faced with a very large wound and minimal donor sites, epithelial cell wound closure is a valuable adjunct to overall patient management. It is generally felt that at least the latter liability is the result of the absence of a dermal element.

### C. Composite Substitutes

Combining epithelial grafts with a dermal analog is a logical objective. This can be done either on the wound, at the time of application of epithelial grafts, or in the laboratory prior to surgery. The first clinical report of the former concept was that by Cuono and coworkers. They described a technique in which epithelial cells are grafted on wounds closed initially with vascularized allograft. Subsequently the allogenic epithelial cells were removed by dermabrasion or tangential excision, leaving behind a vascularized but theoretically nonantigenic allogenic dermal layer (74–76). The method has been favorably reported (77,78), but the technique has not been universally effective and has not been widely adopted. Perhaps the epithelial excision either leaves behind nests of antigenic epithelial cells if too superficial, or removes the epidermal–dermal attachment structures if too deep. The application of epithelial cells onto Integra or AlloDerm has been attempted without known reliability, and no nonanecdotal data exists.

Combining epithelial cells with a dermal analog in the laboratory prior to use on human wounds also seems a logical approach. This effort began perhaps with the work of Boyce and Hansbrough, who have produced a completely biologic composite skin substitute, culturing human fibroblasts in a collagen–glycosaminoglycan membrane upon which are grown keratinocytes (79,80). Although this com-

**Figure 17.5** An example of efforts to develop a composite skin substitute includes culturing autogenic epithelial cells onto allogenic dermis.

posite membrane would successfully engraft in a nude mouse model (81), engraftment rates were found to be suboptimal in a small clinical series (82). Further investigations of this potentially exciting technology continue (83). Another example of this approach is work going on at the Shriners Hospital in Boston, where autogenic epithelial cells are being cultured onto allogenic dermis (84). This material was also successful in an animal model and is in early clinical pilot trials (Fig. 5).

## V. CONCLUSIONS

Although it has saved lives, the increasing success of burn resuscitation and supportive care has created a growing clinical problem: the need for temporary and permanent closure of wounds. As the burn and wound care field has evolved, the biomaterials sector has kept pace, with a series of products that have enormously facilitated the care of these patients. The future looks increasingly bright, with new temporary and permanent wound membranes on the horizon. These new products may include populations of allogeneic epithelial cells genetically modified to express essential growth factors to facilitate underlying wound healing. However the problem of definitive wound closure is solved, it is certain that biomaterials scientists will play an essential role in the solution.

### I. INTRODUCTION

The Federal Food, Drug, and Cosmetic Act (FD&C Act) defines cosmetics as “articles other than soap which are applied to the human body for cleansing, beautifying, promoting attractiveness, or altering the appearance” (1). The Food and Drug Administration (FDA) has classified cosmetics into 13 categories: skin care (creams, lotions, powders, and sprays), fragrances, eye makeup, manicure products, makeup other than eye (e.g., lipstick, foundation, and blusher), shampoos, permanent waves and other hair products, deodorants, shaving products, baby products (e.g., shampoos, lotions, and powders), bath oils and bubble baths, mouthwashes, and tanning products.

It is against the law to distribute cosmetics that contain poisonous or harmful substances that might injure users under normal conditions. Manufacturing or holding cosmetics under insanitary conditions, using nonpermitted colors, or including any filthy, putrid, or decomposed substance is also illegal.

Except for color additives and a few prohibited ingredients, a cosmetic manufacturer may use any ingredient or raw material and market the final product without government approval. The prohibited ingredients are: biothionol, exachlorophene, mercury compounds (except under certain conditions as preservatives in eye cosmetics), vinyl chloride and zirconium salts in aerosol products, halogenated salicylanilides, chloroform, and methylene chloride.

Manufacturers must test color additives for safety and gain FDA approval for their intended use.

It is important for both consumers and manufacturers to understand the difference between cosmetics and drugs. Different regulations are applied to each type of product. The FDA’s Office of Cosmetics and Colors, which is part of the Center for Food Safety and Applied Nutrition, handles issues related to cosmetics and color additives. The agency’s Center for Drug Evaluation and Research handles issues related to drugs.

The FD&C Act defines drugs as “articles intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease . . . and articles (other than food) intended to affect the structure or any function of the body of man or other animals.” Over-the-counter (OTC) drugs are drugs that can be purchased without a doctor’s prescription. The agency is conducting a review of all OTC drugs to establish monographs (rules) under which the drugs are generally recognized as safe and effective, and not misbranded. These rules are established on a class-by-class basis (e.g., fluoride dentifrices, cough suppressants, antihistamines). OTC drugs must meet the requirements of the appropriate class once that rule is published as a final regulation.

OTC drugs are often marketed side by side with cosmetics, and some products qualify both as cosmetics and as OTC drugs. This may happen when a product has two intended uses, with ingredients intended to do two different

things. For instance, a shampoo is a cosmetic, since its intended use is to cleanse the hair. An antidandruff treatment is a drug, since its intended use is to treat dandruff. Consequently, an antidandruff shampoo is both a cosmetic and a drug. Among other cosmetic/drug combinations are toothpastes that contain fluoride, deodorants that are also antiperspirants, and moisturizers and makeup marketed with sun-protection claims. Certain claims may cause a product to qualify as a drug, even if the product is marketed as if it were a cosmetic. Such claims establish the product as a drug because the intended use is to treat or prevent disease or otherwise affect the structure or functions of the human body. Some examples are claims that products will restore hair growth, reduce cellulite, treat varicose veins, or revitalize cells. The same is true of essential oils in fragrance products. A fragrance marketed for promoting attractiveness is a cosmetic. But a fragrance marketed with "aromatherapy" claims such as assertions that the scent will help the consumer sleep or quit smoking meets the definition of a drug because of its intended use.

In light of these considerations, and in respect of the actual regulation, cosmetics have purely the main function to maintain the skin in *good condition*. For dermocosmetics we need knowledge of skin biology and physiology. To allow the cosmetic to support the skin's natural physiological state, the cosmetic function has to be involved in the biological and physiological processes of the skin structure.

The scientific developments derived from biological research applied to dermatology have profoundly changed numerous concepts in skin physiology and physiopathology (2). Ideas of skin homeostasis and skin purely as a protective barrier have been corrected with the idea of the skin as a dynamic *equilibrium* of a complex system: the skin function as a barrier is a result of the balance between proliferation, differentiation, and loss of keratinocyte cells. Moreover, experimental data has shown that the keratinocytes, melanocytes, and Langerhans cells are functionally coordinated by autocrine and/or paracrine mechanisms; their actions confer a functional autonomy on the epidermis, so removing it, at least in part, from the conditioning of the dermis.

## II. BIOCHEMICAL SECTION

### A. Introduction

Studying and searching for new functional cosmetics require deep knowledge about the normal function of cells and structural elements in skin. Moreover, the terms that

describe the skin are used repeatedly in discussing the goals of skin-directed products.

The skin divides conveniently into four regions or zones, layered one on top of the other:

- Epidermis
- Basement membrane zone
- Dermis
- Subcutaneous tissue

In certain parts of the body these regions and zones are highly modified, reflecting very special needs. For example, the scalp is ordinarily covered with thick hair (a product of the epidermis) and the palms are covered with a highly thickened epidermis. On the other hand, the face contains large numbers of sebaceous oil glands that are susceptible to inflammation (acne), and the face exhibits a special susceptibility to the development of basal cell carcinomas (3).

#### 1. Epidermis

The upper layer, the epidermis, is an unusual structure, being composed almost entirely of cells (keratinocytes, melanocytes, Langerhans cells). These cells are locked together into a tight membrane that covers the entire skin surface. The most common epidermal cell is the keratinocyte, making up 95% of the skin surface. Concepts of the activities of keratinocytes have expanded greatly in the last ten years to go far beyond their capacity to protect skin through barrier formation. In fact, keratinocytes are now known to produce a wide spectrum of cytokines and to express important adhesion molecules.

Two other resident populations of epidermal cells include melanocytes and Langerhans cells, each with a specialized function. Melanocytes manufacture the pigment melanin, which is then released and taken up into the adjacent keratinocytes to provide a protective barrier against ultraviolet light. Langerhans cells, on the other hand, are components of the immune system and serve as the most remote aspect of foreign antigen recognition in the skin. Importantly, keratinocytes are able to influence the functions of these two cells through cytokines and adhesion molecules.

#### 2. Basement Membrane Zone

The basement membrane zone is a noncellular attachment zone that links the epidermis to the dermis. The proteins within the basement membrane zone are manufactured by cells on both sides, epidermis and dermis.

### 3. Dermis

The underlying dermis provides nutrition through blood vessels and strength through large bundles of the protein collagen. Cells that reside normally in the dermis include fibroblasts, endothelial cells (in blood vessels), and mast cells.

### 4. Subcutis

Deep beneath the dermis one finds the subcutis, which contains large blood vessels, large nerves, and fat cells.

### 5. Specialized Structures

Hair, sweat glands, and sebaceous glands are all specialized structures that are produced through the coordinated efforts of both epidermis and dermis.

## B. Epidermis

The epidermis is a multilayered structure (stratified epithelium) that renews itself continuously by keratinocyte division in its deepest layer, the basal layer. The cells produced by cell division in the basal layer constitute the prickle cell layer, and as they ascend toward the surface they undergo a process known as keratinization, which involves the synthesis of the fibrous protein keratin. The total epidermal renewal time is 52–75 days. The cells on the surface of the skin, forming the horny layer (*stratum corneum*), are fully keratinized dead cells, which are gradually abraded by day-to-day wear and tear from the environment (4–6).

The basal layer is composed of columnar cells that are anchored to a basement membrane (this lies between the epidermis and the dermis). The basement membrane is a multilayered structure from which anchoring fibrils extend into the superficial dermis. Interspersed amongst the basal cells are melanocytes, large dendritic cells responsible for melanin pigment production.

The prickle cell layer acquires its name from the spiky appearance produced by intercellular bridges (desmosomes) that connect adjacent cells. Scattered throughout the prickle cell layer are numbers of dendritic cells called Langerhans cells. Like macrophages, Langerhans cells originate in the bone marrow and have an antigen-presenting capacity.

Above the prickle cell layer is the granular layer, which is composed of rather flattened cells containing numerous darkly-staining particles known as keratohyaline granules. Also present in the cytoplasm of cells in the granular layer are organelles known as lamellar granules (Odland bodies). Lamellar granules contain lipids and enzymes, and

they discharge their contents into the intercellular spaces between the cells of the granular layer and the *stratum corneum*, providing something akin to “mortar” between the cellular “bricks.” In the granular layer the cell membranes become thickened as a result of deposition of dense material on their inner surfaces.

The cells of the stratum corneum are flattened keratinized cells that are devoid of nuclei and cytoplasmic organelles. These cellular components degenerate in the upper granular layer. Adjacent cells overlap at their margins, and this locking together of cells, together with intercellular lipid, forms a very effective barrier. The stratum corneum varies in thickness depending on the region of the body, being thickest over the palms of the hands and soles of the feet.

The rate of cell production in the germinative compartment of the epidermis must be balanced by the rate of cell loss at the surface of the stratum corneum. The control mechanism of epidermopoiesis consists of a balance of stimulatory and inhibitory signals. Wound healing provides a model to examine the changes in growth control that occur in establishing a new epidermis. Wounding of the skin is followed by a wave of epidermal mitotic activity, which represents the effects of diffusible factors spreading from the wound into the surrounding tissue. These factors include cytokines and growth factors. Their production is not limited to immune cells, as they are produced by keratinocytes in vitro and can be found in physiological amounts in normal human skin.

#### a. Regulation of Epidermopoiesis: Stimulatory Factors

The growth factors that stimulate the epidermal cells include epidermal growth factor (EGF), transforming growth factor alpha (TGFalpha), interleukins (IL) and other immunological cytokines, and basic fibroblast growth factor (bFGF).

EGF binds to specific cell-surface receptors (EGFR, a transmembrane glycoprotein receptor) present in the basal layer of the human epidermis. Following binding of EGF to EGFR, the receptor is internalized and carries EGF into an intracellular cycle within the cytoplasm and the nucleus to mediate all its effects. EGF has been shown to increase the growth and persistence of epidermal keratinocytes and to promote wound healing in vitro. EGF transcripts are not found in the epidermis, but in salivary glands and the intestinal tract.

TGFalpha was the first growth factor known to be produced by keratinocytes. Its mRNA predominates in the basal compartment of the epidermis. TGFalpha is related

to EGF; it binds to and activates the EGF receptor. It stimulates keratinocyte growth.

The normal epidermis also contains large amounts of Interleukin-1. There are two forms, alpha and beta, and unlike macrophages, the epidermis largely produces IL-1 alpha. IL-1 has been shown to be mitogenic for keratinocytes (other effects include fibroblast proliferation and synthesis of collagenase, stimulation of IL-2 production, stimulation of B-cell function, and fever induction). IL-1 releases IL-6 from keratinocytes. IL-6 appears to stimulate growth of keratinocytes and can be detected in epidermal cells. Keratinocytes also synthesize IL-3, IL-4, IL-8 (neutrophil activating protein), and granulocyte-macrophage colony stimulating factor.

Thus the epidermal keratinocytes can, under activation conditions, secrete a large number of cytokines, which can modulate lymphocyte activation and granulocyte function. These factors do not work in isolation but have complex interactions and may be synergistic or antagonistic. The factors controlling synthesis and secretion of these factors may be important in the pathogenesis of skin disease as well as epidermal growth control.

The regulation of the effects of growth factors includes the control of expression of the specific growth-factor receptors. The epidermal cell cycle is also controlled by the intracellular concentrations of the cyclic nucleotides: cAMP and cGMP. These are small molecules that are formed and broken down intracellularly as a response to external signals acting on the cell membrane. Cyclic AMP is believed to be the intracellular agent or "second messenger" of those hormones, i.e., catecholamines and polypeptides, which do not themselves penetrate the surface of cells. Cyclic AMP inhibits epidermal cell division, while cGMP stimulates it. Epidermal mitosis exhibits a circadian rhythm that is inversely related to blood adrenaline levels.

Steroid hormones like testosterone enter the target cells. Epidermal keratinocytes contain a 5 alpha-reductase enzyme, and they can convert testosterone to 5 alpha-dihydrotestosterone (DHT). DHT binds to specific cytoplasmic receptors, which then translocate to the nucleus, thereafter, altering protein synthesis via messenger RNA. Androgens and vitamin A stimulate epidermal mitosis, while glucocorticoid hormones inhibit it.

Prostaglandins, which are metabolic products of arachidonic acid, can affect nucleotide metabolism. Prostaglandins of the D and E series can increase cAMP, although not all such components are present in the epidermis. The main prostaglandin formed in the epidermis is PGE<sub>2</sub>. On the other hand, lipoxygenase products of arachidonic acid metabolism, namely HETE (12-hydroxy-eicosa-tetraenoic acid) and the leucotrienes, are capable of inducing epidermal cell proliferation *in vitro*. Polyamines, including

spermidine, putrescein, and spermine, stimulate mitosis. Ornithine decarboxylase is a particularly important enzyme for the generation of this group of substances.

#### *b. Regulation of Epidermopoiesis: Inhibitory Factors*

Growth inhibitors for keratinocytes include chalones, transforming growth factor beta (TGF beta), alpha and gamma interferons (IFN-gamma), and tumor necrosis factor (TNF).

Chalones are polypeptides produced by suprabasal cells which slow basal mitosis.

TGF beta stimulates fibroblast growth and increases fibrosis but inhibits the growth of keratinocytes. Thus although it may have an inhibitory effect on epidermal growth, the effect on wound healing is complex, because of mesenchymal effects (on fibroblasts), and it has been reported to stimulate wound healing.

Alpha and gamma interferons have cytostatic effects on keratinocytes both *in vivo* following systemic administration and *in vitro*. Following stimulation with IFN-gamma, keratinocytes express class II antigens, predominantly HLA-DR. High doses of interferon-gamma are cytotoxic.

Thirty percent of administered TNF localizes in the epidermis, suggesting the presence of many TNF binding sites. Keratinocytes also secrete TNF. TNF can cause release of IL-1. It stimulates fibroblast proliferation and cytokine production. TNF has also been shown to be reversibly cytostatic to keratinocytes.

### 1. Sensory System

The skin is innervated with around one million afferent nerve fibers. Most terminate in the face and extremities; relatively few supply the back. The cutaneous nerves contain axons with cell bodies in the dorsal root ganglia. Their diameters range from 0.2 to 20  $\mu\text{m}$ . The main nerve trunks entering the subdermal fatty tissue each divide into smaller bundles. Groups of myelinated fibers fan out in a horizontal plane to form a branching network from which fibers ascend, usually accompanying blood vessels, to form a mesh of interlacing nerves in the superficial dermis. Throughout their course, the axons are enveloped in Schwann cells, and as they run peripherally, an increasing number lack myelin sheaths. Most end in the dermis; some penetrate the basement membrane but do not travel far into the epidermis.

Sensory endings are of two main kinds: corpuscular, which embrace nonnervous elements, and "free," which do not. Corpuscular endings can, in turn, be subdivided into encapsulated receptors, of which a range occurs in the

dermis, and nonencapsulated, exemplified by Merkel's "touch spot," which is epidermal.

Each Merkel's touch spot is composed of a battery of Merkel cells borne on branches of a myelinated axon. A Merkel cell has a lobulated nucleus and characteristic granules; it is embedded in the basal layer of epidermal cells, with which it has desmosomal connections; it contains intermediate filaments composed of low molecular weight keratin rather than neurofilament protein. The Pacinian corpuscle is one of the encapsulated receptors. It is an ovoid structure about 1 mm in length, which is lamellated in cross section like an onion and is innervated by a myelinated sensory axon that loses its sheath as it traverses the core. The Golgi-Mazzoni corpuscle found in the subcutaneous tissue of the human finger is similarly laminate but of much simpler organization. These last two lamellated end organs are movement and vibration detectors.

The Krause end bulb is an encapsulated swelling on myelinated fibers situated in the superficial layers of the dermis. Meissner corpuscles are characteristic of the papillary ridges of glabrous (hairless skin) skin; they are touch receptors; they have a thick lamellated capsule 20–40  $\mu\text{m}$  in diameter and up to 150  $\mu\text{m}$  long. Ruffini endings in the human digits have several expanded endings branching from a single myelinated afferent fiber; the endings are directly related to collagen fibrils; they are stretch receptors.

"Free nerve endings," which appear to be derived from nonmyelinated fibers, occur in the superficial dermis and in the overlying epidermis; they are receptors for pain, touch, pressure, and temperature. Hair follicles have fine nerve filaments running parallel to and encircling the follicles; each group of axons is surrounded by Schwann cells; they mediate touch sensation.

#### a. Physiology of Sensory Receptors

*Adaptation.* When a maintained stimulus of constant strength is applied to a receptor, the frequency of the action potentials in its sensory nerve declines over time. There are two types of receptors: (1) tonic slowly adapting receptors: as the nociceptors (pain receptors) that continue to transmit impulses to the brain as long as the stimulus is applied, thus keeping the CNS continuously informed about the state of the body, and (2) phasic rapidly adapting receptors: as Pacinian corpuscles, these receptors adapt rapidly and cannot be used to transmit a continuous signal to the CNS; they are stimulated only when the stimulus strength is changed.

Touch sensation is provoked by a harmless stimulus to the skin allowing us to distinguish between hard and soft objects; touch receptors belong to the class of mechano-

receptors, and many of them can be found around hair follicles, so that removal of hair decreases touch sensitivity; the tips of the fingers and lips are rich in touch receptors.

*Tickle and itch.* The heparin-containing tissue cells called mast cells have a high histamine content in their granules. They also contain serotonin. Mast cells are particularly numerous in the skin (about 7,000 mast cells per cubic millimeter in normal skin in the subpapillary dermis) and play an important role in type I immediate hypersensitivity reaction (IgE-mediated anaphylactic reaction).

*Temperature sensation.* Receptors for warmth and cold are specialized free nerve endings; a rise in skin temperature above body temperature causes a sensation of warmth, while a fall in skin temperature below body temperature is experienced as a cold sensation; pain is felt if skin temperature increases above 45°C or decreases below 10°C; the mucous membrane of the mouth is less sensitive than the skin, so tea can be drunk at a temperature that is painful to fingers. Paradoxical cold: cold receptors are stimulated by intrinsic heat (e.g., shivering that occurs with fever).

Pain is evoked by nonspecific stimuli (chemical, mechanical, thermal, or electrical) of an intensity that can produce tissue damage. Pain is a high-threshold sensation. The nociceptors (pain receptors) are free nerve endings. Cutaneous pain may be sharp and localized or dull and diffuse. A painful stimulus causes at first sharp pain followed by dull aching pain. Reflex withdrawal movements also occur, with an increase in heart rate and blood pressure. Fast sharp (pricking) pain is mediated by nociceptors innervated by group A delta thick myelinated nerve fibers, which transmit pain impulses at a velocity of 20 m/s. Slow, chronic (dull aching or burning) pain is mediated by nociceptors innervated by group C thin unmyelinated nerve fibers that conduct pain at a low velocity of 1 m/s.

## 2. Vascular System

Circulation through the skin serves two functions, nutrition of the skin tissue and regulation of body temperature by conducting heat from the internal structures of the body to the skin, where it is lost by exchange with the external environment (by convection, conduction, and radiation). (See also "Sweat Glands" below.)

The cutaneous circulatory apparatus is well-suited to its functions. It comprises two types of vessels, (1) the usual nutritive vessels (arteries, capillaries, and veins) and (2) vascular structures concerned with heat regulation. The latter include an extensive subcutaneous venous plexus that can hold large quantities of blood (to heat the surface of the skin) and arteriovenous anastomoses, which are large,

direct vascular communications between arterial and venous plexuses. Arteriovenous anastomoses are only present in some skin areas that are often exposed to maximal cooling, as the volar surfaces of hands and feet, the lips, the nose, and the ear.

The specialized vascular structures just mentioned bear strong muscular coats innervated by sympathetic adrenergic vasoconstrictor nerve fibers. When constricted, blood flow into the subcutaneous venous plexus is reduced to almost nothing (minimal heat loss); while, when dilated, an extremely rapid flow of warm blood into the venous plexus is allowed (maximal heat loss).

The cutaneous circulation also serves as a blood reservoir. Under conditions of circulatory stress, e.g., exercise and hemorrhage, sympathetic stimulation of subcutaneous venous plexus forces a large volume of blood (5–10% of the blood volume) into the general circulation.

Reactive hyperemia occurs if one, for example, sits on one portion of his skin for 30 minutes or more and then removes the pressure. In such conditions, the individual will notice intense redness of the skin at the site of previous pressure, which resulted from the accumulation of vasodilator metabolites at that site (due to decreased availability of nutrients to the tissues during compression).

### 3. Pigmentary System

The melanin pigmentary system is composed of functional units called epidermal melanin units. Each unit consists of a melanocyte that supplies melanin pigment to a group of keratinocytes (about 36). Pigmentation is determined primarily by the amount of melanin transferred to the keratinocytes.

The melanocyte is a dendritic cell present in the basal layer of the epidermis with no desmosomes (intercellular bridges) or tonofilaments. Melanocytes arise from the neural crest as melanoblasts and migrate to the dermis, hair follicles, leptomeninges, uveal tract, and retina. By the eighth week of intrauterine life, they start to migrate from the dermis to the epidermis. Although full melanocyte migration is normally completed prior to birth, residual dermal melanocytes are sometimes left (clinically appearing as mongoloid spots in the sacral area of oriental and black infants).

