

An increasing number of proprietary semipermeable membrane dressings provide a vapor and bacterial barrier and control pain while the underlying superficial wound or donor site re-epithelializes. Most consist of a single semipermeable layer that provides a mechanical barrier to bacteria and has physiologic vapor transmission characteristics (30,31). These can be used with good effect on clean superficial wounds and split thickness donor sites. Biobrane® (Dow-Hickham, Sugarland, TX) is a two-layer membrane consisting of an inner layer of nylon mesh that allows fibrovascular ingrowth and an outer layer of silastic that serves as a vapor and bacterial barrier (32). It has been used to good effect in clean superficial burns and donor sites.

Hydrocolloid dressings generally consist of three layers and attempt to create a moist wound environment while absorbing exudate. A moist wound environment has been found to favor wound healing in experimental and clinical trails (33). There is commonly a porous gently adherent inner layer, a methylcellulose absorbent middle layer, and a semipermeable outer layer. Also available are a number of pastes and powders made from hydrocolloid materials that are well applied to the control of wound exudate and maintenance of a moist wound environment.

All synthetic membranes are more or less occlusive. As such they must be used with caution if wounds are not clearly clean and superficial. If placed over devitalized tissue, submembrane purulence can occur with potentially disastrous results (34).

#### E. Combined Allogenic and Synthetic Membranes

There are an increasing number of growth factors thought to play important roles in wound healing: epidermal growth factor, transforming growth factor-beta, insulinlike growth factor, platelet-derived growth factors, and fibroblast growth factors (35,36). In an effort to apply some of these topically to wounds, investigators have placed both viable and nonviable allogenic cell types into temporary dressings which are then placed on superficial wounds and donor sites (37). These cells persist for no more than 14 days, but it is hoped that factors secreted by the allogenic cells, or released upon their dissolution, will provide signals to the host that enhance wound healing. Scientific support for this presumption remains elusive.

Perhaps the first group to attempt the manufacture of a biologic composite skin substitute to this end was that led by Bell, who developed a completely allogenic dermal/epidermal product that used a collagen lattice as scaffold for culturing both cell types (38). After it was demonstrated in an athymic mouse model that this device would successfully engraft (39,40), it went into clinical trials. Although it has not been demonstrated to have a clinical role in burn patients, the device is being explored for utility in chronic ulcers of the lower extremity (41–45). Allogenic fibroblasts grown into the nylon inner layer of Dow-Hickam's Biobrane is undergoing evaluation in wound healing (46–50). Although stimulation of wound healing by topical application of mixed growth factors in this fashion is an intriguing concept, convincing evidence of the concept's general validity is awaited. Viral transfection has been used to modify keratinocytes so that they overexpress platelet-derived growth factor, human growth hormone, insulinlike growth factor-1, and other growth factors (51). It is likely that such cell lines will be applied to wounds as components of wound membranes over the next few years (52).

#### IV. PERMANENT SKIN SUBSTITUTES

A durable permanent skin substitute will make an enormous difference to patients with burns and other difficult wounds. The "perfect" substitute is described in Table 1. Currently, no such substitute exists. However, there are a

**Table 17.1** The Perfect Skin Substitute

---

Prevents water loss
Barrier to bacteria
Inexpensive
Long shelf-life
Flexible
Conforms to irregular wound surfaces
Can be used "off the shelf"
Does not require refrigeration
Cannot transmit viral diseases
Does not incite inflammatory response
Durable
Easy to secure
Grows with a child
Can be applied in one operation
Does not become hypertrophic

---

number of partial substitutes in clinical use that are valuable and may be the forerunners of this hypothetical ideal. In this section, dermal, epidermal, and composite substitutes will be described.