Melanosomes are membrane-bound organelles located in the cytoplasm of melanocytes and bearing tyrosinase enzyme. They are responsible for melanin synthesis and pigment transfer from the melanocyte to the surrounding keratinocytes. During their passage from the perinuclear area of the melanocyte to the dendrites, the melanosomes show four stages of development: I and II (with no melanin deposition), III (with high levels of tyrosinase activity and is partially obscured by melanin deposition), and

IV (with low levels of tyrosinase activity and is completely obscured by melanin deposition). Pigment transfer occurs by keratinocyte phagocytosis of melanosome-containing dendritic tips. As squamous cells differentiate, the melanosomes within them are degraded by lysosomal enzymes.

The differences in racial pigmentation are not due to differences in the number of melanocytes but rather to differences in melanocyte activity. In black skin, there is greater production of melanosomes, a higher degree of melanization of melanosomes, and larger unaggregated melanosomes showing a slow rate of degradation.

#### a. Melanin: Types, Synthesis, and Hormonal Regulation

Melanin is a brown-black light-absorbing pigment that protects the skin against ultraviolet rays. Two major forms of melanin exist in humans: eumelanin, a brown-to-black pigment synthesized from indole 5,6-quinone and found within the ellipsoid melanosomes, and pheomelanin, a yellow-red sulfur-containing pigment found within the spherical melanosomes (Fig. 1).

Tyrosinase is a copper-containing enzyme that can catalyze two distinct reactions, the orthohydroxylation of a monophenol (hydroxylase activity) and the conversion of an *o*-diphenol to the corresponding *o*-quinone (oxidase activity). The two enzymatic activities are intimately coupled and are also referred to as cresolase or phenolase and catecholase or diphenolase activities, respectively (Fig. 2). Typical substrates of tyrosinase are mono- and *o*-diphenols (catechols) devoid of bulky groups or crowded substituent patterns adjacent to the hydroxyl group(s) on the aromatic ring. Traditionally, studies on the biosynthesis of melanins have showed that all steps following the tyrosinase-catalyzed formation of dopaquinone are envisaged as proceeding more or less spontaneously, without any further enzymatic assistance. There are, however, a number of biological observations suggesting that tyrosinase, though essential for melanogenesis to occur, is not the sole requirement (16–18). Once dopaquinone is generated, its metabolic fate is ultimately dependent upon the sulfhydryl content within melanocytes. Thus, by implication, enzymes that influence the redox state of the glutathione system can indirectly affect the level of melanization, even if tyrosinase is normally expressed (19–20). In addition, evidence has been accumulating indicating the existence of a number of other enzymes and cofactors that can play a critical role in the later stages of melanogenesis. There are receptors on the surface of melanocytes for melanocyte-stimulating hormone (MSH). MSH, ACTH (adrenocorticotropin, similar to MSH in the arrangement of first 13 amino acids), estrogen, androgens, and progesterone all

Figure 1 Scheme of melanogenesis.

stimulate pigmentation through increasing cAMP and tyrosinase activity, resulting in increased melanin formation and transfer.

*b. Photobiology and Photochemistry of Melanogenesis*

Exposure of human skin to solar radiation or UV light from artificial sources results in a profound alteration of metabolism, structure, and function of epidermal melanocytes. The visible outcome is a marked increase in skin pigmentation, commonly known as tanning (21). When viewed from the standpoint of photobiology, skin tanning involves two distinct phenomena: (1) immediate tanning (IT), sometimes referred to as immediate pigment darkening (IPD); and (2) delayed tanning (DT). This latter is but one of a complex cascade of events beginning with cell injury and leading to inflammation (erythema) and enhanced keratinocyte proliferation (22). The end result is an increased protection of skin against the harmful effects of UV radi-

Figure 2 Enzymatic activity of tyrosinase.

tion. Multiple exposures further increase this protection, but excessive doses of UV radiation result in the long term in a number of pathological changes in skin, such as atrophy, aging, actinic keratoses, and development of many cutaneous cancers, for example, squamous cell carcinoma and basal cell carcinoma. A number of authors have also expressed concern that UV exposure might be responsible for the increased incidence of malignant melanomas (23–24). However, this view has not reached general consensus (25–26).

Our incomplete knowledge of skin photobiology makes it difficult to attempt to explain individual susceptibility to the harmful effects of UV radiation. What seems clear is that skin with high melanogenic activity, be it constitutive or UV induced (facultative), is by far less susceptible to actinic damage than white unpigmented skin. Thus, for example, albinotic and vitiliginous skins, which lack melanin, sunburn easily and exhibit little or no ability to tan. Redheads also show a pronounced sensitivity to sunlight, but whether this results from the presence of pheomelanins in the skin is controversial.

Kaidbey et al. (27), using spectroscopic techniques, found that the transmission and protection factors of the stratum corneum of black and white skin toward UVB rays (280–320 nm) are quite similar, but the dark pigmented epidermis transmits much less and protects much more than the white epidermis. Thus, since the stratum corneum and epidermis are of essentially equal thickness in all races, it follows that melanin is the most important skin photoprotective agent. However, the picture is not so simple, since other products of melanocyte activity may be implicated to account for the apparent relationship between skin color and photoprotection.

#### c. *Skin Phototypes*

The concept of sun-reactive skin typing was introduced by Fitzpatrick (28) for the specific purpose of selecting the correct initial doses of UV light for photo- and chemotherapy. Based on the individual's tendency to sunburn and tan, six main phototypes were recognized. In the proposed classification, persons of skin types I and II have less constitutive pigmentation and less capacity to tan than individuals with skin types III, IV, or V, in that order, while type VI is represented by African and American blacks. Another classification, proposed by Cesarini (29), takes also into consideration some genetic markers, such as freckles and hair color, which allow a more precise definition of skin phototypes.

Though these classifications serve the purpose for Caucasian subjects, they do not work well when applied to darker populations. For example, in Japan, it is necessary

to define a local skin typing system that allows for a burning reaction to UV in the minimal range and a tanning reaction in the moderate to intense range (30). Currently, when a more objective determination of sensitivity of skin to UV radiation is desired, the usual method is measurement of the minimal erythral dose (MED), as evaluated either visually or more accurately by chromameters (31). In terms of MED, it has been estimated that the protection offered by melanin pigmentation reaches a maximum value of 10–15 for very black individuals, whereas for Hispanics or Kuwaitis or dark mediterraneans it reaches a value of 2.5 (32). Yet within each skin there may be a wide range of variability in the photobiological response to UVB, suggesting the involvement of another variable that has not been identified so far.

#### d. *Melanin, Melanogenesis, and Skin Photoprotection*

The role of melanin in photoprotection is either obvious or wholly obscure. Certainly, pigmented skin is by far less susceptible than white skin to sunburn and phototoxic reactions. However, whether this is solely related to the epidermal content of melanin or other products of melanocyte activity is not clear. Confusion also exists as to the actual mechanism by which melanin would provide photoprotection.

A widely accepted view, which was first proposed in 1820 by Sir Everald Home, is that melanin absorbs UVR and therefore acts as a passive screening filter to protect the underlying tissue against actinic damage. Advocates of this view often refer, as supporting evidence, to the umbrellalike distribution of the melanin granules over the keratinocytes and the increased skin photoprotection following suntanning. However, if we analyze the epidermal response to UVR without prejudices, we find that it has all the features of a nonspecific hyperplasia in response to damage and death of cells, as hyperpigmentation of skin occurs in response to a variety of other traumas such as ionizing radiation, heat, abrasion, and inflammation. In any case, suntanning comes about too long after the UV radiation has done its worst damage. In passing, it may be worth noting that black people tend to avoid sunning because they are not exempt from sunburn, although their skin is heavily pigmented (33). Kaidbey and Kligman (34) exposed eight volunteers to UVA twice a week for 8 weeks and compared the photo protection 1 week after the last irradiation against UVA and sunlight. Although much pigment was generated, the minimal protection against a MED was only 2 to 3 times higher with respect to control unpigmented skin.

These observations and others in both human and ani-

mal models (35) suggest that melanin alone may not be such a good photoprotective agent. In fact, when compared with conventional sunscreens, natural or synthetically produced eumelanins appear to have little effectiveness in protecting skin from UVR exposure (L. J. Wolfram, unpublished). It could be argued, however, that a melanin-containing cream or lotion applied over the skin is far from a reproduction of the potential photoprotection afforded by the strategic distribution and aggregation of melanosomes in the epidermis. In any case, a role of melanin as a neutral sunscreen is unlikely and would not be in keeping with the insoluble character of the pigment granules, giving rise to scattering rather than absorption of light.

An alternative interpretation of the photoprotective role of melanins comes from recent studies, discussed earlier, showing that melanin is by no means an inert passive material, as previously believed, but a rather unstable chemical entity exhibiting an impressive range of physicochemical properties. Among these, perhaps the most relevant from the physiological viewpoint is the ability to scavenge oxygen-derived radicals, such as superoxide anion and hydrogen peroxide, which are normally formed during biochemical or photochemical processes. Both species are known to produce several biological effects, most of which are deleterious to cell homeostasis. While host defenses are adequate to remove these toxic species under physiological conditions, on exposure to UVR or other inflammatory stimuli their concentration increases, and thus the presence of an *in situ* residing quencher such as melanin becomes important.

In this context, the possible contribution of other products of melanocyte activity should not be overlooked. In a preliminary study at Naples (G. Prota et al, unpublished), it was found that 5,6-dihydroxyindole (DHI) is capable of inhibiting lipooxygenase-induced oxidation of arachidonic acid, the major unsaturated fatty acid present in mammalian phospholipids. DHI and 5,6-dihydroxyindole-2-carboxylic acid (DHICA) are also endowed with excellent antioxidant properties and are capable of capturing oxygen radicals, themselves being eventually converted to melanin. Viewed in this way, melanin pigmentation could be regarded as a visible indicator of the ability of DHI and related colorless metabolites to counteract noxious effects induced by internal or external stimuli, including UV light. A further contribution to this picture follows from several studies showing that 5,6-dihydroxyindoles and other melanogenic precursors for example cysdopas, undergo photodestruction when irradiated with biologically relevant UV light (i.e., with wavelengths greater than 300 nm). As a result of their photochemical reactivity, a number of free-radical species can be generated. Whether such photodegradation products of melanin precursors are formed *in vivo*

is not yet documented; however, *in vitro* studies suggest that they may play a role in the acute and chronic response of human skin to sunlight.

#### 4. Functions of the Skin

The most obvious function of skin is to create a barrier between humans and their environment. The barrier to infectious organisms and toxic chemicals is created by the surface cells of skin, keratinocytes, which divide slowly but continuously throughout life. After cell division, keratinocytes move to the surface where they flatten into a very tough and durable membrane. As these cells slowly come off of the surface, they are replaced by the underlying dividing cells.

Establishing a barrier to ultraviolet light is a special requirement of skin. In fact, ultraviolet light from the sun has the capacity to cause skin cancer and to produce accelerated skin aging. One of the defense mechanisms against ultraviolet light in skin is the elaboration of protective melanin by melanocytes.

##### a. *The Role of Lipids in the Structure and Junctional Organization of the Horny Layer*

The skin is structured to prevent loss of essential body fluids, and to protect the body against the entry of toxic environmental chemicals. In the absence of a stratum corneum we would lose significant amounts of water to the environment and rapidly become dehydrated. The stratum corneum, with its overlapping cells and intercellular lipid, makes diffusion of water into the environment very difficult (7–8).

In the horny layer the intercellular spaces contain formations of overlaid lamellae derived from the lamellar granules localized close to the cell membrane of the living cells below. When the granule membrane fuses with the cell membrane by the process of exocytosis, the contents of the granules are expelled into the intercellular spaces. Initially they are arranged in discoidal form deposited between the cells of the horny layer, thus being transformed into wide lamellae in the terminal phase of the keratinocyte differentiation process (9).

The following play an important role in the assembly of the granules:

- Acylglucosyl ceramides, during the dispersion of the lamellar discs, mediated by the removal of the saccharide residue
- A Ca-dependent phospholipase, which hydrolyses the phospholipids present in the granular layer as substrate

The concomitant increase of fatty acids in the zone, which separates the granular layer from the horny layer

Also the cholesterol esters have a functional as well as a structural role. In fact, the desquamation of horny layer cells, which constitutes the final act of epidermal differentiation, is accompanied by hydrolysis of cholesteryl sulphate.

The epidermal lamellar bodies, rich in glycosphingolipids, sterols, and fatty acids, are the source of all the intercellular lipids of the horny layer. These ellipsoid organelles are assembled in the spinous and deep granular layers. In the outer areas of this latter layer, the lamellar bodies arrange themselves along the lateral and apical surfaces so that they can be quickly exocytosed. Their secretion brings about not only the release of the lipids they contain but also the dispatch of numerous hydrolytic enzymes into the intercellular spaces of the horny layer (acid lipases, phospholipases, sphingomyelinases, glycosphingohydrolases, acid phosphatases, and carboxypeptidases).

Consequently, in the granular and horny layers an intense metabolic activity takes place on the complex lipids present in the lamellar bodies and initially “deposited” in the intercellular spaces. This accounts for the structural changes and qualitative and quantitative variations in the composition of the epidermal lipids (Table 1).

The ceramides constitute almost 50% of the total lipids present in the horny layer. Several molecular species have been identified, different as regards their hydrophobic sections: sphingosine, phytosphingosine, and fatty acids, these last often being hydroxylated. The hydroxyl can be esterified with linoleic acid residues (which are sometimes also present in the glucose residues of glucosyl ceramides present in the cellular layers). Particular to the horny layer is a ceramide linked to a very long chain hydroxyacid (30–32 carbon atoms), in its turn esterified with a fatty acid whose major component is linoleic acid.

In conclusion, the characteristics of the horny layer and

the associated lipid “mantel” organized in a double layer can be summarized as follows:

- An almost complete absence of phospholipids
- The structural and functional substitution of phospholipids (as the essential fatty acid reserve) by neutral glycolipids
- Large quantities of nonesterified cholesterol, which by esterification reactions allow the regulation of lipid layer fluidity
- The presence of free fatty acids, many of which have peculiar structures not detectable in other organs and tissues
- The need for both saturated and unsaturated fatty acids to be present in a precise ratio in order to ensure the optimal barrier effect
- The presence of water, therefore, making it more appropriate to talk of a hydrolipid barrier and of a lamellar structure composed of various layers

The skin is also part of the innate immunity (natural resistance) of the body against invasion by microorganisms. The dryness and constant desquamation of the skin, the normal flora of the skin, the fatty acids of *sebum* and lactic acid of sweat, all represent natural defense mechanisms against invasion by microorganisms. Langerhans cells present in the epidermis have an antigen-presenting capacity and might play an important role in delayed hypersensitivity reactions. They also play a role in immunosurveillance against viral infections. Langerhans cells interact with neighboring keratinocytes, which secrete a number of immunoregulating cytokines.

Melanin pigment of the skin protects the nuclear structures against damage from ultraviolet radiation.

The skin is also a huge sensory receptor for heat, cold, pain, touch, and tickle. Parts of the skin are considered as erogenous zones. The skin has great psychological importance at all ages. It is an organ of emotional expression and a site for the discharge of anxiety. Caressing favors emotional development, learning, and growth of newborn infants.

The skin is a vital part of the body’s temperature regulation system, protecting us against hypothermia and hyperthermia, both of which can be fatal (specialized vascular structures of the dermis, insulation by fat in subcutaneous tissue, evaporation of sweat).

The skin plays an important role in calcium homeostasis by contributing to the body’s supply of vitamin D. Vitamin D<sub>3</sub> (cholecalciferol) is produced in the skin by the action of ultraviolet light on dehydrocholesterol. It is then hydroxylated in the liver and kidneys (needs parathyroid hormone to activate alpha-hydroxylase) to 1,25 dihydroxycholecalciferol, the active form of vitamin D. This

**Table 1** Lipidic Composition of the Epidermis (% Distribution)

Class of lipid	Layers with nucleate cell	Horny layer
Phospholipids	40	traces
Sphingolipids	10	35
Cholesterol sulphate	—	2–5
Cholesterol	15	20
Triglycerides	25	traces
Fatty acids	5	25
Sterol esters, squalene	5	10

antirachitic vitamin acts on the intestine, increasing calcium absorption (through stimulation of the synthesis of calcium-binding proteins in the mucosal cells of the intestine), as well as on the kidneys, promoting calcium reabsorption.

### b. Keratin

Electron-microscopic examination of cells from all tissues reveals that they contain a complex, heterogenous, intracytoplasmic system of filaments. The components of this system include actin, myosin, and tubulin, whose diameters average approximately 60Å, 150Å, and 250Å, respectively. In addition, other intracytoplasmic filaments were noted, and since the diameter of these latter structures was found to be between 70 and 100Å, they were called intermediate filaments (10–12).

Intermediate filaments form a major part of the cytoskeleton of most cells and fulfill a variety of roles related to cell shape, spatial organization, and perhaps informational transfer. The nucleus contains structures related to these intermediate filaments, and many intracellular components including polyribosomes, mitochondria, nucleic acids, enzymes, and cyclic nucleotides are attached to the cytoskeleton.

Based on their biochemical, biophysical, and antigenic properties, a number of classes of intermediate filaments can be recognized in different cell types: desmin (skeleton) in muscle cells, glial fibrillary acidic filaments in glial cells, neurofilaments in neurons, vimentin in mesenchymal cells, and keratin in epithelial cells. In cultured epidermal cells, keratins account for up to 30% of the cellular protein, while in the stratum corneum, keratin accounts for up to 85% of the cellular protein.

At least 19 keratin proteins can be identified ranging in molecular weight from approximately 40,000 to 68,000 micrograms. The polypeptide structures of all the intermediate filaments have a similar skeletal part composed of structural blocks of polypeptide subunits. The number of subunits varies between one and 30. The proteins are products of separate genes, which by cross-hybridization fall into two gene subfamilies: type 1 (basic) and type 2 (acidic). The molecular weights of the members of one (the basic subfamily) are larger than those of the members of the other (the acidic subfamily).

The fundamental polypeptide chain of keratin is a classical alpha helix with repeated groups of seven aminoacids. It is composed of four separate helical zones linked by interhelical sequences and is preceded and followed by nonhelical carboxyterminal and aminoterminal sequences. During keratinization two polypeptide chains (one basic and one acidic) are assembled as a heterodimer called a

protofilament. Two protofilaments then assemble into larger protofilaments so forming a protofibril, the basic element of the keratin fiber heterodimer. In epithelial cells, keratin filaments radiate from the perinuclear region to the internal face of the plasma membrane. Bundles of these filaments are associated with specialized structures of the plasma membrane called desmosomes. Looking at their chemical structure it is evident that keratin filaments are heterogeneous. This heterogeneity explains how the filaments perform diverse functions in different tissues, i.e., there are different types of keratin for keratinized epidermis, hyperproliferative epidermis of palms and soles, corneal epithelium, stratified epithelium of the esophagus and cervix, and simple epithelium of the epidermal glands. As mentioned before, keratin is the main structural protein of the epidermis (13). The keratinocytes in the basal layer and prickle cell layer synthesize keratin filaments (tonofilaments), which aggregate into bundles (tonofibrils). In the cells of the stratum corneum, these bundles of keratin filaments form a complex intracellular network embedded in an amorphous protein matrix. The matrix is derived from the keratohyaline granules of the granular layer; filagrin is the substance produced by keratohyalin granules, which links the tonofilaments and allows their alignment into microfibrils. Epidermal keratinization results in the production of a barrier that is relatively impermeable to substances passing into or out of the body (14,15).

### C. Ultrastructure of the Dermoepidermal Junction

The most superficial component of the junction is the basal plasma membrane of keratinocytes, melanocytes, and Merkel cells.

Hemidesmosomes have a complicated ultrastructure that resembles half a desmosome. Hemidesmosomes consist of an intracellular component, the attachment plaque, which is associated with tonofilaments, and an extracellular component, known as the subbasal dense plate. This latter structure is located in the lamina lucida (see below) and resembles a fine, dense line parallel to and just beneath the plasma membrane. Hemidesmosomes are important in maintaining adhesion between dermis and epidermis.

Immediately beneath the basal plasma membrane is the basement membrane, which consists of three layers: the lamina lucida, the lamina densa, and the lamina fibroreticularis (sublamina densa).

Distributed throughout the lamina lucida are anchoring filaments. Anchoring filaments are very fine structures that are oriented vertically between the lamina densa and the basal plasma membrane.

The lamina densa is an electron-dense amorphous layer that lies parallel to and below the lamina lucida.

Anchoring fibrils are the major constituent of the fibroreticular layer of the basement membrane. These are short, often curved structures, with an irregular cross-banding, that insert into the lamina densa and extend into the upper part of the dermis. They may also insert into amorphous bodies in the superficial dermis known as anchoring plaques, or curve back to have a second insertion in the lamina densa.

Another component of the lamina fibroreticularis is the elastic microfibril bundles, each consisting of many microfibrils that extend into the dermis and may enmesh with the microfibrillar system of dermal elastic fibers.

Laminin, a high molecular weight glycoprotein required for cell adhesion, and fibronectin have been immunolocalized to the lamina lucida.

Type IV collagen antigen has been immunolocalized to the lamina densa. Type VII collagen antigen has been immunolocalized to anchoring fibrils and plaques. Type VII collagen has a role in normal dermoepidermal adherence.

#### D. Dermis

The dermis accounts for approximately 90% of the cutis. It can be considered an aqueous gel "held" in a structure composed of collagen and elastin fibers. Compared to the relatively rapid turnover of the epidermis, the connective tissue of the dermis is regenerated more slowly even though it is more highly vascularized, being pervaded by a woven network of arterioles, venules, and capillaries. Like all differentiated connective tissues, it is composed of an abundant intercellular matrix and specialized cells or fibroblasts. Other cell types found in the dermis are the macrophages and mast cells, and in addition lymphocytes and plasma cells frequently populate the dermis in response to injury or other stimuli.

##### 1. Principal Function of the Cells Present in the Dermis and the Characteristic of the Molecules They Synthesize

Fibroblasts are bound to the matrix by fibronectin, and their main function is the synthesis and remodeling of connective tissue proteins. The remodeling process is mediated by specific enzymes, collagenase and elastase, whose presence is particularly high in the dermal papillae found immediately below the basal lamina and which therefore delimit the epidermal region. The main product of fibroblast synthesis in the papillary layer is type III collagen, characterized by high hydroxyproline content and a small

percentage of hydroxylysine, which has few glycosylation sites. Type I collagen is synthesized by fibroblasts of the underlying reticular dermis, organized in large fibrillary bundles interspersed by bundles of mature elastin fibers. Macrophages represent the final stage of differentiation of progenitor cells, which originate in the bone marrow and mature into monocytes in the blood circulation. Their principal function is the processing and presentation of antigens to the immunocompetent lymphoid cells. They synthesize and secrete interleukin 1, growth factors, prostaglandin, interferon, as well as components of the complement system and diverse hydrolytic enzymes. Mast cells are present in all layers of the dermis but are found in highest concentrations around the blood vessels. They synthesize granules, which contain vasoactive or chemotactic factors for the neutrophils and eosinophils that are released in response to stimuli of various kinds. These cells are able to respond to stimuli such as light, cold, acute trauma, vibrations, variations in pressure, and other stimuli of chemical and immunological nature.

##### 2. Biosynthetic Processes of the Dermis

The main classes of molecules biosynthesized by the dermis are collagen and elastin, which constitute the fibrous proteins; and proteoglycans and structural glycoproteins, which are the main components of the ground substance.

The timing of biosynthesis of these molecules is different but occurs in a manner coordinated with the morphogenesis of the dermis fibrous network and has the following characteristics:

1. The first characteristic is determined by the affinity "coded" within the structure of the classes of macromolecules mentioned previously and in particular by the structural glycoproteins, which govern the interactions between fibroblasts and collagen fibers, and by proteoglycans, which determine the three-dimensional arrangement of the collagen fibers themselves.

2. Considerable changes are seen with age following modifications in the biosynthetic program, alterations in the relationship between synthesis/degradation and under the influence of hormonal, environmental, and nutritional factors.

##### 3. Biochemical-Molecular Aspects of Biosynthesis of Collagen and Elastin

Collagen is an extracellular protein, but it is synthesized intracellularly in the form of a precursor, which undergoes extensive posttranslation modifications before becoming a mature collagen fibril. The molecule initially synthesized at the ribosome is procollagen (37). The main metabolic

steps that lead to the synthesis of mature collagen and the intra- and extracellular sites where it occurs are schematically reported in Table 2. Elastin is present in the skin in lower concentrations than collagen and is the principal component of elastic fibers. It is synthesized and “refined” by a process essentially similar to that described above. The amino acid composition of elastin is highly analogous to that of collagen; it is rich in glycine and proline residues, although it contains little hydroxyproline, no hydroxylysine, and a high quantity of alanine and other nonpolar aliphatic amino acids.

Mature elastin contains many cross-bonds due to numerous lysine-containing domains separated by two-three alanine residues that can give rise to two types of cross-links:

1. Condensation of an oxidated residue, with an unmodified residue (norleucine–lysine)
2. Condensation of four different residues—three oxidated and one nonoxidated residue to give a compound called desmosine (Fig. 3).

These cross links are typical of elastin and allow the elastic fibers to regain their proper form and dimension after any stretching that they may be subjected to.

Elastin biosynthesis must be coordinated with that of the structural glycoproteins, as the two classes of molecules associate to give the “young” elastin fibers rich in microfibrils. As the process of maturation proceeds, the concentration of polymerized elastin increases following the cross-linking of tropoelastin chains and desmosine residues.

From a biomolecular point of view, the genes that code for these molecules constitute a many-gene family. In the case of collagen, for example, about 20 genes have so far been identified that code for at least 11 different types of

**Table 2** Sequence and Localization of the Collagen Synthesis Process

Nucleus and ribosomes	
Site of process	Functional significance
Gene selection	Determines the type of protein that will be synthesized
Transcription	Formation of primary mRNA transcript
Processing	Formation of final mRNA
Translation	Formation of polypeptides and the initiation of their assembly
Control of expression	Determines the quantity of polypeptides synthesized
Endoplasmic reticulum and Golgi apparatus [cotranslational and posttranslational modifications of repetitive sequences (Gly-X-Y) <sub>n</sub> ]	
Site of process	Functional significance
Removal of signal peptide	Necessary for secretion into the extracellular space
Hydroxylation of 4-proline residues	Still not clear but probably the signal for subsequent hydroxylations
Hydroxylation of 3-proline residues	
Hydroxylation of lysine residues	Necessary to mark lysine residues for glycosylation
Glycosylation	
Formation of intra- and interchain S–S bonds	Start of tertiary structure assembly
Formation of procollagen triple helices	
Extracellular environment (further posttranslational modifications)	
Site of process	Functional significance
Proteolysis of N and C terminal fragments	Elimination of alignment peptides and start of final assembly
Oxidative deamination of lysine, unglycosylated and glycosylated hydroxylysine	Prerequisite for the formation of cross bonds
Formation of interchain cross bonds mediated by aldonic condensation and by the formation of Schiff's bases	
Degradation by specific collagenases	Removal of old damaged extracellular fibers

**Figure 3** Structure of desmosine.

collagen protein. Observed structural differences reflect the different functions that the collagens perform in the various tissues and cell sections in which they are found: tendons and ligaments, the skin, renal glomeruli, bones, and teeth.

At least two pertinent molecular biological problems are still to be clarified:

1. How the genes necessary for the synthesis of a certain type of collagen in a particular cell are selected (in other words, how cells of a given tissue produce a structurally defined type of collagen)
2. How the expression of these genes is regulated (in other words, has a given cell the capacity to produce more than one collagen protein, and it only expresses one of them as a function of time, or does the synthesis of a certain type of collagen contemporaneously inhibit the production of other chains?)

Concerning elastin, the domains in which the cross-links are concentrated are rich in glycine, proline, and valine and are highly conserved structures easily forming beta spirals. Elucidation of the three-dimensional structure of these regions in relation to the elastic characteristics of the protein and the control of expression of the genes coding for the sequences mentioned above are still objects of in-depth research.

#### 4. Fibrous Proteins and Their Degradation: Collagenases and Elastases

From a metabolic point of view collagen is not an "inert" protein. In an individual's lifetime collagen undergoes processes of maturation, remodeling, cicatrization and aging, processes in which the mature and/or aged fibers are progressively substituted by young fibers. The degradation begins with the intervention of specific proteases, which transform polymeric collagen into monomers, which are then hydrolyzed by collagenases. Collagenases, whose activity is regulated by specific protein factors, are derived from an inactive precursor by the proteolytic removal of the amino terminal portion.

Vertebrate collagenases are metal-enzymes containing  $\text{Ca}^{2+}$  and  $\text{Zn}^{2+}$  and are synthesized and secreted by fibroblasts, leucocytes, polymorphonucleates, macrophages, cutaneous epithelial cells, and chondrocytes. Their synthesis is controlled by hormones (parathyroid hormone is a positive effector in contrast to progesterone and hydrocortisone). Hormonal action is probably mediated by a specific prostaglandin and other factors, heparin for example.

The situation with elastin is different: the thin elastic fibers present in the subpapillary region disappear at about 40 years of age, when the first lysis of elastin appears. With advancing age, the dermis fibroblasts secrete large quantities of elastases, which degrade the fibers of both the dermis and the epidermis, fibers that cannot be replaced because the activity of the lysyl oxidases diminishes drastically.

#### 5. Ground Substance Biosynthesis and the Role of Structural Proteins, Glucosaminoglycans, and Proteoglycans

As previously stated, the structural glycoproteins (GPS) are synthesized *in situ* by mesenchymal cells of the connective tissue and are found in the basal membrane and intercellular spaces, either free or associated with other matrix proteins. Some of these can be imbricated with collagen or elastin, others with proteoglycans, thus playing an important role in the three-dimensional organization of the fibrous framework and in the positioning of cells, especially the fibroblasts, in the body of the matrix itself. Therefore they are directly involved in fibrillogenesis, a process that is accelerated *in vitro* by the addition of GPS to a tropocollagen solution. Given their high affinity for lipids, it is likely that the GPSs have an important role in the aging process, in a characteristic way in the case of diabetes and atherosclerosis, conditions in which the dermis accumulates lipids, especially cholesterol esters.

From a chemical point of view, the GPSs contain many

dicarboxylic amino acid residues and also aromatic (tryptophan), sulphurated (cysteine), and aliphatic (glycine, proline, and valine) amino acids. The saccharide content (glucose, galactose, mannose; *N*-acetyl esosamine, fucose, and sialic acid) varies from one molecular species to another. Generally they are not very soluble and are often composed of subunits linked by disulphide bridges. Their biosynthesis is not dissimilar to that of other glycoproteins.

*Fibronectin* is one of the best-studied GPSs synthesized by fibroblasts. It is found either associated with the cell membrane or to the collagen of the intercellular matrix. It is most probably responsible for the “anchorage” of fibroblasts to the fibrous framework. The binding both to fibroblasts and to collagen and proteoglycans is mediated by specific amino acid sequences. Fibronectin is composed of two polypeptide chains linked by disulphide bridges close to the carboxyl terminal end. The gene for this GPS contains more than 50 exons, which code for “variations” in three principal sequences. In the protein the domain, that binds to collagen possesses three modules: one that performs a different specific function (that of binding fibrin) and two with another type of amino acid sequence. The module, which contains the sequence *Arg-Gly-Asp-Ser*, seems to be responsible for binding to the intercellular matrix and/or to certain proteoglycans.

Experimental data indicate that cancer cells or cells transformed by oncogenic viruses lose the ability to fix fibronectin to their membrane surfaces, and this could be responsible for their inability to form organized tissues and their progression to malignancy.

Finally it should be mentioned that a single mRNA primary transcript, which undergoes different splicing, codes these “different” fibronectins.

*Laminin* is another adhesion glycoprotein of the extracellular matrix and allows the epithelial cells to adhere to the connective tissue that surrounds them. It is able to bind to type IV collagen, the characteristic component of the basal membrane. Like fibronectin it possesses different domains with specific binding functions.

The connective tissue is also rich in *proteoglycans*, which are essentially composed (approximately 90%) by polysaccharide residues. These are important in the determination of the skin’s viscoelastic properties in that being negatively charged they are able to bind water and different cations. The proteoglycan heteropolysaccharide chains are formed by glucosaminoglycans (GAG) composed of repetitive disaccharide units containing an amino sugar (glucosamine or galactosamine) and a sugar containing a carboxylic or sulphate group (38).

Principal GAGs are hyaluronic acid, the chondroitin sulphates, dermatan sulphate, and heparan sulphate. In pro-

teoglycans the GAGs are covalently linked to a peptide matrix (“core protein”). Approximately 140 protein residues are then linked at regular intervals of approximately 300 Å to a long filament of hyaluronic acid, thus forming high molecular weight complexes. The interaction with hyaluronic acid is mediated by two small peptides: one links the protein, the other links hyaluronic acid. The schematic structure of a generic proteoglycan in its monomeric form is shown in Fig. 4

The proteoglycans represent the final product of a complex “assembly” process that involves both the protein synthesis apparatus of the ribosomes and the Golgi system, where posttranslational modifications of splicing and glycosylation occur. The schematic view of the synthesis of a generic proteoglycan in monomer form, not yet conjugated with a hyaluronic acid, is shown in Fig. 7. Functionally, GAG and proteoglycans are strictly associated with tropocollagen molecules, which “control” the level of polymerization. They also contribute to the correct “alignment” of the collagen and elastin fibrils and change the chemical and physical state of the dermis from a fibrous structure to a gel containing a high percentage of water.

Hyaluronic acid itself contributes not only to this hydrating effect but also to the elastic properties of the dermis. The “viscosity” level of the gel can be reduced following depolymerization of hyaluronic acid and the subsequent “disorganization” of the aggregates. This may occur under the action of hyaluronidases, the influence of chemical agents (cysteine, ascorbic acid, and hydroqui-

**Figure 4** Schematic structure of a generic proteoglycan in its monomeric form. a, core protein; b, chondroitin sulphates; c, keratan sulphates; d, peptide linker (junction); e, hyaluronic acid.

nonese), and finally due to the presence of free radicals produced by ultraviolet radiation on the skin.

## E. Skin Annexes

### 1. Hair

Hairs grow out of tubular invaginations of the epidermis known as follicles, and a hair follicle and its associated sebaceous glands are referred to as a pilosebaceous unit. Hair follicles extend into the dermis at an angle. A small bundle of smooth muscle fibers, the arrector pili muscle, extends from just beneath the epidermis and is attached to the side of the follicle at an angle. Arrector pili muscles are supplied by adrenergic nerves, and are responsible for the erection of hair during cold or emotional stress (gooseflesh). The sebaceous gland is attached to the follicle just above the point of attachment of the arrector pili (36).

At the lower end of the follicle is the hair bulb, part of which, the hair matrix, is a zone of rapidly dividing cells that is responsible for the formation of the hair shaft. Hair pigment is produced by melanocytes in the hair bulb. Cells produced in the hair bulb become densely packed, elongated, and arranged parallel to the long axis of the hair shaft. They gradually become keratinized as they ascend in the hair follicle.

The average rate of growth of human scalp hair is 0.37 mm per day. In women, scalp hair grows faster and body hair grows more slowly than in men. The rate of growth of body hair is undoubtedly increased by androgens, since it can be reduced by treatment with antiandrogenic steroids.

### 2. Hair: Types and Growth Cycle

The type of hair produced by any particular follicle can change. The most striking example is the replacement of vellus by terminal hair at puberty, which starts in the pubic regions. This leads us to the definition of androgen-dependent hair. It is obvious from the events of puberty that pubic, axillary, facial, and body hair are hormone dependent. So, paradoxically, is pattern baldness (male), in which terminal hair is replaced by fine, short hair resembling vellus. The growth of the male beard depends on testicular hormones. The action of testosterone in general involves its reduction to 5 alpha-dihydrotestosterone and binding to an intracellular receptor.

The most important feature of hair follicles is that their activity is intermittent (cyclical). As the hair reaches a definitive length, it is shed and replaced by a new hair. Thus a hair follicle will pass into three stages: an active (anagen) stage, a resting (catagen) stage, and a telogen stage wherein the hair stops growing and is finally shed. In human scalp

hair, the anagen stage takes about three years, the catagen stage takes three weeks, and the telogen phase takes three months. The hair cycle occurs in different hair follicles asynchronously, i.e., at a given time, each individual hair follicle is at a different stage of the hair cycle.

### 3. Nails

The nail acts as a protective covering to the end of the digit and assists in grasping small objects. The nail has also a cosmetic function. The major part of this appendage is the hard nail plate, which arises from the matrix (see below). The nail plate is roughly rectangular and flat in shape but shows considerable variation in different persons. The pink color of the nail bed results from its extensive vascular network and can be seen because of the transparency of the plate.

Usually in the thumbs, uncommonly in other fingers and in the large toenails, a whitish crescent-shaped lunula is seen projecting from under the proximal nail folds. The lunula is the most distal portion of the matrix and determines the shape of the free edge of the nail plate. Its color is due in part to the effect of light scattered by the nucleated cells of the matrix and in part to the thick layer of epithelial cells making up the matrix.

As the nail plate emerges from the matrix, its lateral and proximal borders are enveloped by folds of the skin termed the lateral and proximal nail folds. The skin underlying the free end of the nail is referred to as the hyponychium and is contiguous with the skin on the tip of the finger.

The nail plate is formed by a process that involves flattening of the basal cells of the matrix, fragmentation of the nuclei, and condensation of cytoplasm to form horny flat cells that are strongly adherent to one another.

### 4. Sebaceous Glands

Sebaceous glands are found on all areas of the skin with the exception of the palms, soles, and dorsa of the feet. They are holocrine glands, i.e., their secretion is formed by complete destruction of the cells.

Most sebaceous glands have their ducts opening into hair follicles (pilosebaceous apparatus). Free sebaceous glands (not associated with hair follicles) open directly to the surface of the skin, e.g., Meibomian glands of the eyelids, Tyson's glands of the prepuce, and free glands in the female genitalia and in the areola of the nipple.

The production of sebum is under hormonal control, and sebaceous secretion is a continuous process. Sebaceous gland development is an early event in puberty, and the prime hormonal stimulus for this glandular development is androgen. Although the sebaceous glands are very small throughout the prepubertal period, they are large at

the time of birth, probably as a result of androgen stimulation in utero, and acne may be seen in the neonatal period. It should be noted that (1) sebum production is low in children; (2) in adults, sebum production is higher in men than in women; (3) in men, sebum production falls only slightly with advancing age, whereas in women it decreases significantly after the age of 50. Orchidectomy causes a marked decrease in sebum production. Therefore it can be assumed that testicular androgen maintains sebum production at high levels in men. The role of adrenal androgens is also important, especially in women where they play a contributory role in sebum production together with the ovaries.

Estrogens have a profound effect on sebaceous gland function that is opposite of that of androgens. In both sexes, estrogen administration decreases the size of the sebaceous glands and the production of sebum.

The sebum is composed of triglycerides and free fatty acids, wax esters, squalene, and cholesterol. The sebum controls moisture loss from the epidermis. The water-holding power of cornified epithelium depends on the presence of lipids. The sebum also protects against fungal and bacterial infections of the skin due to its contents of free fatty acids. Ringworm of the scalp becomes rare after puberty.

### 5. Sweat Glands

Generalized sweating is the normal response to exercise or thermal stress by which human beings control their body temperature through evaporative heat loss. Failure of this mechanism can cause hyperthermia and death. (See also "Vascular System" above).

Humans have several million eccrine sweat glands distributed over nearly the entire body surface (except the labia minora and the glans penis). The total mass of eccrine sweat glands roughly equals that of one kidney, i.e., 100 g. A person can perspire as much as several liters per hour and 10 liters per day, which is far greater than the secretory rates of other exocrine glands such as the salivary and lacrimal glands and the pancreas.

Each eccrine sweat gland consists of a secretory coil deep in the dermis and a duct that conveys the secreted sweat to the surface. The secretory activity of the human eccrine sweat glands consists of two major functions: (1) the secretion of an ultrafiltrate of a plasmalike precursor fluid by the secretory coil in response to acetylcholine released from the sympathetic nerve endings, and (2) reabsorption of sodium in excess of water by the duct, thereby producing a hypotonic skin surface sweat. Under extreme conditions, where the amount of perspiration reaches several liters a day, the ductal reabsorptive function assumes a vital role in maintaining homeostasis of the entire body.

In addition to the secretion of water and electrolytes, the sweat glands serve as excretory organs for heavy metals, organic compounds, and macromolecules. The sweat is composed of 99% water, electrolytes, lactate (provides an acidic pH to resist infection), urea, ammonia, proteolytic enzymes, and other substances.

The term apocrine glands was given to sweat glands present in the axillae and anogenital area that are under the control of sex hormones, mainly androgens. But nowadays by electron microscopy, these apocrine glands (apocrine = apical part of the cell is destroyed during the process of secretion) proved to be merocrine in nature (merocrine = no destruction of the cell during the process of secretion). The "apocrine" sweat of humans has been described as milky (because it is mixed with sebum due to shared ducts) and viscid, without odor when it is first secreted. Subsequent bacterial action is necessary for odor production. Unlike eccrine glands, which have a duct that opens onto the skin surface independently of a hair follicle, apocrine glands have a duct that opens into a hair follicle.

## III. DERMOCOSMETIC SECTION

### A. Introduction

The skin can be defined as healthy when its physical, biochemical, and structural components are all in equilibrium. The use of a cosmetic sometimes does not affect this equilibrium and has purely aesthetic functions, while at other times it can and must provide correction and prevention of changes in the skin brought about by both internal and external factors.

In a cosmetic, both the active principle and the excipient can perform this function. The active principles are all those substances or mixtures of substances used in cosmetics to obtain a defined nutritional, hydrating, stimulative, or protective action. Naturally, the use of active principles in cosmetics must be directed exclusively at the treatment of healthy skin, and when substances with pharmacological activity are used (e.g., vitamins or antimicrobials), the percentage content must be lower than the dosage utilized in the treatment of pathological changes.

### B. Skin and Hydration

As water is life for the entire body, so it is for the skin. Hydration represents the most important parameter in the health of our skin. Numerous factors determine the water content of the skin, although overall it is directly related to the ambient humidity, and the skin can only retain adequate concentrations of water at a relative humidity of 60%.

The skin's factors that govern the maintenance of its hydration are epidermal lipids, surface hydrophilic film, natural moisturizing factors (NMF), the horny layer, and organic substances (salts, amino acids, hyaluronic acid).

Epidermal lipids have a fundamental role both in binding water and in occluding the intercellular spaces. Their action is expressed in the correct structure of the lamellae in the horny layer, which otherwise would not be able to retain water.

The hydrophilic film covers the epidermis with a thin protective layer that softens it, slows down its desquamation, and defends it against both chemical and bacteriostatic agents. Removal of the film by excessive cleansing, for example, leads to damage of the horny layer, which desquamates and loses intercellular lipids, so opening the door to the entry of germs and harmful substances.

The NMF, are a series of substances produced by the epidermal cells and by sweating, which function to bind water both intracellular and extracellular together with the intercellular lipids. Of the NMF components the most important are pyrrolidone carboxylic acid and urea, but many other organic substances and mineral salts are part of the group.

Below the epidermis, in the dermis, there is a larger quantity of water. It is this water of the dermis that hydrates the epidermis by two principal mechanisms, sweating and transpiration (*perspiratio insensibilis*). The latter is essential for life; the body must continuously exchange the heat produced by the energy reactions that occur uninterruptedly in all its cells.

In the dermis, the majority of water is bound to glycosaminoglycans and proteoglycans. Sugar complexes with organic acids and proteins form them, respectively. Of particular interest is hyaluronic acid, which is able to bind many molecules of water. All substances that bind water are defined as hygroscopic, while the property of being soluble in water is defined as hydrosolubility. Hyaluronic acid is also present in the epidermis where, in addition to hydration, it is also involved in other activities connected with the life of keratinocytes.

Many specific and nonspecific hydrating substances are used in the cosmetic sector.

Hyaluronic acid (HA) is the main component of a polysaccharide family defined as mucopolysaccharides or glycosaminoglycans, which all have similar structure and behavior. The HA (39) molecule is composed of a repeating disaccharide (*beta-N-acetyl-D-glucosamine-beta-glucuronic acid*)<sub>n</sub> organized as a random coil. Its molecular weight can approach 10 million daltons. It takes on a huge volume of water of hydration that makes it a very expansive molecule. It can expand its solvent domain up to 10,000 times its actual polymer volume. Hyaluronic acid

is the simplest of the GAGs, the only one not covalently linked to a core protein, and it is the only nonsulfated GAG.

Hyaluronic acid maintains skin moisture, organizes the extracellular matrix, and has an immunosuppressive function. HA also lubricates joints and maintains the necessary turgor of the eye. Understanding the metabolism of HA, its reactions within skin, and the interactions of HA with other skin components, will facilitate the ability to modulate skin moisture in a rational manner.

Recent progress in the details of the metabolism of HA has also clarified the long-appreciated observations that premature aging of the skin has two causes, chronic inflammation and sun damage caused by ultraviolet light (UV). These processes, as well as normal aging, all use similar mechanisms that cause loss of moisture and changes in HA distribution (40). UV light causes dramatic changes in the arrangement and distribution of HA in skin (41). In addition, HA has some unusual features that, at present, cannot be explained. The turnover rate of HA in the body as well as in the skin is very rapid, much of it being degraded and renewed every hour (42).

The HA molecule is critical from the onset of human development, and it promotes cell movement and cell proliferation. When HA is removed by hyaluronidases, cells are able to make contact with each other, undergo compaction or condensation, and begin to interact with each other. Cell movement slows, permitting these units to differentiate into tissues and organs (43).

Thus it seems that HA must be removed by hyaluronidases before commitment and differentiation can begin. This also documents how important HA is as a signalling and informational molecule. It is not just a sugar polymer that feels and hydrates space.

The HA molecule belongs to the class of compounds termed glycosaminoglycans (GAGs). Other members of this class include heparan, dermatan, keratan, and chondroitin sulfates. In skin, however, HA is the major GAG.

It is present in the dermis and in the epidermis (44). In the epidermis, the HA provides a means of cell motility. It creates an environment for cell movement by swelling the extracellular space. HA molecules simultaneously endow cells with motility by binding with receptors that interact with the cytoskeleton. That action initiates cascades of signal transduction events (45,46). The basal keratinocytes, in cultures, in the presence of low calcium, remain undifferentiated and proliferate rapidly. They also synthesize large volumes of HA. When calcium is added to this medium, these cells cease growing, begin differentiation, and become stratified, so that they appear like the layers of true skin epidermis. They also start making great amounts of hyaluronidase. The HA becomes degraded, and

the cells remain relatively depleted of HA. The HA of the dermis is in contiguity with the body's bloodstream and lymphatic system. It is the dermal fibroblasts that make dermal HA. However, when such cells are grown in tissue culture, they do not demonstrate the calcium sensitivity exhibited by epidermal keratinocytes. Here is another example to justify the claim that dermis and epidermis are different organs, even though they lie immediately adjacent to each other.