#### A. Dermal Substitutes

A functioning dermis is essential for normal skin durability and function. Perhaps the first dermal substitute used clinically was Integra® "artificial skin" (Integra LifeSciences Corp., Plainsboro, NJ). This material was developed in the 1980s by a biomaterials research team from the Massachusetts General Hospital and Massachusetts Institute of Technology and was recently released for general use (53). The research team, lead by Burke and Yannas, conceived a membrane that would both provide a temporary vapor and bacterial barrier and serve as a scaffold for dermal regeneration. The material was designed for use in freshly excised burn wounds and is now approved for clinical use in patients with life-threatening burns. The inner layer of this material is a 2-mm thick combination of fibers of collagen isolated from bovine tissue and the glycosaminoglycan chondroitin-6-sulfate, which has a pore size of 70 to 200  $\mu\text{m}$  and a structure that allows fibrovascular ingrowth, after which it is designed to biodegrade (54,55). To fabricate this device requires precipitation of glycosaminoglycan and collagen fibers, which are then freeze-dried and cross-linked by gluteraldehyde. The outer layer is 0.009 in. polysiloxane polymer with vapor transmission characteristics similar to epithelium. This material is placed on excised full thickness burns, and the outer silicone membrane is replaced with an ultrathin epithelial autograft 2 to 3 weeks later, after fibrovascular ingrowth has occurred into the in-

ner layer (Fig. 3) (56). Clinical reports in patients with large burns have been favorable (57–59), and post marketing trials of Integra artificial skin are in progress. As in any occlusive wound dressing, submembrane purulence must be watched for and promptly treated.

Biodegradable polyglactin mesh, seeded with allogeneic fibroblasts from neonatal foreskin, has also been explored as a dermal analog in burn wounds. The carrier material biodegrades by hydrolysis, while the allogeneic fibroblasts are hoped to facilitate the formation of a neoderms. This material, like Integra, is designed to be combined with an ultrathin epidermal autograft (60–62). Its clinical utility remains to be demonstrated.

Cryopreserved allogeneic dermis is another strategy designed to contribute to permanent coverage of wounds by providing for a replacement of the lost dermis. This material, designed to be combined with a thin epithelial autograft at the time of application, is marketed as AlloDerm® (LifeCell Corporation, The Woodlands, TX) (63,64). Split thickness skin allograft skin is procured from cadaver donors, properly screened for disease. Using hypertonic saline, the epithelial elements of the grafts are removed and the remaining dermis is treated in a detergent to inactivate any viruses. The material is then freeze-dried. This process results in a nonantigenic complete dermal scaffold with basement membrane proteins, including laminin and type IV and VII collagen. The material is rehydrated and applied to wounds with an overlying ultrathin epithelial autograft (Fig. 4). Clinical experience with this material in

acute and reconstructive burn wounds has been favorably reported (65,66).

### B. Epidermal Substitutes

In the 1970s, Rheinwald and Green developed a method of culturing epithelial cells from a small skin biopsy (67,68). This technique has become the basis for the widespread clinical use of cultured epithelial grafts. From a full thickness skin biopsy, epithelial cells are separated with trypsin. The resulting epithelial cell suspension is plated in culture dishes containing culture medium with fetal calf serum, insulin, transferrin, hydrocortisone, epidermal growth factor, and cholera toxin, overlying a layer of murine fibroblasts that have been treated with a nonlethal dose of radiation that prevents them from multiplying. Isolated colonies of epithelial cells then expand into broad sheets of undifferentiated epithelial cells. These cultures are treated with trypsin, and the cells are taken to secondary culture using the same techniques. The resulting sheets are removed from the dishes after treatment with dispase, which digests the proteins attaching the epithelial cells to the dish. The sheets of epithelial cells are attached to a petrolatum gauze carrier to make it easy to handle in the operating room. Shortly after they were developed, epithelial cultures were used in patients with large burns (69–71). Epithelial grafts are now commercially available, most notably by Genzyme Tissue Repair of Cambridge, MA. With more frequent use of epithelial grafts, certain liabilities have been seen (72,73). These include suboptimal engraftment rates and long-term durability. However, when