Why 50% of HA in the body is located in the dermis is not known, other than that it serves as a control of interstitial fluid volume.

The HA of the dermis is loosely bound to tissue, in equilibrium with the rest of the body, and is easily removed by the lymphatic. On the other hand, the HA of the epidermis is tightly bound, not easily removed, and appears to be tightly regulated in conjunction with differentiation of epidermal skin cells. HA synthesis, degradation, and the attendant control mechanisms are distinct and separate in epidermis and dermis. It is necessary to begin to think about attempts to modulate HA deposition in skin, therefore, in relation to two separate compartments. Whether the desired moist, soft, and supple appearance of skin is a reflection of HA in one or the other, or possibly in both compartments, is yet to be established.

### 1. Implications for the Cosmetic Industry

The HA field is a rapidly growing area of research, and continued research is assured. A number of discoveries should be noted that might have impact on the cosmetics industry and among skin-care researchers. Attempts are frequently made to enhance the moisture and appearance of skin by using agents topically that stimulate HA content, increasing the level and the length of time HA is present in skin, preserving optimal chain length of this sugar polymer, and inducing expression of the best profile of HA binding proteins to decorate the molecule. Agents that stimulate HA production should be separated, distinguishing those that act upon epidermal HA and those whose target is the HA of the dermis.

The size of the HA polymer is critical in vivo. In fact, opposite biological effects can be achieved from two different chain lengths of HA. High molecular weight (HMW) HA, in the range of millions of daltons, is present in cartilage, in the vitreous of the eye, and in the synovial fluid of normal joints. This HMW material inhibits the growth of blood vessels (47).

On the other hand, HA fragments are highly angiogenic and are potent stimulators of blood vessel growth (48). Small HA fragments can also stimulate the inflammatory response. In skin pathology, for example, the accumulation

of fragmented HA molecules in dermal papillae supports the growth of psoriatic lesions, which stimulate the growth of capillaries and attract inflammatory cells (49).

In cosmetics, one might consider that the size of the HA molecule might be important. However, little, if any, of the HA molecules actually get through the horny layer when applied topically. Therefore HA size may be of little importance in cosmetic preparations.

Following application to the skin, HA forms a thin, light-permeable, viscoelastic surface film. This fixes the moisture on the surface of the skin and supports the skin's natural protective mechanism. The HA regulates water balance and osmotic pressure, functions as an ion-exchange resin, and regulates ion flow. It functions as sieve, to exclude certain molecules, to enhance the extracellular domain of cell surfaces (particularly the lumen surface of endothelial cells), to stabilize structures by electrostatic interactions, and also to act as a lubricant. HA also acts as an organizer of the extra cellular matrix. It is the central molecule around which other components of the extracellular matrix distribute and orient themselves (50).

Since it is an excellent water reservoir and an ideal lubricant, HA, when incorporated in cosmetics, leads to a perceptible and visible improvement in skin condition.

The anomalous ability of HA to be both hydrophobic and hydrophilic, to associate with itself, with cell surface membranes, with proteins, or with other GAGs speaks to the versatility of this remarkable molecule.

HA as well as other glycosaminoglycans can be extracted from animals, e.g., fish cartilage, or alternatively from plants. For example, the seed extract of the St. John's bread tree (*Ceratonia siliqua*, *Leguminosae*) is locust bean gum, a branched galactomannane. This gum has moisturizing and skin-smoothing properties just like HA and is now in use for cosmetic preparations (Fig. 5). A sulfated heteropolysaccharide, rich in glucuronic acid, is extracted from a green seaweed (*Codium tomentosum*) and has the natural function of moisturizing agent.

Another class of molecules of cosmetic interest is that of molecules with a high affinity to keratin, that form a moisturizing, semioclusive, protective, antiwrinkle film on the skin surface. For example, from the mulberry silkworm (*Bombix mori*) is obtained a water-soluble biopolymer, a high molecular weight glycoprotein that shows high affinity with keratin of the skin and of the hair, to form a protective film, imparting an immediate, long-lasting, smooth, silky feeling.

### C. Skin and Defense System

The skin is the first line of the body's nonspecific defense system. Unlike the immune system, which defends by

Figure 5 Chemical structure of locust bean gum.

forming antibodies against specific invaders, the skin provides a nonspecific barrier of cells and an environment that most bacteria, viruses, and other pollutants cannot penetrate (51). Skin is no different from any other organ in the body with a whole host of immune cells. Perhaps the most important of these defenses is the activity of the Langerhans cells, the skin resident macrophages. Activating the macrophages sets up a cascade reaction in the skin, resulting in fibroblast activation and the production of cytokines and epidermal growth factor (EGF), which aid the healing of wounds. In aged or wrinkled skin, increased production of EGF increases the production of collagen and elastin, thus improving the skin's appearance and causing fine lines and wrinkles to disappear (52). In the last two decades the role of *beta-glucan* in stimulating the immune system of the human body has been confirmed (53,54).

Glucans are natural polysaccharides found in oats, barley, wheat, yeast, and fungi. The term glucan refers generically to a variety of naturally occurring homopolysaccharides or polyglucoses, including polymers such as cellulose, amylose, glycogen, and starch. Glucan encompasses branched and unbranched chains of glucose units linked by 1-3, 1-4, and 1-6 glucosidic bonds that may be of either the alpha or beta type.

Polybranched beta-1,3-D-glucan is a naturally occurring polysaccharide that can be found in a variety of fungal cells including cell walls of yeast, i.e., *Saccharomyces cerevisiae*. Out of different glucans, the beta-1,3-D-glucan configuration has been shown to act as a nonspecific immune activator (55).

A macrophage cell surface receptor specific for a small oligosaccharide of the beta-(1,3)-D-glucan series has been identified (56). This receptor is a protein complex that appears to be present throughout the whole differentiation

cycle of macrophages, starting in the bone marrow. Mature macrophages are found in virtually all the tissues including the central nervous system. When a macrophage encounters beta-1,3-D-glucan, it becomes activated. All the functions, including phagocytosis, release of certain cytokines, and the processing of antigens are improved and brought up to date.

#### 1. Implications for the Cosmetic Industry

Glucan is an excellent wound healer. In experiments, glucan-treated wounds showed a higher number of macrophages in the early, inflammatory stage of repair, with fewer polymorphonuclear neutrophilic leukocytes than did control wounds. Both reepithelization and the onset of fibroplasia commenced at an earlier stage in glucan-treated wounds than in control wounds (57).

In humans, topical glucan treatment resulted in a 73% improvement in chronic decubitus ulcers with complete closure and epitalization in 27% of treated ulcers. All wounds remained clean, and no infections occurred during this treatment (58).

Considering the data above, a topical combination of an antibiotic and beta-1,3-D-glucan as an adjuvant for wound healing applications seems to be appropriate.

An interesting effect of the topical application of glucan was observed in regard to nonwounded aged skin. Revitalizing, such as reducing the number, depth, and length of wrinkles, thickening, and reducing roughness and dryness of the skin was shown in a group of female volunteers.

Applied topically, glucan activates epidermal macrophages (Langerhans cells). This mechanism plus its free-radical scavenging effect makes it a photoprotective agent. Glucan application resulted in the reduction of after-UV

erythema and preservation of the amount of Langerhans cells in the epidermis (59), so that a combination of a sun-screen and glucan is suggested.

The anti-irritant effect of beta-(1,3)-D-glucan was also shown in combination with otherwise severe irritation caused by high level of lactic acid. Glucan also has a synergistic effect with another antiaging topical ingredient: retinoic acid. Similar to corticosteroids, retinoic acid significantly increases the number of beta-glucan receptor sites on phagocytic cells.

Beta-glucan of the *Schizophyllum commune* mushroom has a beta-(1,6) branch on every third glucose residue of the beta-(1,3) main chain (Fig. 6). Moo-Sung et al. (60) show that beta-(1,6)-branched beta-(1,3)-glucan from *Schizophyllum commune* is an active ingredient that can help to increase skin cell proliferation, collagen biosynthesis, and sunburn recovery. It can effectively reduce skin irritation. In addition, this beta-glucan is water soluble and stable under conditions of changing pH and temperature. The authors suggest that beta-(1,6)-branched beta-(1,3)-glucan from *S. commune* is an effective ingredient for use in antiaging and anti-irritant dermocosmetic formulations.

Carboxymethylated beta-(1,3)-Glucan (CM-Glucan) (61) enhances the renewal rate of the stratum corneum significantly compared to untreated skin (62). CM-Glucan also offers a concentration-dependent protection against

UV-A irradiation. Skin pretreatment with a formulation containing 0.2% CM-Glucan showed an almost complete inhibition of lipid peroxidation compared to placebo. Protection against lipid peroxidation induced by UV-A irradiation is usually only observed by the application of antioxidants (63). Colin et al. (64) reported an inhibition of about 90% upon the application of 0.2% D-alpha-tocopherol but only an inhibition of less than 25% by the application of the cosmetically stable vitamin E acetate at the same concentration. Since CM-Glucan is neither an antioxidant nor an iron chelator, it must use mechanisms other than extracellular radical scavenging or activities related to it. CM-Glucan appears to stimulate cells to produce endogenous factors that protect the skin against oxidative stress and other environmental insults.

The pretreatment of skin with cosmetic formulations containing CM-Glucan at different concentrations showed substantial protecting effects against skin damage caused by detergent challenge. In a concentration-dependent manner, CM-Glucan protected the skin against the decrease of skin humidity and the increase of transepidermal water loss (65).

The treatment of aged skin (age of volunteers >60 years) with an oil-in-water emulsion containing 0.04% CM-Glucan clearly improved skin firmness and eye wrinkle depth even compared to the placebo control, and not

Figure 6 Structure of a monomer of beta-glucan in *Schizophyllum commune*.

only to untreated skin. However, the exact mode of CM-Glucan activity has not been fully elucidated and warrants further investigations. The increase of skin firmness is related to the reduction of wrinkles. It seems that CM-Glucan stimulates the production of skin factors, which improve the elasticity and smoothness of the skin. In addition, the film-forming properties and the UV-A protecting effects of CM-Glucan could also contribute to the observed results.

Considerable attention has been recently given to *Aloe Vera* extract, which was found to carry one of the macrophage activating polysaccharides, mannan or polyman-nose. While mannan has some macrophage activating potential, it is very slight compared to that of glucan (66).

#### D. Biopolymers as Hydrocolloids

Gums, hydrophilic colloids, mucilages, and water-soluble polymers are but a few designations for materials that have the ability to thicken or gel aqueous systems (67,68). These materials were first found in exudates from trees or bushes, or were extracts from plants or seaweeds, flours from seeds or grains, gummy slimes from fermentation processes, and many other natural products. In more recent times, new and modified gums have been made by chemical modification and derivation of many of the natural gums. In addition, some very new gums were developed by complete chemical synthesis to yield new polymers having completely new hydrophilic properties. The origin of these hydrocolloids is shown in Table 3, and a classification of natural and synthetic polymers is shown in Table 4.

Natural gums have a long history of usage. Many have been used in food applications, so their safety is well documented. There are several drawbacks to this product category: a standardization problem due to their natural origin (i.e., the difficulty in predicting viscosity buildup), possible contamination by microorganisms and environmental pollutants, their natural color and odor (which may bring formulation problems), and the great number of cellulose derivatives with different structures and qualities (that make the proper choice difficult), and possible incompatibilities with other ingredients of the formulation (69).

##### a. Functional Properties

The utility and importance of hydrocolloids are based upon their functional properties. Hydrocolloids are long-chain polymers that dissolve or disperse in water to give a thickening or viscosity-producing effect. The water-thickening property is common to all hydrocolloids; the degree of thickening varies between gums. The rheological characteristics of a hydrocolloid solution are useful aids to the selection of the proper gum for a specific formulation.

**Table 3** Origins of Biopolymers

---

<i>Exudates</i> from specific trees or bushes in teardrop or flake shapes, then ground to a powder.
<i>Extracts</i> from specific seaweed species are made by heating with water and separating from the insoluble plant material. Then the aqueous liquid is purified, dried, and ground to a fine powder. In similar fashion, pectin is isolated as an aqueous extract of citrus fruit peel, and gelatin is extracted not only from cowhides, pigskins, or animal bones, but also from plants.
<i>Flours</i> separated by purely mechanical means from the cereal or plant seed. Purified or clarified material can be made by dissolving the gums in water, filtering the solution, then drying.
<i>Fermentation</i> or <i>biosynthesis</i> of pure polymers produced by controlled bacterial strains and substrates.
<i>Chemical modification</i> and derivatization of natural polymers to remove inherent limitations and deficiencies that restrict their overall utilization. While normal guar gum is quite soluble in cold water, its solubility can be greatly increased by forming the hydroxypropyl guar derivative, while simultaneously giving a greatly increased viscosity. Pure cellulose is completely insoluble in water as well as poorly absorptive in its native form. By chemical treatment to form cellulose ether compounds—such as methyl cellulose and hydroxypropyl cellulose—water solubility can be imparted, thus making a useful series of water-soluble functional polymers.
<i>Chemical synthesis</i> of new and better synthetic polymers.

---

While all hydrocolloids thicken and impart stickiness to aqueous solutions, a few biopolymers also have another major property of being able to form a gel. Gellification is the phenomenon involving the association of cross-linking of the polymer chains to form a three-dimensional continuous network that traps or immobilizes the water within it to form a rigid structure that is resistant to flow under pressure.

In addition to thickening and gelling, hydrocolloids have many other functional properties in cosmetics: they are conditioners, emulsifiers, film formers, foam stabilizers, stabilizers, suspending agents, and swelling agents.

The properties of these biopolymers are largely due to physical effects, primarily those dealing with their interaction with water.

Most hydrocolloids are polysaccharides. The physical effects of these materials derive from the interaction of the polysaccharide molecules both with themselves and with the molecules in their environments. Environmental molecules, with which polysaccharides may interact, range from protein molecules to provide suspension and solution stability, to lipid molecules to provide viscous and emulsification effects. In almost all uses, however, polysaccharides

**Table 4** Natural and Synthetic Polymers in Cosmetics

Natural Polymers
1. <i>Vegetal Origin</i>
Starch
Cellulose and cellulose derivatives
Seaweed gum
Extracts from leaves and flowers
Chondroitin sulfate and hyaluronic acid of marine origin
Branched galactomannan derived from the seeds of the St. John's bread tree ( <i>Ceratonia siliqua</i> , <i>Leguminosae</i> )
Sulfated heteropolysaccharide, rich in glucuronic acid synthesized by the green seaweed <i>Codium</i> .

Polyvinyl methylethers. Copolymers methylvinylether/maleic anhydride (MVE/MA). Polyvinyl quaternary PVM/MA decadiene crosspolymer (INCI) or sodium PVM/VA decadiene cross-polymer (INCI of the neutralized molecule)

exist in an environment rich in water molecules. Thus polysaccharides must primarily and continuously react with water molecules. By such interactions, polysaccharides perform their function to provide viscosity, solution stability, suspending ability, emulsifying action, and gelation.

#### b. Structure

Polysaccharides are either branched or linear (70). The structure of the polymer is of great importance in determining its application, because the structure controls the functional properties. Linear polysaccharides generally have

high viscosity, because they will come into contact with each other more easily, and increase the friction or viscosity characteristics of the solution at much lower dilutions than will highly branched molecules. Linear uncharged polymers usually tend to produce unstable solutions because of their behavior in solution. As linear molecules, such as starch amylose, move about in solution, they collide, shear off absorbed water molecules, and stick together. Other molecules come into contact in the same manner, adhere, and consequently build up, one molecule on another, so that a colloidal particle and eventually a particle large enough to precipitate from solution develops. The solubility of linear molecules can be improved by changes in the molecules that would reduce or prevent the fit or planar association of one molecule to another, or by introducing charges that, by Coulombic repulsion, would facilitate solution of the molecules and while in solution prevent their extensive attraction so as to produce a precipitate. Highly branched structures tend to give solutions with lower viscosities than those of linear molecules of equal molecular weights; however, these solutions tend to be quite stable and will not retrograde or precipitate out of solution. Highly branched molecules, because of their high affinity for water, also have excellent adhesive properties (gum arabic or amylopectin).

Native polymers, such as guar gum, have extending side chains, which do prevent close polymeric association and thus give these polymers greatly improved solubility properties in water. Cellulose and starch polymers, deficient in side chains, have been reacted with various reagents to introduce specific side chain groups and thus produce solubilization.

A classification of polysaccharides is

#### A. Homopolysaccharides

*Linear*—Polysaccharides formed from a single sugar unit and having a straight chain (unbranched) structure. These substances are most often found in structural or cell wall materials of plants and lower animals (Table 5).

*Branched*—Single sugar unit polysaccharides having a branched structure. For the most part, these polysaccharides serve as energy reserves and not as structural elements, although mannans are known to have structural functions. Branched homopolysaccharides usually have a

**Table 5** Representative Linear Homopolysaccharides

Polysaccharides	Sugar component and linkage
Cellulose	Glucose, $\beta$ 1 $\rightarrow$ 4
Amylose	Glucose, $\alpha$ 1 $\rightarrow$ 4
Chitin	<i>N</i> -Acetylglucosamine, $\beta$ 1 $\rightarrow$ 4
Galactan (pectin)	Galactose, $\beta$ 1 $\rightarrow$ 4

**Table 6** Representative Branched Homopolysaccharides

Polysaccharides	Sugar components and linkages
Amylopectin <sup>a</sup>	Glucose, $\alpha$ 1 $\rightarrow$ 4, 6 $\leftarrow$ 1 $\alpha$
Glycogen	Glucose, $\alpha$ 1 $\rightarrow$ 4, 6 $\leftarrow$ 1 $\alpha$
Dextrans	Glucose, $\alpha$ 1 $\rightarrow$ 6, 4 $\leftarrow$ 1 $\alpha$ , $\alpha$ 1 $\rightarrow$ 6, 3 $\leftarrow$ 1 $\alpha$
Galactan	Galactose, $\beta$ 1 $\rightarrow$ 6, 3 $\leftarrow$ 1 $\beta$
Mannan	Mannose, $\alpha$ 1 $\rightarrow$ 2 and $\alpha$ 1 $\rightarrow$ 3, 6 $\leftarrow$ 1 $\alpha$

<sup>a</sup> There are numerous representatives of each of these types throughout animal and plant systems. Differences will lie mainly in branching frequency, but occasionally unusual linkages or other minor sugar components are present.

linear main chain with uniform linkages with respect to position and configuration. At the branch points, new chains of the same general type are initiated with all branch points alike (Table 6).

### B. Heteropolysaccharides

**Linear**—Polysaccharides of this group contain two or more sugar units. Mostly, they are connective tissue polysaccharides, such as chondroitin-4-sulfate and hyaluronic acid. Many carbohydrates in this group are linked covalently to proteins or lipids.

**Branched**—These complex polysaccharides may contain up to six different sugar units and, like the linear variety, may be covalently bound to protein or fat. The polysaccharides of this class may be "type specific" for microorganisms or animals (blood group substances) or may serve a recognition function for cell surfaces (Table 7).

## 1. Vegetal Biopolymers

### a. Gums

**Gum arabic.** This is the dried exudate of the acacia tree (*Acacia senegal* or related species of *Acacia* Fam. Leguminosae). Gum arabic is a complex mixture of Ca, Mg, and K salts of arabic acid (a complex, highly branched polysaccharide colloid) that contains galactose, rhamnose, glucuronic acid, 4-O-methylglucuronic acid, and arabinose residues; it shows a broad molecular weight distribution, e.g., 260,000 to 1,160,000 (Fig. 7). The gum is highly soluble in water, and solutions of up to 50% gum concentration can be prepared; the solution is slightly acidic. Physically, gum arabic is considered to be a complex, highly branched, globular molecule, which is closely packed rather than linear, thus accounting for its low viscosity. High viscosities are not obtained with gum arabic until concentrations of about 40 to 50% are obtained. Rheologically, gum arabic solutions exhibit typical Newtonian behavior at concentra-

**Table 7** Representative Heteropolysaccharides

Polysaccharides	Sugar components and linkages
Pectin	Galacturonic acid, galacturonic acid methyl ester, $\alpha$ 1 $\rightarrow$ 4
Alginate acid	D-mannuronic acid, L-glucuronic acid <sup>a</sup> $\beta$ 1 $\rightarrow$ 4
Hyaluronic acid	Glucuronic acid, <i>N</i> -acetyl glucosamine $\alpha$ 1 $\rightarrow$ 3, $\beta$ 1 $\rightarrow$ 4
Chondroitin sulfate C	Glucuronic acid, <i>N</i> -acetyl galactosamine 6- <i>O</i> -sulfate, $\beta$ 1 $\rightarrow$ 3, $\beta$ 1 $\rightarrow$ 4
Chondroitin sulfate B (Dermatan-SO <sub>4</sub> )	L-iduronic acid, <i>N</i> -acetyl galactosamine 4- <i>O</i> -sulfate, $\alpha$ 1 $\rightarrow$ 3, $\beta$ 1 $\rightarrow$ 4
Keratosulfate	D-galactose, <i>N</i> -acetyl galactosamine 6- <i>O</i> -sulfate, $\beta$ 1 $\rightarrow$ 3
Heparitin sulfate	D-glucuronic acid, <i>N</i> -acetyl galactosamine 6- <i>O</i> -sulfate, $\alpha$ 1 $\rightarrow$ 4
Heparin	D-glucuronic acid, <i>N</i> -sulfoglucosamine ester sulfate, $\alpha$ 1 $\rightarrow$ 4

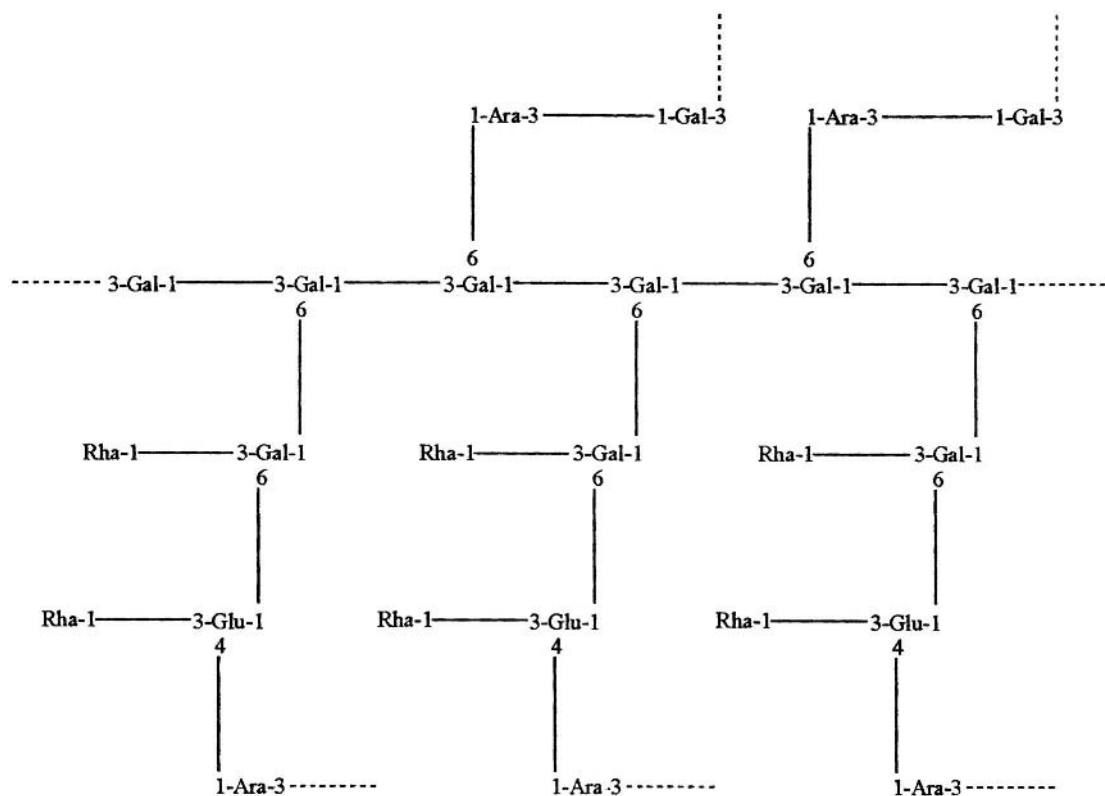

<sup>a</sup> C-5 epimer of D-mannuronic. Contrast with L-iduronic in dermatan sulfate.

tions up to 40%. Above 40%, solutions become pseudoplastic, as is shown by a decrease in viscosity with increasing shearing stress (71).

In cosmetic products, gum arabic acts as binder and stabilizer of O/W emulsions (72), and it facilitates the smoothness and fluency of the products and softens the epidermis forming a protective film.

In high doses it constitutes a good fixative for hair, not greasy. In smaller doses it is useful in detergents for foam stabilizing and in pastes and toothpastes as a gingival emollient.

**Gum tragacanth.** Gum tragacanth is the exudation of small shrub-like plants of the *Astragalus* species (Leguminosae). Structurally, gum tragacanth is a heterogeneous, highly branched polymer composed of a major acidic polysaccharide and a minor neutral polysaccharide plus insignificant amounts of associated cellulose, protein, and starch. The acidic, water-swallowable component, tragacanthic acid (formerly called bassorin) accounts for 60 to 70% of the polymer and upon acid hydrolysis yields D-xylose, L-fucose, D-galacturonic acid, D-galactose, and a very small amount of L-rhamnose. This acidic portion of the molecule is associated with calcium, magnesium, and potassium cations. The neutral, water-soluble polysaccharide component of tragacanth (also called tragacanthin) is an arabinogalactan in which L-arabinose is the preponderant sugar. The highly branched arabinogalactan is believed to consist of a core of D-galactose residues to which highly ramified chains of L-arabinofuranose residues are attached.

**Figure 7** Schematic structure of gum arabic. Ara = arabinose, Rha = rhamnose, Gal = galactose, Glu = glucuronic acid.

Gum tragacanth swells in water to give thick viscous dispersions or pastes similar in texture to soft gels. Gum tragacanth solutions are acidic, usually in the pH range of 5 to 6. Its maximum initial viscosity is at pH 8, but its maximum stable viscosity was found to be near pH 5; the stability is definitely decreased at a pH below 4 or above 6 (73). Gum tragacanth has well-defined surface activity properties and produces a rapid lowering of the surface tension of water at low concentrations (0.25–0.50%). This property when used in O/W mixtures lowers the interfacial tension between the oil and water surfaces and accounts for its effective functioning as an emulsifying agent.

In cosmetic applications, this vegetal biopolymer is used to form gels and protective films. In toothpastes, it acts as a softener and gingival emollient.

**Gum karaja.** Gum karaja is the dried gummy exudates from *Sterculia urens* and other species of *Sterculia* (Fam. Sterculiaceae).

Gum karaja occurs naturally as a complex, partially acetylated branched polysaccharide having a very high molecular weight of about 9,500,000 (74). It contains about 37% uronic acid residues and approximately 8% acetyl groups. Gum karaja contains a central chain of D-galactose, L-

rhamnose, and D-galacturonic acid units (in the molecular ratio of 6:4:5) with some side chains containing D-glucuronic acid. The exudates occur in a salt form containing calcium and magnesium ions.

Gum karaja is water-swallowable rather than water-soluble and adsorbs water very rapidly to form viscous colloidal dispersions at low concentrations. In dilute solutions of gum karaja, the viscosity increases linearly with concentration up to about 0.5%; thereafter karaja dispersions behave as non-Newtonian solutions.

In cosmetic applications, gum karaja, at concentrations above 2 to 3% (viscosity 5,000 to 10,000 cps), forms thick, nonflowing pastes resembling spreadable gels. This natural biopolymer has film-forming properties when plasticized with compounds such as glycols to reduce its brittleness (it has found some use in hair-setting preparations). At higher concentrations of 20 to 50%, gum karaja exhibits strong wet-adhesive properties, which find major applications in denture adhesion products where strong bonding properties are required.

**Gum ghatti.** Gum ghatti, also known as Indian gum, is an amorphous, translucent exudate of the *Anogeissus latifolia* tree of the Combretaceae family. Structurally, gum

ghatti is a mixed calcium and magnesium salt of a complex polysaccharidic acid. Complete acid hydrolysis has shown the polymer to consist of L-arabinose, D-galactose, D-mannose, D-xylose, and D-glucuronic acid in a molar ratio of 10:6:2:1:2 plus traces (less than 1%) of 6-deoxyhexose (75). The gum contains alternating 4-*O*-substituted and 2-*O*-substituted alpha-D-mannopyranose units (76) and chains of 1,6 linked beta-D-galactopyranose units, which are mostly single L-arabinofuranose residues but may also be short chains of L-arabinose sugar units (77). Gum ghatti does not form true aqueous solutions but forms viscous dispersions in water at a concentration of about 5% or higher and exhibits typical non-Newtonian behavior common to most hydrocolloids. It is a moderately viscous gum, lying intermediate between arabic and karaja. Gum ghatti normally forms viscous dispersions having a pH of about 4.8. Viscosity increases sharply with pH up to a maximum at about pH 5 to 7 and then drops off gradually down to pH 12. At all pHs, upon aging, the viscosity decreases noticeably over time (78).

The main cosmetic application of gum ghatti is to stabilize O/W emulsions, and thus has the same uses as gum arabic.

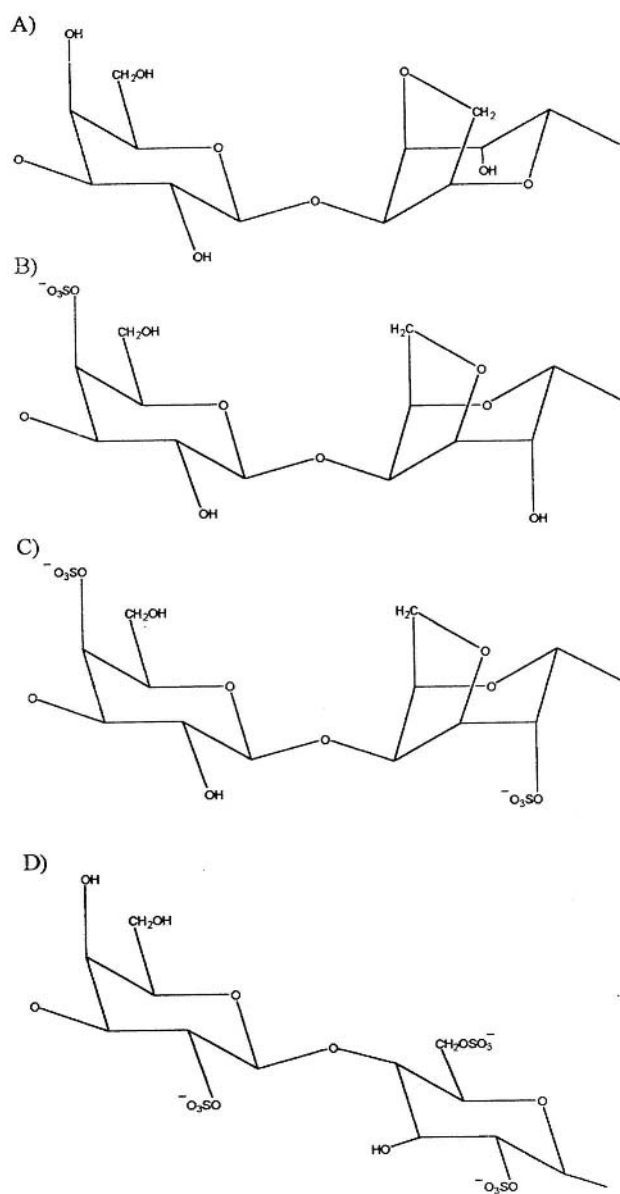

#### b. Extracts

Hydrocolloids extracted from seaweeds are very important because of the large quantity of extracts that can be obtained and their wide field of application in cosmetics. The seaweed extracts are divided into two groups: extracts from red algae and from brown algae.

**Agar.** Agar is extracted from several genera of marine algae of the class red algae (*Rhodophyceae*). Agarose, the gelling portion of agar, has a double helical structure, forming a three dimensional framework that holds the water molecules within the interstices. Chemically, agarose consists of chains of alternate beta-1,3-linked-D-galactose and alfa-1,4-linked 3,6-anhydro-L-galactose. 6-*O*-Methyl-D-galactose may also be present in variable amounts from about 1 to 20% depending upon the algal species (79) (Fig. 8). Agarpectin is probably a mixture of polysaccharides. It contains sulphated residues (3 to 10% sulfate), glucuronic acid, and in some species a small proportion of pyruvic acid linked in acetal linkage.

Agar is insoluble in cold water but soluble in boiling water. The viscosity at temperatures above its gelation point is relatively constant (80). Agar finds some cosmetic uses as a consistency agent in shampoos and toothpastes (81), in hand gels, and in eye makeup.

**Carrageenans.** Carrageenan is a structural polysaccharide found in red seaweed (*Rhodophyceae*), mainly *Chondrus crispus* L., *Eucheuma*, and *Gigartina stellata*.

**Figure 8** Basic structures of agarose and carrageenans. (A) Agarose = D-galactose + 3,6-anhydro-L-galactose (left and right, respectively); (B) kappa carrageenan = D-galactose-4-sulphate + 3,6-anhydro-D-galactose (left and right, respectively); (C) iota carrageenan = D-galactose-4-sulphate + 3,6-anhydro-D-galactose-2-sulphate (left and right, respectively); (D) lambda carrageenan = D-galactose-2-sulphate + D-galactose-2,6-disulphate (left and right, respectively).

Carrageenans are sulphated polymers made up of D-galactose residues linked alternately alpha-(1,3) and beta-(1,4) as a main chain (Fig. 8). The molecular weight is 100,000 to 1,000,000. According to the half-ester sulfate group linkages to one or more of the galactose OH-groups, iota-, kappa-, lambda- micro-, and nu-carrageenans can be distinguished, of which only the first two form gels. Carrageenan is soluble in hot water, forming viscous solutions, which gel on addition of cations such as  $K^+$ ,  $NH_4^+$ ,  $Ca^{2+}$  (72); the presence of alcohol can lead to precipitation.

In cosmetic products, carrageenans lead in O/W emulsions to high viscosity, suspensive ability, and emulsion stabilizing. They are used as foam stabilizers of beard creams and have immense applications, under gel shapes, as excipients in lotions and creams for the face and hands, beauty masks, and above all in toothpastes. The gels of carrageenans introduce moreover one interesting property: they can be incorporated without breaking off the gel in numerous products like alcohols, detergents, solutions, and also weak acids.

*Alginates.* Algin occurs in all members of the class *Phaeophyceae*, i.e., brown seaweed, as a structural component of the cell walls in the form of the insoluble mixed Ca, Mg, Na, and K salts of alginic acid. Algin (INCI) is the sodium salt of alginic acid. The molecular weight of alginic acids is approximately 240,000. Alginates can be attached from microorganisms, and so they have to be preserved.

In cosmetics they are used as coemulsifiers and thickeners for gels [the viscosity of these gels can be regulated with Ca salts (81)], and in lotions, emulsions, shaving foams, toothpastes, and shampoos; they create also excellent protective films.

*Pectins.* Pectin is a generic term for a group of mucilaginous polysaccharides. For extraction, we use materials from some plants particularly rich in pectins like the rinds of some citrus fruits (the lemon, for example, family of the Rutaceae) or apple pulp (*Pyrus*, family of the Rosaceae). Pectins are primarily composed of (1,4)-linked alpha-D-galactopyranosyluronic acid units, partially esterified with methanol. They contain some L-rhamnose residues and some galactose, arabinose, and xylose units. Pectins are readily soluble in water to give viscous, stable solutions; they possess some surfactant properties. Pectins possess strong water-retaining capacities and form on the skin a refreshing and easily absorbable styptic film (81).

In cosmetics, pectins, especially the high methoxylated ones, are used mainly for gels (72,81) (Fig. 9); they give high viscosity, stability, and suspend ability to emulsions and toothpastes. Because of their emulsifier property, these natural biopolymers have been proposed as natural substi-

Figure 9 Structure of pectin.

tutes for synthetic detergents to use in cosmetic preparations.

### c. Mucilages from Plants

*Althea officinalis*, *Calendula officinalis*, *Linum usitatissimum*, *Malva sylvestris*, *Plantago psillium*. The hydrocolloids extracted from these plants are a mix of polysaccharides and polyuronic acids; after hydrolysis, they provide galacturonic acid, rhamnose, galactose, xylose, arabinose, glucose, and glucuronic acid.

Mucilage extracted from *Althea* contains galacturonic acid, glucuronic acid, rhamnose, and galactose; it associates with starch and pectin. Mucilage from *Calendula* contains glucuronic acid, rhamnose, arabinose, and galactose. Mucilage from *Linum* contains galacturonic acid, rhamnose, xylose, and galactose; it associates with a high percentage of oil. Mucilage from *Malva* contains galacturonic acid, rhamnose, arabinose, and galactose. Mucilage extracted from *Plantago* contains galacturonic acid, xylose, and arabinose (85).

These extracts can be used in cosmetics to soothe, soften, refresh, hydrate, and create a protective film.

*Aloe barbadensis.* The biopolymer obtained from the plant contains mainly uronic acid, glucose, mannose, and in smaller quantity xylose, arabinose, rhamnose, and galactose. These last carbohydrates seem to give to Aloe mucilage great soothing properties. In Aloe extract are also present amino acids, citric acid, succinic acid, malic acid, sterols, and partially acetylated glucomannans. These last compounds give to this mucilage its strong gel-forming capacity.

Aloe gel is used in moisturizing, after-sun, and soothing cosmetic preparations.

### d. Fermentation Gums

*Xanthan gum.* Xanthan gum is a secondary metabolite polysaccharide, produced by industrial fermentation of a carbohydrate under aerobic conditions with the microorganism *Xanthomonas campestris*. The xanthan gum polymer backbone consists of 1,4 linked beta-D-glucose units

as in cellulose. At the 3-position of the alternate glucose monomer units trisaccharide side chains branch out consisting of one beta-D-glucuronic acid and two 2-alpha-mannose residues. To about half of the terminal alpha-D-mannose residues a pyruvate group is linked by an acetal linkage to the 4- and 6-carbon positions.

The D-mannose units adjacent to the main chain contain an acetyl group at position 6 (86). The presence of a glucuronic acid unit and a pyruvate group imparts an anionic character to xanthan gum. Xanthan gum dissolves readily in water at ambient temperature and over broad pH ranges and salt concentrations. It is soluble in glycerol at 65°C but is insoluble in other organic solvents or cosmetic oils. Nevertheless, once dissolved in water, up to 40% acetone, ethanol, or isopropanol can be added without precipitating the gum. Concentrations used typically range between 0.3 and 1.0%. The characteristics of aqueous solutions of xanthan gum are

1. High viscosity at low concentration
2. Pseudoplasticity with yield value
3. Insensitivity of the viscosity to heat, electrolytes, prolonged shearing or pH
4. Pleasing skin-feel when used in cosmetics
5. Imparting freeze/thaw stability

#### e. Cellulose Derivatives

Cellulose is the most ubiquitous structure-polysaccharide. It constitutes half of the cell-membrane material of wood and other vegetable products. Cotton consists of practically pure cellulose. Cellulose consists of chains of beta-anhydroglucose units, joined together by acetal linkages. Cellobiose (Fig. 10) and cellotetraose are obtained by the controlled hydrolysis of cellulose. The molecular weight of cellulose is 300,000 to 500,000, which corresponds to 3,000 to 5,000 glucose units. Cellulose consists of amor-

phous and crystalline regions. It is the prototype unbranched linear colloid which is resistant even to hot water and has to be derivatized, e.g., carboxymethylated or hydroxyalkylated to become water soluble (82,83). For this purpose, cellulose is dissolved in soda lye and reacted with monochloroacetic acid, ethylene oxide, propylene oxide, methylchloride, or methylchloride/propylene oxide mixture, etc. Thus water or organosoluble cellulose derivatives are obtained. The solution characteristics of these cellulose derivatives depend on the type of substituent R, the average chain length or degree of polymerization, and the degree of substitution. They can be used in the pH range 3 to 12.

*Ethyl cellulose.* This is the cellulose ethyl ether ( $C_2H_5 Cl$ ); the percentage of  $C_2H_5$  groups is 40–50%. The substitution degree is 2–3. Ethyl cellulose in cosmetics is used as a film-creating agent in lipsticks, enamels for nails, and hair fixing.

*Ethylmethyl cellulose.* This is the cellulose ethyl methyl ether ( $C_2H_5 Cl + CH_3 Cl$ ); it is water soluble and confers high viscosity and stability to cosmetic emulsions and gels.

*Hydroxyethyl cellulose.* This is the cellulose hydroxyethyl ether ( $(H_2COCH_2)_n$ ), a nonionic polymer that is water soluble. It forms solutions with gel and has film-forming capacity. The viscosity of hydroxyethyl cellulose solutions depends upon the degree of polymerization.

In cosmetic preparations, hydroxyethyl cellulose solution with high viscosity is utilized at low concentration in toothpastes; solutions with average viscosity are used at higher dosages to suspend and to make viscous emulsions; low viscous solutions of hydroxyethyl cellulose are used at maximal concentration to create a protective film over the skin.

**Figure 10** Chemical structure of cellobiose, the disaccharide units of cellulose.

*Methyl cellulose, methyl-hydroxyethyl cellulose, methyl-hydroxypropyl cellulose, and hydroxypropyl cellulose.* Methyl cellulose is the cellulose methyl ether; it is a protective colloid with the ability to stabilize emulsions, suspend, and disperse.

Methyl-hydroxyethyl cellulose has a property similar to hydroxyethyl cellulose and methyl cellulose. Methyl-hydroxypropyl cellulose is a nonionic polymer with the ability to protect, stabilize emulsions, suspend, and disperse.

Hydroxypropyl celluloses have the capacity to increase remarkably the viscosity of anionic mixtures and reduce them in nonionic solutions.

#### f. Starch and Starch Derivatives

Natural starch consists of 20% of a water-insoluble linear amylose and 80% water-soluble branched amylopectin. By stepwise acid or enzymatic hydrolysis, starch is hydrolyzed to dextrans (polysaccharides of lower molecular weights), (+)-maltose and finally to D-(+)-glucose. Because of the property of amylose to swell in water, it is used in the manufacture of tablets. A starch-ether called amyllum non mucilaginosum (ANM) is a modified starch used in skin powders for the treatment of acne, because of its strong liquid-absorbing power, without the inconvenience of swelling (84).

## 2. Animal Biopolymers

### a. Polysaccharides

Hyaluronic acid, glycosaminoglycans, sodium carboxymethyl beta-glucan: these polysaccharides have been treated in Sections III.B and III.C.

### b. Polypeptides

Protein hydrolysates are added to hair-care products (to “repair” broken hair thanks to their strong affinity to keratin), soaps, bath gels, creams, etc. These peptides derive from the hydrolysis mainly from collagen, keratin, elastin, milk, wheat, almond, and silk. They are particularly important for the water-binding capacity which regulates the skin’s moisture content, and also for the high affinity for skin proteins resulting in a tightening, antiwrinkle effect. Protein hydrolysates form a uniform substantive semiocclusive film.

### c. Gelatin

Gelatin is a natural protein colloid, possessing gelling and stabilizing properties in aqueous phases. It is obtained by

the partial hydrolysis (molecules with an average molecular weight of 500–1,500) of the collagen contained in skin, conjunctive tissues, and bones of animals. In common with all other proteins, gelatin comprises L-amino acids linked by peptide bonds. Gelatin contains all the amino acids essential to man with the exception of tryptophane (87,81). Technical application of gelatin is in facial masks and protective and conditioning creams for hair and hand care. Vegetal substitutes of gelatin have been proposed.

### d. Elastin

Elastin from bovine tendons is hydrolyzed to obtain peptides with a molecular weight that ranges from 5,000 to 85,000. It is used in cosmetic formulations as a moisturizing and conditioning agent. Recently, vegetal substitutes of elastin have been studied. An extract from the seaweed *Ulva lactuca* seems to have some properties similar to those of animal elastin, or *perhaps* inhibiting elastase activity.

### e. Keratin

The controlled lysis of hair, nails, and other keratinic materials (of bovine origin usually) supplies polypeptides characterized by the presence of sulphured amino acids (above all cystein), typical horny structures. Thanks to the presence of this reservoir, these keratinlike polypeptides show more analogy to hair and epidermis than those of collagen.

Keratinic hydrolysates are added to hair-care products, soaps, bath gels, creams, etc.

### f. Melanin

Throughout nature, melanin is used in such diverse areas as protection from ultraviolet radiation. It is insoluble and difficult to work with, making it impractical for inclusion in creams and lotions. A great result is the discovery of methods for creating melanin derivatives that dissolve readily in water and, when incorporated into cosmetic products, can be spread evenly on the skin to instantly produce a tan.

Sunscreens are most efficient at absorbing and thus protect from the burning UV-B rays. There are many conventional sunscreens available. However, the ideal is to have a sunscreen containing the best natural protectant nature has to offer: melanin. Melanin naturally protects the skin from cancer induced by ultraviolet light. Perhaps synthetic melanin would do the same. Skin cancers are the most prevalent type of cancer in the world, so even a small reduction in their incidence would make an impact on a significant number of people.

Melanin-containing skin-care and hair-care products make melanin available for topical application to the skin. Soluble melanin formulated into cosmetics protects the skin against harmful UVR and also has the photoprotective ability to scavenge free radicals.

These specially formulated products will also moisturize the skin to help protect against dryness and dehydration. Many manufacturers are even putting suncreening ingredients in their cosmetic products (foundation, eye makeup, lipstick, and face creams) to provide the skin with even further protection.

Pre-tan accelerators, applied at least 24 hours before exposure, usually contain tyrosine, an amino acid that helps induce the melanocytes into producing additional melanin prior to actual sun exposure.

Sunscreens are also being added to hair styling products including shampoos, sprays, gels, mousses, and conditioning packs. Melanin-based hair-care cosmetics nourish the scalp with a special combination of pH-balanced ingredients. For strong, healthy hair, they also minimize dryness, brittleness, and split ends.

Shampoo containing a combination of amino acids and melanin cleanses without stripping the hair shaft of its natural moisture.

Conditioning hair and scalp treatment, enriched with proteins, vitamins, minerals, and melanin, penetrates the hair follicles to moisturize and protect the hair, leaving it shiny, healthy and more manageable. On the scalp, it soothes and nourishes it, while reducing itchy and flaking scalp.

Moisturizing leave-in-conditioner containing a combination of vitamins and melanin protects the hair from the damaging effects of the sun's UVR.

Hair balm containing a combination of oils plus melanin leaves hair with luster, body, and sheen as nature intended.

## E. Conclusion

The state of the art in cosmetology has evolved in the last few years, enriched by knowledge acquired from wider and wider fields of research, from chemistry to biochemistry, from medicine to biophysics and biotechnology. This has allowed the pursuit of research into new formulations with intrinsic cosmetic functionality that is identified and tested in its mechanisms. This functionality expresses itself on the biological structure of the cutaneous tissue often modifying it in a significant way. These are in synthesis the needs of dermocosmetics:

Research into new active ingredients

Research into new sources of natural active ingredients (biotechnologies)

Knowledge of skin biochemical mechanisms

Knowledge of the way cosmetically functional substances work

Often, new sanitary emergencies force a rapid evolution in the research and utilization of alternative cosmetic ingredients. The potential contamination of bovine collagen with bovine spongiforme encephalopathy (BSE, the fatal mad cow disease) and its human variant, Creutzfeldt–Jakob disease, has led to numerous efforts (1) to define effective methods of eliminating any risk of BSE in material containing collagen and (2) to research new sources of natural collagen (for example, biotechnology has developed a recombinant human collagen).

## Textile-Based Biomaterials for Surgical Applications

C. C. Chu

*Cornell University, Ithaca, New York*

### I. INTRODUCTION

Textile-based biomaterials have the longest history in biomaterials. In ancient China and Egypt as far back as 2000 B.C., natural fibers like linen, silk, bark, horsehair, and dried guts were used as suture materials for wound closure. The introduction of steel wire and synthetic fibers like polypropylene, nylon, and polyester during and after World War II brought the first revolution of medical textiles and greatly expanded the chemical composition of textile-based biomaterials beyond natural sources. Owing to their precisely controlled manufacturing processes and uniform and reproducible properties, these synthetic fibrous biomaterials have received a great deal of attention from both surgeons and researchers. However, the basic textile structure has not kept up the pace of the development of materials.

The advancement of textile-based biomaterials made another major breakthrough in the early 1970s after the successful introduction of two synthetic absorbable wound closure biomaterials, i.e., Dexon<sup>®</sup> and Vicryl<sup>®</sup>. The availability of this class of absorbable aliphatic polyester-based biomaterials opened a new chapter for medical textiles, particularly in wound closure, cardiovascular implants, and body wall repair. Today, surgeons can choose among a large number of textile-based biomaterials with various chemical, physical, mechanical, textile structural, and biological properties for their specific clinical applications.

Textile-based biomaterials are different from other biomaterials largely in their physical form and anisotropic mechanical behavior. They are the only class of polymeric biomaterials that could have a wide range of three-dimensional porous structure. The four most widely used textile structures as biomaterials are woven, knitted, nonwoven, and braided. Within each of these four classes of textile structure, there are many other variations, such as weft knit vs. warp knit. These structural features and the wide range of structural possibilities and mechanical strength orientation provide the basis for their numerous applications in biomedical fields, such as (1) the requirement of tissue ingrowth for fastening devices, as with the suture ring of an artificial heart valve, (2) the requirement for integration with surrounding tissues for achieving better tissue biocompatibility, as with vascular grafts, (3) the requirement of large surface and pore area in a 3D structure, as with tissue engineering scaffolds, (4) the requirement to fill void space and provide mechanical support, as with surgical meshes for body wall repair, (5) the requirement to carry physiological force anisotropically, as with wound closure, and tendon/ligament prostheses, and (6) the requirement of mechanical strength, as with fiber and fabric reinforced composites in a variety of surgical implants such as total artificial hearts, penile implants, bone fixation devices, to name a few.

In addition to the textile-based implants, medical textiles have been used outside the human body in hospital

linens, surgical gowns and drapes, antiembolism stockings, the reinforced components of casts, etc. In this chapter, we focus on the use of medical textiles that human lives are dependent on, particularly in the areas of wound closure, cardiovascular implants, and surgical meshes for body wall repair. Among these three areas of application, the textile biomaterials for wound closure are the most important not only because they are used in virtually every surgery for the fastening of surgical implants but also because other textile-based biomaterials like those for vascular grafts and surgical meshes have largely been based upon the same fibrous polymers as suture materials.

## II. WOUND CLOSURE BIOMATERIALS

Wound closure biomaterials are generally divided into three major categories: suture materials, tissue adhesives, and staplers. Only the suture materials are in textile form, and they have received the most research and development attention. They are also the most widely used in wound closure.

A suture, by definition, is a strand of textile material, natural or synthetic, used to ligate blood vessels and to draw tissues together. It consists of a fiber with a metallic needle attached at one of the fiber ends. An ideal suture should

- Handle comfortably and naturally.
- Show minimum tissue reaction.
- Have adequate tensile strength and knot security.
- Be unfavorable for bacterial growth and easily sterilized.
- Be nonelectrolytic, noncapillary, nonallergenic, and noncarcinogenic.
- If it is absorbable, its tensile strength loss must match the healing rate of the tissues to be closed, and the degradation products must be biocompatible and be metabolized by normal body metabolic mechanisms.

Suture materials are commonly classified by absorbability in biological tissues, size, physical configuration (monofilament vs. multifilament), and type of coating materials used to facilitate handling properties. Suture materials have vast differences in chemistry, physical/mechanical properties, and biological characteristics.

The four most important properties of suture materials are physical and mechanical properties, handling properties, biological properties, and biodegradation properties. Table 1 summarizes individual properties under each of the four categories. It is important to recognize that these properties are interrelated. For example, the capillarity of a suture material under physical/mechanical characteristics is closely related to the ability of the suture to transport bacteria, which is a biological characteristic. The modulus of elasticity under physical/mechanical characteristics is frequently used to relate to pliability of sutures under handling characteristics. A brief description of each of those essential properties will be given below and they are listed in Tables 2 through 4. The wide range of data in these tables indicates the complexity of the issues and the difficulty of drawing general conclusions. Nevertheless, the information in these tables should provide readers with an overall view of the various essential properties of suture materials. Readers should be aware that the data in the tables vary depending on specific clinical and/or physical environments that suture materials are subject to and constant refining of the manufacturing processes by suture manufacturers. Readers are referred to a recently published book for its comprehensive review of these four major properties (1).

### A. Chemical Structure and Manufacturing Processes

Suture materials are generally classified into two broad categories: absorbable and nonabsorbable. Absorbable suture materials lose their entire tensile strength within two to

**Table 19.1** Four Major Categories of the Characteristics of Suture Materials

Physical/mechanical	Handling	Biocompatibility	Biodegradation
USP vs. EP	Pliability	Inflammatory reaction	Tensile breaking strength and mass loss profiles
Size (diameter)	Memory	Propensity toward wound infection, calculi formation, thrombi formation, carcinogenicity, allergy	Biocompatibility of degradation products
Mono vs. multifilament	Packing		
Tensile breaking strength and elongation	Knot tie-down		
Modulus of elasticity	Knot slippage		
Bending stiffness	Tissue drag		
Stress relaxation and creep			
Capillarity			
Swelling			
Coefficient of friction

three months; those which retain their strength longer than two to three months are nonabsorbable. This definition has recently become questionable because a new absorbable suture, Panacryl<sup>®</sup>, from Ethicon can retain some strength longer than six months. The absorbable suture materials are catgut (collagen sutures derived from sheep intestinal submucosa), reconstituted collagen, polyglycolide (PGA),

poly(glycolide-lactide) random copolymers (Vicryl<sup>®</sup> and Panacryl<sup>®</sup>), poly-*p*-dioxanone (PDS<sup>®</sup>, PDSII<sup>®</sup>), poly(glycolide-trimethylene carbonate) block copolymer (Maxon<sup>®</sup>), poly(glycolide- $\epsilon$ -caprolactone) (Monocryl<sup>®</sup>), and Glycolide-trimethylene carbonate block copolymer (Biosyn<sup>®</sup>). The nonabsorbable sutures are divided into the natural fibers (i.e., silk, cotton, linen), and manmade fibers

### 1. Catgut and Reconstituted Collagen Sutures

Multifilament twisted plain catgut was the first natural absorbable suture and was described as early as A.D. 175. The basic constituent is collagen. Collagen is a protein consisting of three polypeptides interweaved in a left-hand triple-helical structure. Each polypeptide chain has the general amino acid sequence of  $(-\text{Gly-X-Y-})_n$ , where X is frequently proline (Pro) and Y is frequently hydroxyproline (Hyp) (3). One important aspect of collagen is its essential electrical neutrality under physiological conditions due to the approximately equal number of acidic (glutamic and aspartic acids) and basic (lysine and arginine) side groups (4). Because the pKs for amino and carboxyl groups are about 10 and 4, respectively, the electrostatic interactions among the acidic and basic groups are expected to be significantly disturbed at pH either  $<4$  or  $>10$  (5). Thus any pH change would lead to a weakening of the inter- or intramolecular electrostatic interactions in collagen fibers. Such a weakening in fiber structure due to pH change is evident in the observed swelling of the fibers, which would be ultimately reflected in the observed accelerated loss of strength and mass of catgut sutures at highly acidic or alkaline conditions. The use of intermolecular cross-linking agents like formaldehyde or glutaldehyde could stabilize fiber structure against the pH-induced change.

Catgut suture is derived from the submucosa of sheep intestines or serosa of bovine intestine. The jejunum and

ileum portions of the intestine of sheep or cattle are split into two or more longitudinal ribbons, and then the mucosa muscularis and other unwanted layers are removed by chemical and mechanical treatments. The remaining portion is treated in diluted formaldehyde to block the  $-\text{OH}$  and  $-\text{NH}_2$  groups on collagen in order to increase the strength and the resistance to enzyme attack. Several ribbons are then twisted into strands, dried, machine ground, and polished by a centerless grinder to a correct and smooth size. This grinding and polishing process can produce unpredictable amounts of weak points and local tearing of fibrils. Thus fibrils could fray during use. Reproducible strength is also difficult to achieve.

The resulting untreated catgut suture is called plain catgut. If the plain catgut is further tanned in a bath of chromium trioxide, it is called chromic catgut, a variant first developed by Lister in 1840. There are two types of chromicizing processes: tru and surface chromicizings. The former is done to each ribbon before it is spun into strands, while the latter is conducted on the finished strand. This treatment changes the color of plain catgut from a yellowish tan shade to a darker shade of brown. Depending on the concentration of the chromic bath and the duration of chromicizing, mild and extra chromic catgut are available. Of course, the degrees of absorption and tissue response are also affected by the severity of the tanning process. Chromic catgut suture is generally more resistant to absorption and causes less tissue reaction than plain catgut suture. Catgut sutures are packaged in alcohol solution like ethanol or isopropanol to retain their flexibility, and the packages are sterilized by either  $\text{Co}^{60}$   $\gamma$ -irradiation or ethylene oxide.

Davis and Geck introduced a glycerin-coated chromic catgut (Softgut®) to eliminate the need for alcohol in packaging catgut and to improve handling qualities (6). The glycerin-treated chromic catgut sutures have a smoother and more uniform surface appearance than untreated catgut, and, as a result of glycerin treatment, the sutures are thicker. Davis and Geck, Ethicon, and Deknatel all have plain gut and chromic gut sutures.

Collagen can be reconstituted either from enzymatic digestion of native collagen-rich tissues or via the extraction of these tissues with salt solutions to form reconstituted collagen sutures. Reconstituted collagen, however, exhibits various polymorphic aggregated forms that are different from the native collagen. Piez reported that the formation of polymorphic aggregates of collagen depends on the environment of reconstitution (7). Reconstituted collagen sutures are prepared from the long flexor tendons of cattle. The tendon is cleaned, frozen, sliced, treated with ficin, and then swollen in dilute cyanoacetic acid. The resulting viscous gel is extruded through a spinneret into an acetone

bath for coagulation. The coagulated fibril is stretched, twisted, and dried or treated with chromic salts before twisting and drying. These sutures are similar in appearance to catgut. They are made only in fine sizes and thus are almost exclusively used in microsurgery.

## 2. Polyglycolic Acid Suture (Dexon®) and Poly(glycolide-lactide) Copolymer Suture (Vicryl®)

Polyglycolic acid (PGA) was the first synthetic absorbable suture introduced in the early 1970s (8–10). It was developed by Davis and Geck under the trade name Dexon®. PGA can be polymerized either directly or indirectly from glycolic acid. The direct polycondensation produces a polymer of  $M_n$  less than 10,000 because of the requirement of a very high degree of dehydration (99.28% and up) and the absence of monofunctional impurities (11,12). For

PGA of molecular weight higher than 10,000 it is necessary to proceed through the ring-opening polymerization of the cyclic dimers of glycolic acid. Numerous catalysts are available for this ring-opening polymerization. For biomedical applications, stannous chloride dihydrate, stannous octoate, or trialkyl aluminum are preferred. The resulting PGA polymer having  $M_w$  from 20,000 to 140,000 is suitable for fiber extrusion and suture manufacturing. Dexon suture fibers are made through the melting spinning of PGA chips. The fibers are stretched to several hundred percent of their original length at a temperature above the glass transition temperature (about 36°C), heat-set for improving dimensional stability and inhibiting shrinkage, and subsequently braided into final multifilament braid suture forms of various sizes. Before packaging, all Dexon sutures are subject to heat under vacuum to remove residual unreacted monomers or very low molecular weight volatile oligomers according to a patented procedure (13,14). De-

Figure 19.1 Continued

xon sutures are sterilized by ethylene oxide because of the well-known adverse effect of  $\gamma$ -irradiation, i.e., accelerated loss of tensile strength.

The glycolide-L-lactide random copolymer suture material (Vicryl), sometimes called polyglactin-910, is also copolymerized in the same manner as PGA. For suture use, the glycolide-L-lactide copolymers must have a high concentration of glycolide monomer (90/10 molar ratio of glycolic to L-lactic acids) for achieving proper mechanical and degradation properties. This is because, for wound closure use, synthetic absorbable sutures must have some level of crystallinity to achieve a proper tensile strength and its retention during biodegradation in vivo. Absorbable polymers of very low crystalline or totally amorphous structure would biodegrade too fast to be useful as wound closure biomaterials. Figure 2 illustrates such a relationship between the rate of degradation in vivo and the composition of glycolide to L-lactide (15). Glycolide-lactide copolymers with L-lactide composition between 25 and 75% are totally amorphous and hence would degrade the fastest. For this reason, a 90:10 molar ratio of glycolide to L-lactide has been used as the optimal comonomer ratio for Vicryl suture use. The very recent introduction of Panacryl absorbable suture, however, breaks away from this high glycolide-to-L-lactide composition ratio approach. Panacryl has a glycolide-to-L-lactide ratio almost opposite to

**Figure 19.2** The effect of glycolide-to-lactide composition on the in vivo degradation rate of polyglactin implanted under the dorsal skin of rat. The degradation rate was expressed in terms of the time for 50% weight loss of the implant. (From P. A. Miller, J. M. Brady, and D. E. Cutright. *J. Biomed. Mater. Res.* 11:719 (1977). With permission.)

that of the Vicryl suture. Please refer to Sec. II.A.6 Panacryl for details.

If DL-instead of L-lactide is used as the comonomer, however, the U-shape relationship between the level of crystallinity and the glycolide composition disappears. This is because polylactide from 100% DL-lactide composition is totally amorphous.

Multifilament braided Vicryl sutures are coated with 2–10% of a 50:50 mixture of an amorphous polyglactin 370 (a 65/35 mole ratio of lactide–glycolide copolymer) and calcium stearate. Vicryl sutures are sterilized by ethylene oxide like other synthetic absorbable sutures.

### 3. Poly-*p*-dioxanone Suture (PDS® & PDS II®)

Unlike the multifilament absorbable sutures (Dexon and Vicryl), PDS and PDSII sutures are the first commercially available monofilament absorbable sutures that derive from the glycolide family. They are poly(ester-ethers). These synthetic degradable monofilament sutures are polymerized from *p*-dioxanone monomers. The monomer 1,4-dioxanone-2,5 dione or *p*-dioxanone is obtained from the reaction of chloroacetic acid with metallic sodium dissolved in a large excess of ethylene glycol (16). The resulting *p*-dioxanone is purified by multiple redistillation and crystallization. Fiber-grade high-molecular-weight PDS polymer is made from the ring-opening polymerization of highly purified *p*-dioxanone (>99%) in the presence of organometallic catalysts such as  $\text{Et}_2\text{Zn}$  or zirconium acetylacetonate (17). The resulting polymer has an inherent viscosity of 0.70 (0.1% polymer solution in tetrachloroethane at 25°C) and a degree of crystallinity of 37%. Poly-*p*-dioxanone polymer has  $T_g = -16$  to  $-10^\circ\text{C}$  and  $T_m = 110$ – $115^\circ\text{C}$ . Monofilament PDS sutures are made from the melt-spinning of the dried polymer chips through a spinneret into monofilaments of any desired suture diameter (16). The extruded fibers are then drawn about five times at  $T > 43^\circ\text{C}$  and heat set to orient the molecules for better physical and mechanical properties. The drug/cosmetic violet dye #2 is added to make violet-colored PDS sutures.

PDS and PDSII are chemically identical, but the PDSII suture differs from the PDS in fiber morphology resulting from different fiber spinning conditions. PDSII sutures are made by subjecting the melt-spun PDS fibers to a short period of annealing at a temperature above  $T_m$  of PDS (about  $125^\circ\text{C}$ ) (18). This additional heated drawing treatment, not used in the PDS suture, partially melts the surface layer of PDS fibers and subsequently modifies the near-surface crystalline structure of the PDS monofilament suture. Thus a distinctive skin-core morphology that PDS sutures do not have is observed in PDSII sutures (18). The core of the PDSII suture has a more highly ordered and

larger spherulitic crystal structure than the surrounding annular area characterized by smaller crystals, while the untreated PDS suture shows a relatively even crystalline structure throughout its cross section. In general, PDSII sutures have a lower modulus of elasticity with improved flexibility and handling characteristics. Recently, there are a few varieties of PDS-related copolymers reported in the literature that may have use as wound closure biomaterials (19–22). A copolymer of PDS and PGA (20%) has an absorption profile similar to Dexon and Vicryl sutures, but it has compliance similar to PDS. A copolymer of PDS and PLLA (15%) results in a more compliant suture than homopolymer PDS but with similar absorption profiles as PDS.

PDS sutures are sterilized by ethylene oxide in the same way as other synthetic absorbable sutures, and no coating is used. Based on the PDS chemical structure, i.e., ether and ester linkages separated by a methylene group ( $\text{CH}_2$ ), PDS is expected to be and has been found to be sensitive to oxidative, photo-oxidative, and  $\gamma$ -irradiation degradation.

#### 4. Poly(glycolide-trimethylene carbonate) Copolymer Suture (Maxon<sup>®</sup>)

Another commercially available monofilament absorbable suture, Maxon, is made from block copolymer of glycolide and 1,3-dioxan-2-one (trimethylene carbonate or GTMC). It consists of 32.5% by weight (or 36 mol%) of trimethylene carbonate (23,24). Maxon is a poly(ester-carbonate). The polymerization process of Maxon suture is divided into two stages. The first stage is the formation of the middle block, which is a random copolymer of glycolide and 1,3-dioxan-2-one (trimethylene carbonate). Diethylene glycol is used as an initiator, and stannous chloride dihydrate ( $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ ) serves as the catalyst. The polymerization is conducted at about 180°C. The weight ratio of glycolide to trimethylene carbonate in the middle block is 15:85. After the synthesis of the middle block, the temperature of the reactive bath is raised to about 220°C to prevent the crystallization of the copolymer, and additional glycolide monomers as the end blocks are added into the reaction bath to form the final triblock copolymer. The undyed Maxon has a natural clear appearance, while green Maxon is dyed by green DG#6 with <0.3% by weight. The maxon suture is sterilized by ethylene oxide, and no coating is used.

#### 5. Glycolide-Caprolactone Copolymer Suture (Monocryl<sup>®</sup>)

Monocryl is a monofilament absorbable copolymer suture of glycolide and  $\epsilon$ -caprolactone. The Monocryl suture is a segmented block copolymer consisting of both soft and

hard segments. The purpose of having soft segments in the copolymer is to provide good handling properties like pliability, while the hard segments are used to provide adequate strength. Monocryl is made in a two-stage polymerization process (25). In the first stage, soft segments of prepolymer of glycolide and  $\epsilon$ -caprolactone are made. This soft-segmented prepolymer is further polymerized with glycolides to provide hard segments of polyglycolide. Monocryl has a composition of 75% glycolide and 25%  $\epsilon$ -caprolactone.

An aspect of Monocryl monofilament suture is its pliability as claimed by Ethicon (25). The force required to bend a 2/0 suture is only about  $2.8 \times 10^4 \text{ lb-in}^2$  (193 MPa) for Monocryl, while the same size PDSII and Maxon monofilament sutures require about  $3.9$  and  $11.6 \times 10^4 \text{ lb-in}^2$  (269 and 800 MPa) force, respectively. This inherent pliability of Monocryl is due to its low glass transition temperature resulting from the  $\epsilon$ -caprolactone comonomer unit. Its  $T_g$  is expected to be between 15 and  $-36^\circ\text{C}$ . Unlike Maxon and PDSII, the Monocryl suture appears to have less out-of-package memory, which improves its handling characteristics.

#### 6. Poly (glycolide-L-lactide) Copolymer Suture (Panacryl<sup>®</sup>)

The latest addition to the arsenal of synthetic absorbable sutures is Panacryl, a glycolide-L-lactide copolymer absorbable suture from Ethicon, Inc. It is the first and only braided synthetic absorbable suture that provides long-term mechanical strength support over six months. Panacryl is made from the same copolymer components as the Vicryl suture, i.e., glycolide and L-lactide; but the composition ratio of these two components was almost exactly opposed to that of Vicryl, i.e., a 10/90 molar ratio of glycolide to L-lactide. Since poly-L-lactide biodegrades at a significantly longer time than polyglycolide, Panacryl is expected to retain its strength and mass much longer than Vicryl. Ethicon claimed that Panacryl can retain about 80 and 60% of its original tensile strength at the end of 3 and 6 months in vivo, respectively. Based on the tensile strength loss profile, the Panacryl suture appears to bridge the gap between traditional absorbable and nonabsorbable sutures. The coating of Panacryl is  $\epsilon$ -caprolactone/glycolide copolymer.

Panacryl has a unique braided construction that allows for excellent handling and knot tying and provides knot security at four to five throws. Because it is coated, it passes smoothly through tissue and allows for 100% successful knot slides. The undyed Panacryl has a white color that may provide good visibility in the presence of blood and tissue.

The Panacryl absorbable suture is suggested for use in general soft tissue approximation and/or ligation, and tissues that heal slowly like tendons and ligaments, and for reattachment to bone, or patients with compromised wound healing capability due to diabetes, malignancy, deficiency in the immune system, obesity, and malnutrition. Due to its pending patents, there is virtually no published technical information about the Panacryl suture at this time.

#### 7. Glycolide-Trimethylene Carbonate Triblock Copolymer Suture (Biosyn®)

Biosyn is a triblock copolymer, Glycomer 631 from US Surgical (26). This block copolymer consists of glycolide (60%), dioxanone (14%), and trimethylene carbonate (26%). The center block is a random copolymer of 1,3 dioxanone-2-one (65% by weight) and 1,4 dioxane-2-one (35% by weight). The two ends of this center block are capped by a block copolymer consisting mainly of glycolide (>50%) that could be copolymerized with lactide, trimethylene carbonate, *p*-dioxanone, or  $\epsilon$ -caprolactone.

The purpose of using triblock polymer chemistry to design Biosyn is to make synthetic absorbable monofilament sutures having good handling properties like flexibility without compromising other mechanical properties, like knot strength and security and biodegradation properties. As we shall describe later (B.S, Handling Properties), sutures must be bent for packaging. Due to the viscoelastic nature of synthetic polymers, the bent sutures during storage would introduce “packaging memory” to the sutures. Therefore, before use, the packaged suture material must be straightened out from its bent position upon its removal from the package. Such an ability to remove the kinks of a suture after a long period of shelf life is a very important handling characteristic that surgeons like to have during wound closure.

Biosyn has the next lowest modulus of elasticity ( $145 \times 10^3$  psi) among all existing synthetic absorbable suture materials, and its strain energy at both 5 and 10% strain (0.84 and 2.76 kg-mm, respectively) is about half of the corresponding size Maxon sutures (26). The rate of tensile strength loss of Biosyn sutures is similar to that of Vicryl suture in vitro with about 8% of its original tensile breaking strength remaining at the end of 28 days.

#### 8. Silk Suture

Silk is one of the three major fibrous proteins (the others are wool and collagen). Silk fiber is semicrystalline and consists of two major constituents, a fiber protein called fibroin and the gummy substance called sericin that holds the fibers together. As it is spun by the silkworm, silk fiber consists of two triangular filaments stuck together with ser-

icin. The most significant feature of the amino acid composition of silk fibroins is the high concentration of glycine, alanine, and serine (27). Together, these three small amino acids take up about 80 to 85% of the total amino acids in *Bombyx mori* and *Anaphe pernyi*. Such a high concentration of these three amino acids having small and simple side groups in silk fibroins permits the arrangement of polypeptide molecules into an orderly and crystalline manner and is responsible for the desirable mechanical, physical, and chemical properties of silk fibers. The amino acids with bulky side groups like tyrosine consist of a smaller portion of silk fibroins and cannot be accommodated within the three-dimensional, ordered crystalline structure. Thus disordered amorphous regions coexist with the crystalline ones. Silk fibers have about a 60% level of crystallinity (28,29). This arrangement of crystalline to amorphous domains in fibroin bears an important relationship to properties, such as moisture absorption and biodegradation, that occur mainly in the amorphous regions of silk. Cross-sectional views of silk fiber shows somewhat irregular triangular shape.

Sericin is the gummy protein that holds the fibroin filaments together in cocoon silk and consists of about 25% of the cocoon by weight. The hydrophilic nature of sericin derives from the high concentration of amino acids with side polar groups like —OH and —COOH. In most silk sutures, except Virgin Silk for microsurgery, sericin is removed.

The most common form of silk suture is produced by the silkworm *Bombyx mori*. The process of making silk sutures is similar to that for traditional silks. It involves the collection of the raw silk fibers from the cocoon and the removal of the natural waxes and sericin (called degumming). The cleaned silk fibers are then either twisted or braided to form the suture strands. Silk has a relatively high standard moisture regain of 11%. Various types of surface treatments are used to render it noncapillary, serum proof, incapable of the ingrowth of tissues, or all of these. Wax or silicone has been used as the coating material. Tissue ingrowth is prevented by encasing the twisted silk fibers in a nonabsorbable coating of tanned gelatin or other protein substances. The trade name of this specially treated silk suture is Dermal® from Ethicon. Other trademarks of silk sutures are braided Surgical silk and twisted Virgin Silk from Ethicon, and braided Protein Silk (Davis and Geck). With the very fine size silk sutures for microsurgery and ophthalmology, the sericin component of the Virgin Silk is not removed during manufacturing processing. Silk sutures are sterilized by either  $\text{Co}^{60}$   $\gamma$ -irradiation or ethylene oxide.

The mechanical properties of silk closely correlate with the fraction of bulky side groups present and thus with the

crystalline-amorphous ratio as well as the conformational arrangement of chain segments in the amorphous domains. Earland and Robins (30) and Zuber (31) reported that peptide chain segments located in the amorphous domains are interconnected among themselves and to the crystallites via disulfide and ester linkages and hydrogen and ionic bonds where they are appropriate. Silk sutures have a relatively very high modulus of elasticity. This high elastic modulus is attributed to the strong inter- and intramolecular interactions among peptide chain segments in the amorphous domains as well as interactions between these randomly oriented amorphous and highly ordered crystalline peptide chain segments through various types of H-bonds, ionic bonds, and ester and disulfide linkages. If silk sutures are stretched to beyond their yield point, these inter- or intramolecular bonds are broken first, and randomly oriented amorphous peptide chain segments are thus allowed to be extended. At this phase of the stress-strain curve, a characteristic low modulus yield plateau is evident. The degree of yield plateau depends on the strength and amount of inter- and intramolecular force among the amorphous peptide chain segments and between the amorphous and crystalline peptide chain segments. A weaker inter- and intramolecular force would result in a pronounced yield plateau.

The macromolecular structure of silk fibers is also responsible for their well-known loss of tensile strength *in vivo*. Any loss of fiber tensile strength could be attributed to either the scission of primary bonds in the backbone macromolecules or/and the breakage of secondary bonds such as H-bonds due to a reactive species like water. The moisture regain of a typical silk fiber is about 9.9% due to the high concentration of polar side groups in amino acid residues. Water molecules absorbed by silk fibers would reside in the amorphous domains and compete with the amino acids in the amorphous chain segments for inter- and intramolecular interaction (27). This competition by water molecules would lead to a more open amorphous structure by the replacement of relatively strong inter- and intramolecular interaction in the amorphous domains with water. As a result, a lower tensile strength is observed. The observed *in vivo* strength loss of silk sutures might be a combination of the scissions of both primary and secondary bonds; however, the breakage of secondary bonds within silk fibers in water probably plays a more important role than the scission of primary bonds. This is because the high crystallinity level found in most silk fibers should retard the diffusion of relatively large proteolytic enzymes (32) and hence render silk fibers resistant to proteolytic enzymatic hydrolysis.

Because of the undesirable *in vivo* loss of tensile strength and the somewhat higher tissue reactions and in-

growth to silk sutures, Shalaby et al. reported the impregnation of silk with hydrophobic thermoplastic elastomers to improve the performance of silk sutures (33). The rationale behind the approach is to provide an inert barrier between silk sutures and the surrounding tissue so that tissue reactions and cellular invasion could be minimized. This modified silk suture was prepared by treating a multifilament silk suture with a solution of a highly flexible hydrophobic and deformable polymer in a solvent and heating the moving suture to obtain a continuous impregnation of the silk with the elastomer. This elastomer with a molecular weight >10,000 daltons is a segmented polyether-ester and consists of soft segments, poly(polyxytetramethylene) terephthalate, and crystallizable hard segments, polybutylene terephthalate. The elastomer has 5 to 50% by weight of the composite silk suture. *In vivo* evaluation of this composite silk suture in Sprague Dawley rats indicated that the impregnation of silk sutures indeed not only provided better tensile breaking strength retention over a period of 56 days but also significantly reduced tissue reactions and cellular invasion.

## 9. Polyester-Based Sutures

There are three types of nonabsorbable polyester-based sutures: poly(ethylene terephthalate) (PET), poly(butylene terephthalate) (PBT), and the copolymer of poly(tetramethylene ether) terephthalate and poly(tetramethylene terephthalate) (polybutester). PET based polyester sutures are braided Dacron<sup>®</sup>, TI-CRON<sup>®</sup>, from Davis and Geck, Ethibond<sup>®</sup>, Mersilene<sup>®</sup>, Ethiflex<sup>®</sup>, from Ethicon, Surgidac<sup>®</sup>, from US Surgical, Polydek<sup>®</sup> and Tevdek<sup>®</sup> from Deknatel, and monofilament Mirafil<sup>®</sup>, from B. Braun. PBT-based polyester sutures are monofilament<sup>®</sup> from B. Braun. The monofilament copolymeric polybutester suture, Novafil<sup>®</sup> from Davis and Geck, is the most recent polyester-based suture.

PET sutures are made of polyethylene terephthalate, which in turn is polymerized from ethylene glycol and terephthalic acid (or dimethyl terephthalate in the case of Terylene<sup>®</sup>). Polymerization is conducted in a vacuum at a high temperature. The first stage involves the formation of low-molecular-weight oligomers through ester interchange. The oligomers are then polycondensed further to build up high-molecular-weight polyester. The second stage is carried out at about 270°C and reduced pressure (0.5 torr). The resulting polyester chips are melt-spun into round cross-sectional shaped filaments. The filaments are then hot-stretched (above  $T_g$  69°C) to about five times their original length. Further crystallization occurs during the hot drawing. Depending on the degree of drawing, polyester yarns of either normal strength or high tenacity can be

obtained. The molecular weight of PET that is capable of making fibers is of the order of 20,000.

Due to the benzene ring, PET forms a single rigid structure. Consequently, the PET chain is rigid and less flexible than nylon and polyethylene. This accounts for the slow rate of crystallization and high melting point (265°C). The melt-spun PET filaments are thus largely amorphous before drawing. The maximum rate of crystallization of amorphous PET occurs at 190°C. The molecular structure of PET is also winding-speed-dependent during the melt-spinning process. PET yarns wound at a speed <3,000 meters/minute has a low level of crystallinity, while at a higher speed, an increasingly higher level of crystalline structure develops but reaches a plateau at 7,000 meters/min (34). A range of crystal density from 1.455 to 1.515 g/cm<sup>3</sup> has been reported, but the amorphous density has a narrower range from 1.335 to 1.336 g/cm<sup>3</sup>.

Novafil<sup>®</sup> is a relatively new monofilament copolyester suture (Polybutester) and is made from a block copolymer of poly(butylene terephthalate) as the hard segment and poly(tetramethylene ether) glycol terephthalate as the soft segment (35). Novafil suture fibers made from polybutester copolymer are drawn in two stages from 6× to 8× at temperature from 120 to 165°C to provide desirable tensile strength, knot strength, security, flexibility, fatigue life, and low tissue drag. The number average molecular weight ranges from 25,000 to 30,000. The ratio of the hard and soft segments can be adjusted to achieve the desirable handling properties. Novafil suture has the ratio of hard to soft segments of 84/16% (36). Titanium dioxide, carbon black, or iron oxide could be used to color the suture. Novafil sutures can be sterilized by ethylene oxide or  $\gamma$ -irradiation, but they should not be sterilized by heat because the elastomeric property of the sutures could be adversely affected.

Because of its elastomeric character, Novafil has a distinctly different stress-strain behavior than PET based polyester sutures and other synthetic monofilament sutures like nylon and polypropylene. The stress-strain curve of Novafil suture exhibits a biphasic pattern, while both PET-based polyester sutures and polypropylene and nylon monofilament sutures show a monophasic pattern (36,37). Novafil suture elongates to about 10% easily under tension; a steep rise in force is required for further elongation. This mechanical behavior may be advantageous in management of wound edema because the suture loop easily stretches instead of cutting through the edematous tissue. After the resolution of the edema, a Novafil suture loop is expected to return to its original diameter more easily than those sutures exhibiting monophasic stress-strain behavior. As a result of this elastomeric character, Novafil is expected to be less stiff than other monofilament sutures, as is evident in the reported stiffness coefficient of Novafil

(14.81  $\pm$  1.14), which is about two folds less than equivalent size nylon (Dermalon<sup>®</sup>) and polypropylene (Surgilene<sup>®</sup>) based monofilament sutures. The elastomeric characteristic of polybutester block copolymer also renders Novafil less susceptible to package memory than polypropylene and nylon based monofilament sutures.

Although aromatic polyester based sutures are not considered to be degradable and there is no reported clinical case of failed polyester sutures due to the hydrolytic scission of their ester linkages, the presence of these ester linkages inherently provides the opportunity for their eventual hydrolytic scissions. The relatively hydrophobic nature of the polyester sutures and their high glass transition temperatures (relative to body temperature) are responsible for the observed in vivo stability of this class of suture materials. Under alkaline conditions, the hydrolytic degradation of polyester sutures is a surface phenomenon with very little change in molecular weight, and the rate of hydrolysis is inversely proportional to the diameter of the fibers. This is because highly ionized reagents like NaOH cannot readily diffuse into the relatively nonpolar polyesters. Because fiber diameter would decrease with alkaline hydrolysis, tensile strength (force/cross-sectional area) of the fiber would not change. However, the rate of alkaline hydrolysis would increase significantly if the alkaline agent could readily diffuse into the fiber by the addition of chemicals like quaternary ammonium compounds to serve as carriers for —OH anions. Acid catalyzed hydrolysis of polyester fibers is usually significantly slower than alkaline catalyzed hydrolysis. Recent studies have also suggested that Novafil suture may degrade if it is used in areas exposed to sunlight, such as in cataract surgery. Hence the long-term stability of Novafil sutures in ophthalmologic surgery has been reported to be a concern.

## 10. Polyamide Based Sutures

The most successful aliphatic polyamide that polymer scientists have synthesized is nylon. Nylon is polymerized either from polycondensation of a dicarboxylic acid and a diamine, or through a ring-opening polymerization of appropriate lactams. Although there are numerous types of nylon, such as nylon 3, 4, 5, 6, 7, 8, 9, 11, 12, 66, and 610, only 66 and 6 are used to make suture materials. The former is more popular in the United States, while the latter is used in Europe. The tradenames of nylon sutures are braided Surgilon<sup>®</sup> and monofilament Dermalon<sup>®</sup> from Davis and Geck, braided Nurolon<sup>®</sup> and monofilament Ethilon<sup>®</sup> from Ethicon, monofilament Monosof<sup>®</sup> and braided Bralon<sup>®</sup> from US Surgical, and sheath-core structure Supramid<sup>®</sup> from S. Jackson. Surgilon nylon suture is coated with silicone, while Nurolon nylon suture is coated with

wax. Bralon is coated with a proprietary material. All nylon sutures are sterilized with  $\text{Co}^{60}$   $\gamma$ -irradiation.

Nylon 66 is made from adipic acid and hexamethylene diamine. These two chemicals, dissolved separately in methanol, are mixed to form nylon salt as precipitate. Equal moles of adipic acid and diamine are important for achieving high molecular-weight nylon 66. Nylon salt is then melted under an inert gas atmosphere to prevent discoloration. Acetic acid is added as a stabilizer during polycondensation. No catalyst is needed for polymerization; suitable conditions are four hours at a temperature of  $280^\circ\text{C}$ . The molten polymer is extruded in ribbon form, which is quenched with cold water in order to reduce the crystal size, and then cut into chips. The extent of polymerization is determined by the residual moisture content. A vacuum should be applied if high-molecular-weight nylon is desirable (38). Nylon 66 can also be made by interfacial polycondensation (38). The reaction takes place at the interface between a diamine water solution and a dicarboxylic acid chloride in a water-insoluble solvent. The reaction is rapid, and a precise amount of the reactants is unnecessary. This method results in high-molecular-weight nylon 66. Nylon 66 of molecular weight 12,000 to 20,000 is suitable for melt-spinning into fibers.

Nylon 6 is made from caprolactam. Two alternative methods are used (39). The first method involves the liquefying and heating of caprolactam under high pressure. The resulting nylon 6 polymer chain consists of an average of 200 repeating units. The second method needs about 10% water and is carried out at a high temperature with a controlled release of steam. There are three reactions in the second method of polymerization: addition, condensation, and hydrolysis (38).

The resulting nylon 66 or 6 chips are then melt-spun into a cooling chamber in which nylon filaments form. In the case of nylon 66, the filaments are run through a steam chamber to wet them before they are wound. This treatment eliminates the undesirable extension of the yarns after they reach equilibrium by absorbing moisture from the air. The wound yarn is further cold-drawn by stretching about 400% in order to acquire better strength. During this cold-drawing process, vegetable oil is applied to the yarn as a lubricant and is washed off afterwards.

In the case of nylon 6, the same process of melt-spinning as for nylon 66 is used except that the steam chamber is not suitable. The relatively high residual concentration of monomers in nylon 6 would make the filaments sticky and adhere to one another if steamed. The filaments are normally drawn to 350–400%. Higher drawing can be achieved if a stronger fiber is needed. It is well recognized in fiber technology that by increasing the draw ratio (the

ratio of the speed of output and input feed rollers), the tensile strength and elastic modulus increase, while the elongation at break decreases. If the molecular weight of nylon 6 is between 20,000 and 25,000, hot-drawing is used.

Unlike PET, both nylon fibers are fairly crystalline when they are spun. The crystal structures of nylon 66 and 6 fall into  $\alpha$ ,  $\beta$ , and  $\gamma$  phases. Almost all the commercially important nylons exist in either the  $\alpha$  or the  $\beta$  phase.

Because of the inherent susceptibility of the amide linkage to hydrolytic degradation, nylon sutures have been reported to lose strength after implantation. Thus nylon sutures should not be used for fastening implants.

### 11. Polypropylene Sutures

Polypropylene (PP) suture materials are made from isotactic polypropylene, which is polymerized from propylene with a Ziegler–Natta catalyst (40). The Z–N catalyst consists of a transition metal halide (e.g.,  $\text{TiCl}_3$ ) with a reducing agent (e.g.,  $\text{AlR}_3$ ). Ziegler–Natta catalyst systems are quite complex, and the exact structure of the catalysts cannot be determined precisely (41,42). Many factors could influence the activity of the catalyst, such as the crystal structure, the molar ratio of the components, the aging of the complex, impurities, and the temperature of preparation (42a). In addition to isotactic polypropylene suture, a syndiotactic PP suture has recently been reported by Liu et al. (42b).

PP usually has a wide range of molecular weight distribution (MWD) ranging from 2 to 12 polydispersity ( $M_w/M_n$ ). Recently, narrower MWD PP has become available and is called controlled rheology (CR) PP (43). The melting and glass transition temperatures of PP are about  $165^\circ\text{C}$  and  $-15^\circ\text{C}$ , respectively.

PP sutures made from isotactic polypropylene have a molecular weight of about 80,000 or a melt flow rate between 3 and 35. The crystallinity is 50% before melt-spinning and decreases to 33% after spinning and before drawing, and increases to 47% after drawing. Annealing increases the crystallinity further to 68% (43). The currently available monofilament polypropylene sutures are Surgilene<sup>®</sup> from Davis and Geck, Prolene<sup>®</sup> from Ethicon, and Surgipro<sup>®</sup> from US Surgical. PP sutures, in general, do not have any coating material applied, and they are sterilized by ethylene oxide because of their sensitivity toward  $\text{Co}^{60}$   $\gamma$ -irradiation sterilization.

PP fibers are inherently unstable to both heat and light, but they are totally hydrolytically resistant due to the lack of ester and amide linkages. The heat and light instability arise from the high temperature during fiber spinning, which frequently leads to the formation of oxygen-con-

taining functional groups like  $>C=O$  in the molecule. This PP fiber instability may be the cause of the observed clinical failure of PP sutures in ophthalmology.

## 12. Polytetrafluoroethylene Sutures (Gore-Tex<sup>®</sup>)

A nonabsorbable monofilament suture, Gore-Tex<sup>®</sup>, is made from a highly crystalline linear polytetrafluoroethylene (PTFE). This fully fluorinated thermoplastic polyolefin is an addition polymer and is polymerized through a free radical polymerization route in aqueous dispersion under pressure with persulfates and hydrogen peroxide as initiators. PTFE has the highest enthalpy and entropy of polymerization ( $-156$  KJ/mol and  $-112$  J/mol-deg, respectively) in vinyl polymerization (44). Its molecular weight can be as high as  $5 \times 10^6$ .

Due to the extremely stable C—F bond, PTFE has a very high melting temperature,  $327^\circ\text{C}$ , which makes the fabrication of PTFE very difficult. This difficulty is further compounded by a high viscosity above  $T_m$  due to restricted bond rotation and high molecular weight. Thus PTFE is usually fabricated by a combination of heat and pressure, namely sintering, which is usually applied to metal and ceramics. PTFE powders are preformed at high pressure (2,000–10,000 psi, 14–70 MPa) at room temperature and then sintered above their melting point ( $>365^\circ\text{C}$ ) for a brief period. The resulting products can subsequently be machined to the desirable shape and size. Microfibrinous PTFE is made from wet-spinning of a mixture of an aqueous PTFE dispersion and cellulose xanthate to provide fibers that are subsequently sintered at  $385^\circ\text{C}$  by contact with a metal roll to develop fibers of low but useful strength.

The monofilament suture made from PTFE (Gore-Tex<sup>®</sup>), however, is different from molded PTFE in morphological structure. The Gore-Tex suture is an expanded PTFE characterized by two distinctive components: nodes held together by fine fibrils 5–10  $\mu\text{m}$  in diameter and  $>17$   $\mu\text{m}$  long. The most unique property of Gore-Tex is its microporous structure with up to about 9 billion pores/in<sup>2</sup>. Hence the Gore-Tex suture has  $>50\%$  air by volume. The pore size varies but is big enough for ingrowth of fibroblasts and leukocytes similar to those observed with Gore-Tex vascular grafts. The size of the Gore-Tex suture does not follow USP classification and is designated by CV (i.e., cardiovascular). Its suture diameter is measured in its pre-expanded dimension, and the actual diameter of a Gore-Tex suture is obviously much larger because it contains  $>50\%$  air by volume. For example, the CV-4 Gore-Tex suture has a similar diameter (0.35 mm) to a 2-0 Prolene (0.303 mm).

Because of its large pore volume, the Gore-Tex suture has a unique property that other sutures do not have, namely a needle-to-suture diameter ratio of one (45). Other commercial sutures have a needle-to-thread ratio  $>1.0$ , and they frequently range from 2.0 to 3.0. As a result of this high needle-to-suture diameter ratio, the thread portion of a suture cannot fill up the hole generated by a needle in wound closure. Bleeding through this unfilled space at needle holes has been a common problem associated with sutures other than Gore-Tex. Miller et al. reported that a 5-0 Gore-Tex suture had about 1/3 of the needle hole blood leakage of the same size Prolene in the abdominal aorta of mongrel dogs (45). Thus Miller et al. recommended that the Gore-Tex suture should be a better choice for wound closure in multiple arterial anastomoses like complicated extra-anatomic bypasses, fully heparinized patients, and aortic surgery, where larger needle holes are made. The unique porous structure of the Gore-Tex suture also results in very low bending stiffness (46,47). Dang et al. reported that the CV-4 Gore-Tex suture has a bending stiffness coefficient of 1.21, while a 2-0 size Prolene is more than 100 times stiffer with bending stiffness coefficient of 180.07 (46). Similar findings were reported by Chu and Kizil (47)

## 13. Poly (Hexafluoropropylene-VDF) Suture (Pronova<sup>®</sup>)

Pronova<sup>®</sup> is the latest new synthetic nonabsorbable monofilament suture from Ethicon and is a copolymer from polyvinylidene fluoride homopolymer (PVDF) and polyvinylidene fluoride hexafluoropropylene copolymer over a wide range of composition ratio. It appears that Pronova is similar to the PVDF monofilament suture developed by Peters Laboratoire Pharmaceutique (Bobigny, France). PVDF was designed to provide a wound closure biomaterial in vascular surgery that would have very good anti-thrombogenicity, with the same satisfactory handling characteristics as polypropylene sutures, and yet be as durable as polyester sutures. It was the developer's hope to replace polypropylene with PVDF in vascular surgery for some of its unique properties not available with isotactic polypropylene sutures. Combining PVDF with polypropylene into one single entity like Pronova should combine the merits of PVDF and polypropylene and achieve a better nonabsorbable monofilament suture. Ethicon claims that Pronova has excellent handling properties like pliability and low package memory with very good tensile breaking strength and resistance to fraying and damage done by surgical instrument. One of the properties of Pronova is that its chemical composition of PVDF to polyvinylidene fluoride hexafluoropropylene copolymer depends on the suture size.

Pronova sutures of smaller size (4/0 to 10/0) have the polymer composition ratio of 80/20 for the purpose of retaining adequate tensile strength without the expense of their handling characteristics, since finer sutures are inherently weaker than larger ones. Larger Pronova sutures (2/0 to 2 size), however, have a 50/50 composition ratio of the two constituent polymers to achieve better handling properties without the expense of their tensile strength, because larger monofilament sutures are well known to be more rigid and less pliable than finer ones. Pronova sutures are designed mainly for cardiovascular, ophthalmic, and neurological surgeries.

Although the detailed technical information of Pronova is very limited at this time, an examination of PVDF sutures should shine some light on this relatively new nonabsorbable monofilament Pronova suture.

The chemical, physical, mechanical, morphological, and biocompatible properties of 5/0 and 6/0 PVDF sutures (Teflene<sup>®</sup>) were recently reported by Urban et al. (48). PVDF and polypropylene sutures were found to be similar in tensile breaking force and biocompatibility in blood vessels. The three properties that most differentiate PVDF from polypropylene sutures are creep behavior, the extent of iatrogenic trauma by a needle holder, and sterilization by  $\gamma$ -irradiation. Over a period of  $10^3$  minutes there was about a 10% dimensional increase in PVDF sutures, while polypropylene (Prolene) sutures had more than a 50% dimensional increase. Thus it appears that PVDF sutures have a better resistance to creep than polypropylene sutures, and hence they are expected to be more dimensionally stable. However, PVDF exhibited more dimensional change than polypropylene during the initial 30 min of creep testing.

PVDF sutures appeared to sustain the damage from needle holders better than polypropylene sutures, at least from the surface morphological point of view. PVDF sutures showed some flattening with a roughened surface, but they did not have the longitudinal cracks and fibrillar formation found with polypropylene sutures. This morphological difference between PVDF and polypropylene sutures, however, was not reflected to a marked degree in their tensile breaking force values. In other words, the iatrogenic trauma done by needle holders on polypropylene and PVDF sutures did not reduce their tensile breaking force significantly.

PVDF and polypropylene sutures have very similar melting temperatures (165–175°C), but distinctively different levels of crystallinity. PVDF has a level of crystallinity  $59 \pm 7\%$ , while polypropylene has  $43 \pm 3\%$ . Because of the lack of an alkyl group, PVDF can be sterilized by the conventional  $\gamma$ -irradiation method, while polypropylene requires the use ethylene oxide gas. Thus

PVDF can take advantage of the efficiency and convenience of  $\gamma$ -irradiation sterilization. Like the polypropylene suture, the PVDF suture should not have any  $O_2$  in its chemical structure. However the surfaces of PVDF and polypropylene sutures showed oxidation products as confirmed by electron spectroscopy for chemical analysis. The amounts of  $O_2$  on the surface of PVDF and polypropylene sutures were 7.4 and 7.9%, respectively. However, bulk FTIR data failed to reveal such oxidation products. This suggests that oxidation of PVDF and polypropylene is introduced during melt-spinning of fibers and is mainly restricted to the surface of suture fibers.

PVDF sutures showed a similar histological response as a polypropylene suture. At the end of 6 months' implantation in adult mongrel dogs, PVDF sutures were encapsulated by a thin layer of newly formed connective tissue with the absence of inflammatory cells. The explanted and cleaned PVDF sutures revealed no visible surface damage or degradation.

#### 14. Stainless Steel Sutures

The use of iron base metallic sutures started as early as 1666. The most commonly used metallic suture now is stainless steel based. Stainless steel is an alloy of mainly iron, chromium, and nickel, but due to the wide range of possible alloy compositions, the incorporation of trace elements, and fabrications, there are many different grades of stainless steel. Table 6 lists some examples of stainless steels and their structure (49). The three-digit classification in the table is based upon the main composition in the alloy stipulated by the American Iron and Steel Institute (AISI). Series 200 has mainly chromium, nickel, and manganese, Series 300 has mainly chromium and nickel, Series 400 has mainly chromium, and Series 500 has low chromium.

Only 304, 316, and 316L wrought stainless steels are used as sutures. Series 300 stainless steel has high chromium and nickel contents with an austenitic structure and is characterized by high corrosion resistance and ductility. The L in 316L stainless steel indicates extra low carbon content, since a high level of C can result, under certain circumstances, in the precipitation of chromium as chromium carbides ( $Cr_{23}C_6$ ), which depletes the chromium content of the matrix, making the Cr depleted areas more susceptible to corrosion. Thus the use of extra low C would reduce this undesirable precipitation effect. Presently, extra low C stainless steel is made by the electroslag-remelted (ESR) or the vacuum-remelted (VM) processes. Different metallurgical processing conditions and finishing have a large effect on the mechanical properties and degree of corrosion resistance of stainless steel.

Stainless steel sutures are fabricated from cold-worked

mill products to enhance their mechanical properties so that the resulting wire would not fail during bending and twisting when tying knots. It is important, however, to ensure the generation of as few surface defects as possible during cold-working because an irregular surface could promote crevice and fretting corrosion and/or stress concentration effects. Any debris from fabrication is removed by a process called “passivation treatment” in which the surface is treated with, typically, a strong acid like nitric acid. The acid treatment results in an oxide film on the surface, which is considered to be more stable than the natural air-formed film. Whether this passivated oxidative film should not be disturbed during subsequent handling is still debatable. Stainless steel is sterilized by heat or steam with heat. It was reported that steam sterilization also increases its resistance to corrosion (49).

Currently the available stainless steel sutures are twisted Flexon<sup>®</sup> and monofilament Stainless Steel<sup>®</sup> from American Cyanamid, twisted or monofilament Surgical Stainless Steel from Ethicon, and monofilament steel from US Surgical.

## B. Size Classification of Sutures

Suture materials are also classified according to their size. Currently, two standards are used to describe the size of suture materials: the USP (United States Pharmacopoeia) and the EP (European Pharmacopoeia) (2). Table 7 summarizes EP and USP standards. The USP standard is more commonly used. In the USP standard, the size is represented by a series combination of two arabic numbers: a

zero and any number other than zero, like 2-0 (or 2/0). The higher the first number, the smaller the suture material is. Sizes greater than O are denoted by 1, 2, 3, etc. This standard size also varies with the type of suture material.

In the EP standard, the code number ranges from 0.1 to 10. The corresponding minimum diameter (mm) can be easily calculated by taking the code number and dividing by 10. The EP standard does not separate natural from synthetic absorbable sutures as the USP does.

Because a range of diameters is permitted for each USP suture size, the tensile strength (force/cross-sectional area) of sutures of the same USP size may be different from each other. For example, two polypropylene sutures of the same USP size from two different manufacturers having the same tensile breaking load may have different tensile strengths because of a possible difference in suture cross-sectional area due to slightly different diameters. The polypropylene suture with a smaller diameter may have a higher tensile breaking strength than the one with a larger diameter. A recent study by von Fraunhofer et al. reported that some types of sutures have consistently less variability in diameter than others (50). They found that Prolene has the greatest variability in diameter, particularly in the 2/0 and 3/0 sizes among six tested sutures (chromic catgut, Softgut, Dexon Plus, Vicryl, PDS, and Prolene) of USP sizes ranging from 3/0, 2/0, 1/0, to 1. However, Prolene has overall the lowest diameter at all four USP sizes (50). Softgut, a glycerin-coated catgut from Davis/Geck, has a significantly greater diameter than all other five sutures tested at all four USP sizes. The diameters of chromic gut, Dexon Plus, Vicryl, and PDS are comparable at most USP

**Table 19.7** Suture Size Classification

USP size codes		EP size codes	Diameter (mm) Min. Max.
Nonsynthetic absorbable	Nonabsorbable and synthetic absorbable	Absorbable and nonabsorbable materials	
	11/0	0.1	0.01–0.019
	10/0	0.2	0.02–0.029
	9/0	0.3	0.03–0.039
	8/0	0.4	0.04–0.049
8/0	7/0	0.5	0.05–0.069

sizes, as shown in Fig. 3, although PDS is a monofilament and the rest are multifilaments.

### C. Physical Configuration and Surface Treatments

In terms of the physical configuration of suture materials, they can be classified into monofilament, multifilament, twisted, and braided. Suture materials made of nylon, polyester and stainless steel are available in both multifilament and monofilament forms. Catgut, reconstituted collagen, and cotton are available in twisted multifilament form, while PGA, Vicryl, Panacryl, silk, polyester based, and polyamide based suture materials are available in the braided multifilament configuration. PDS, Maxon, Monocryl, Biosyn polypropylene based, Gore-Tex, and Pronova suture materials exist in monofilament form only. Stainless steel metallic suture materials can be obtained in either monofilament or twisted multifilament configurations. Another unique physical configuration of suture material is polyamide (nylon 6), which has the trade name Supramid®. It has a twisted core covered by a jacket of the same material.

Suture materials are frequently coated to facilitate their handling properties, particularly for a reduction in tissue drag when passing through the needle tract and ease of sliding knots down the suture during knotting (i.e., knot tie-down). Although nonabsorbable beeswax, paraffin, sili-

cone, and polytetrafluoroethylene are the traditional coating materials, new coating materials have been reported, particularly those that are absorbable. This is because the coating materials used for absorbable sutures must be absorbable, and traditional nonabsorbable coating materials like wax are not appropriate for absorbable sutures (51–

**Figure 19.3** Variation in suture diameter of five sutures in four different USP sizes. (From J. A. von Fraunhofer, R. S. Storey, I. K. Stone, and B. J. Materson. *J. Biomed. Mater. Res.* 19:595 (1985). Data recompiled with permission.)

53). Furthermore, absorbable coating materials should have better tissue biocompatibility because of the lack of chronic tissue reaction.

The trend of suture coating is to develop coating materials that have a chemical property similar to the suture to be coated. There are basically two types of absorbable coating materials: water soluble and water insoluble. Water-insoluble coating materials have similar chemical constituents to the suture, and they are broken down by hydrolysis. They remain on the suture surface longer than water-soluble coatings. A typical example is polyglactin 370 used for the Vicryl suture. Dexon II sutures have a polycaprolate coating, which is water insoluble. Water-soluble coating materials dissolve promptly to reveal the underlying uncoated suture after wound closure. A typical example is poloxamer 188 found on Dexon Plus. Multifilament sutures are more commonly provided with coating materials than monofilament sutures. For example, multifilament Vicryl and Dexon Plus or II have coating materials applied, while monofilament PDS and Maxon sutures have no coatings.

Although coating of suture materials facilitates easy passage through tissue and handling properties, it frequently results in poor knot security. For example, Dexon Plus and coated Vicryl require four or five square throws to form secure square knots, while the uncoated Dexon and Vicryl sutures form secure knots with only two throws (54,55). Water-soluble coating materials do not have the same adverse effects as water-insoluble ones on suture knot security. This is because the dissolution of water-soluble coating material reveals the underlying substrate, i.e., uncoated sutures, which have better knot security (55).

There is, however, one technical concern about using water-soluble coating material in actual wound closure. Suture materials are frequently soaked in saline after their removal from packages before wound closure. Some or the bulk of the water-soluble coating materials might be removed by this routine soaking practice. Thus it is important to minimize the time of soaking when dealing with water-soluble coated suture materials.

Besides using water soluble coating materials to improve knot security and handling properties, there are several other patented procedures and materials reported recently to improve either knot tie-down performance (the ease of sliding a knot down the suture into place during knotting) or/and knot security (the ability of a knot to hold after knotting) (56–59). In general, a coating designed to improve knot tie-down would reduce knot security. It is difficult to achieve both ease of knot tie-down and enhanced knot security of sutures. There are very few reported treatments that would achieve these two contradictory and mutually exclusive properties. One of them is the

use of a combination of both coating and textured yarns reported by Kawai et al. (56) who used sucrose fatty acid ester, beeswax, paraffin, poly(oxyethylene-co-oxypropylene), polyglactin-370, gelatin, silicone, and polytetrafluoroethylene as coating materials. Textured yarns could be achieved by standard texturing processes employed in the textile industry, and they include false-twist, knit-deknit, stuffing box, and crimping gear methods.

Other recently reported absorbable but not water-soluble coating materials that could improve knot tie-down and knot security are high-molecular-weight poly- $\epsilon$ -caprolactone, copolymer of at least 90% by weight of caprolactone and 10% at most of other biodegradable monomers like glycolide, lactide, and their derivatives (57,58) or a random copolymer of 25–75% by weight of glycolide and the remaining trimethylene carbonate (59). The improved knot tie-down and knot security were attributed to deep penetration and even distribution of the coating materials into the interstices of the suture filaments. The patented random copolymer of glycolide and trimethylene carbonate coating material was suggested to have the advantages of not flaking off from the substrate sutures because of its high molecular weight and low glass transition temperature and of retaining its lubricant property even when the coated suture is wet.

There is relatively little research and development of new coating materials for natural absorbable sutures like catgut and reconstituted collagen sutures. Gaillard recently reported that the widely reported relatively poor in vivo biocompatibility and performance of collagen based sutures could be improved by using biodegradable polymeric coating materials instead of the conventional chromium salts (60). The rationale behind his approach is that a biodegradable protective coating could temporarily shield the substrate catgut sutures from enzymatic biodegradation during the early stage of wound healing, so that the coated catgut sutures should be able not only to retain better strength in this critical period of wound healing but also to delay and reduce the well-known adverse tissue reactions by delaying the onset of enzymatic biodegradation beyond the initial stage of wound healing. The use of synthetic biodegradable polymers as the coating for catgut sutures would also eliminate the known toxicity of chromium salts and improve knot tie-down and security.

#### D. Physical and Mechanical Properties

The physical and mechanical characteristics of suture materials are probably the most important criteria for suture functions, i.e., to close wounds and to carry the physiologic load during healing. They include those related to strength,

stiffness, viscoelasticity, coefficient of friction, compliance, size, form (monofilament or multifilament), fluid absorption and transport, etc. Mechanical properties include knotted and unknotted (straight pull) tensile strength, modulus of elasticity (relating to stiffness), elongation at break, and toughness (the area under the stress-strain curve, which relates to the ability of a material to absorb impact energy).

There is a wide variety of mechanical properties among existing commercial suture materials. The tensile strength property is the most frequently reported and studied mechanical characteristic of suture materials. Because strength is expressed in terms of the cross-sectional area of a material, it is normalized based on the dimension of the material and hence could be used to compare sutures having different chemical structure or/and sizes. Tensile breaking force, however, does not take into account suture size (i.e., diameter). Thus a larger suture would have a higher tensile breaking force than the same suture of a smaller size, even though the two sutures may have the same tensile strength. Therefore a meaningful comparison of tensile breaking forces of sutures should be done under the same suture size (diameter) and physical form. In addition, knotted tensile strength or breaking force is frequently lower than for the unknotted suture. Strength values are obtained in either dry or wet conditions. Among these physical and mechanical properties, viscoelasticity, bending stiffness, and compliance are the least studied and understood and are worthy of brief comments below.

Viscoelasticity relates to the ability of materials to change either their dimension under a constant force (i.e., creep) or their strength under a constant dimension (i.e., stress relaxation). This ability is believed to be related to the quality of a suture to hold a wound. For example, a suture with a high creep phenomenon will become "relaxed" after the recession of wound edema, which could lead to a suture knot loop becoming too loose to appose the wound edges properly. Viscoelasticity of suture materials is also the least studied and understood (61,62).

Bending stiffness is a complex mechanical phenomenon that closely relates to the handling characteristics of suture materials, particularly knot security. There is very little reported data describing the bending stiffness of sutures. Most reported stiffness data were derived from the modulus of elasticity obtained from the tensile strength test. Because a knot involves the bending of suture strands, stiffness data based on the modulus of elasticity do not adequately represent the performance of knot strength, security, or tie-down. There are two reported studies of the bending stiffness of sutures (47,63).

The study of bending stiffness by Chu et al. (47) was based on the force required to bend a suture to a predeter-

mined angle. The measured bending force was converted to flexural stiffness in pounds/in<sup>2</sup> according to an ASTM formula. Sutures with a braided structure were generally more flexible than those of a monofilament structure, irrespective of their chemical constituents. Coated sutures had a significantly higher bending stiffness than the corresponding uncoated ones. This is particularly true when polymers rather than wax or silicone were used as the coating material. This coating-related increase in bending stiffness is attributed to the loss of mobility of constituent fibers under bending force. An increase in suture size significantly increased their stiffness, and the magnitude of increase depended on the chemical constituents of the suture. The large porous volume inherent in the Gore-Tex monofilament suture was the reason for its lowest flexural stiffness. These quantitative bending stiffness data were consistent with the reported semiquantitative stiffness data based on torsional mode (63).

The torsional bending stiffness study of sutures [Tomita et al. (63)] used the technique reported by Scott and Robin (64). In principle, a constant weight was attached to each end of a suture of fixed length (25.5 cm), and the distance between these two ends was measured after one minute loading. The stiffness coefficient ( $G$ ) was calculated by the formula  $G = TD^2/8$ , where  $T$  is the applied force in dynes and  $D$  was the stiffness index, which was the average distance between the two parallel ends of the suture. The bending stiffness data from Tomita et al. generally agree with the data of Chu et al. that braided sutures are generally more flexible than monofilaments, and Gore-Tex suture has the lowest bending stiffness.

Suture compliance is a mechanical property that closely relates to the ease of a suture to elongate under a tensile force. It is believed that the level of suture compliance should contribute to the compliance of tissues at the anastomotic site. Suture compliance is particularly important in surgery where there is a tubular anastomosis, such as vascular anastomoses. There is only one reported study that examined the effect of suture compliance on the compliance of arterial anastomotic tissues closed with sutures (65). Compliance mismatch between a vascular graft and host tissue has long been suggested as one of the several factors contributing to graft failure (66). Compliance mismatch at the anastomotic site constitutes a major component of overall compliance mismatch associated with vascular grafts. Since sutures are the only foreign materials at the anastomotic site, it is expected that a wide range of suture compliance might result in different levels of anastomotic compliance. Megerman et al. (65) very recently tested this hypothesis by using two 6/0 sutures with a vast difference in suture compliance, Novafil and Prolene. Novafil is an elastomeric suture made from polybutester and

is characterized by a high elongation at low tensile force, a low modulus of elasticity, and high hysteresis, while the Prolene suture has a relatively higher modulus of elasticity, low elongation at low tensile force, and low hysteresis. They reported that arterial anastomoses closed with a more compliant suture like Novafil produced arterial anastomotic compliance on average over 75% more than those closed with a less compliant Prolene suture.

Capillarity of a suture describes the ease of a suture to transport liquid along the suture strand and is an inherent physical property of multifilament sutures due to the available interstitial space. Capillarity is thus related to the ability of a suture to transport or spread microorganisms and hence is an important property that relates to wound infection. Bucknall (67) reported that a braided nylon suture could take up three times as many microorganisms as monofilament nylon. There are two methods to evaluate the capillarity of sutures, qualitative according to USP XVII (68) and quantitative as developed by Blomstedt and Osterberg (69). The former method determines whether a 0.1% methylene blue dye solution can transport through a fixed length of a suture weighing under 2 grams to reach the end marked by a white cotton within 8 h. If the cotton becomes blue within 8 h, the suture is classified as capillary; otherwise it is noncapillary.

Table 8 summarizes capillarity data of some size 0 sutures according to the USP XVII qualitative method (69). None of the monofilament sutures exhibited capillarity, while braided polyester (Mersilene®), twisted polyamide with cover (Supramid®), and twisted linen showed capillarity. It was surprising that braided silk with wax coating and catgut (plain and chromic) did not have any capillarity. It appears that the wax treatment on silk was able to reduce capillarity. Although the qualitative USP XVII method is

a fast and easy way to evaluate suture capillarity, it does not distinguish the rate of capillarity.

Blomstedt et al. developed a quantitative method to determine the rate of capillarity of sutures (69). The method is based on the conductivity of suture strands when they are wet via capillarity. There was a more than 10-fold difference in the rate of fluid transport (the slope of the curve) among the three sutures having capillarity based on the USP XVII method. For example, Supramid, Mersilene, and twisted linen had the fluid transport rate constants 0.24, 0.04, and 0.01 cm<sup>2</sup>/s, respectively.

Fluid absorption of sutures, a property relating to capillarity, may also be responsible for the spread of microorganisms in tissues. Table 9 summarizes the level of absorption of saline and blood plasma of several sutures (69). In general, both the chemical nature and the physical structure of the sutures determine the level of fluid absorption; however, it appears that the chemical nature is more important than the physical structure for the wide range of fluid absorption. Synthetic sutures have much lower fluid absorption capability than natural sutures, because the former are more hydrophobic than the latter. Within each type of suture, multifilament sutures have a higher fluid absorption than their monofilament counterparts due to the additional capillarity effect associated with multifilament sutures. Among the sutures tested, plain and chromic catgut sutures showed the highest level of fluid absorption in both saline and blood plasma media. Obviously, bulk fluid absorption in addition to surface fluid absorption is required to reach such a high level of fluid absorption. The protein nature of catgut sutures provides many bonding sites for fluid molecules to attach to, and such attachments are not lim-

**Table 19.8** Capillarity of Different Suture Materials According to the USP XVII Method

ited to the surface of catgut sutures. In contrast, almost all absorbed fluid in synthetic sutures was retained on the surface of the sutures.

### E. Handling Properties

Handling characteristics describe those properties that relate to the feel of suture materials by surgeons during wound closure. These suture characteristics are the most difficult to evaluate objectively. The handling properties of sutures are pliability (or stiffness), knot tie-down, knot security, packaging memory, surface friction, viscoelasticity, tissue drag, etc., and hence are directly and indirectly related to the physical/mechanical characteristics of sutures. For example, the term pliability is a subjective description of how easily a person could bend the suture and hence relates to the surgeon's feel of a suture during knot tying. It is directly related to the bending modulus and indirectly to the coefficient of friction. Packaging memory, another handling property that indirectly relates to pliability, is the ability to retain the kink form after unpacking. The ability to retain such kink form makes surgeons' handling of the sutures more difficult during wound closure, particularly when tying a knot. This is because sutures with high memory, like nylon, polypropylene, PDS and Maxon, tend to untie their knots as they try to return to their kink form. Thus packaging memory should be as low as possible. In general, monofilament sutures have more packaging memory than braided ones. The four exceptions are the newly available Monocryl, Biosyn, Gore-Tex, and Pronova sutures, which are reported to have exceptionally low packaging memory. The easiest means of evaluating the packaging memory is to hang the sutures in air and measure the time required to straighten out the kink.

Knot tie-down and security describe how easily a surgeon can slide a knot down to the wound edge and how well the knot will stay in position without untying or slippage. These handling characteristics relate to surface and mechanical properties of sutures. A relatively smooth surface like that of monofilament or coated braided sutures will have a better knot tie-down than a suture with a rough surface such as an uncoated braided suture, if everything else is equal. The coefficient of friction of sutures also relates to knot tie-down and security. A linear relationship between knot security and the coefficient of friction was reported by Herman (70). A high coefficient of friction will make knot tie-down difficult but will lead to a more secure knot. This is because a high-friction suture can provide additional frictional force to hold the knot together. This high-friction suture surface also makes the passage of suture strands difficult during knot tie-down. It thus appears that knot tie-down and knot security are two contradictory

requirements. There is no reported standard test for evaluating knot tie-down capacity.

Tomita et al. (63) recently reported a method to quantify objectively the knot tie-down capacity of 2/0 silk, polyester sutures, Gore-Tex, and an experimental ultrahigh-molecular-weight polyethylene suture (Nesplon®). Their method was based on the technique developed by Kobayashi (71). The pullout friction test measures the frictional resistances produced by both surface friction and cross-sectional deformation of sutures when tying and holding a knot securely. In principle, a suture thread was wound around a sponge tube, tied with a square knot, and placed in a tensile testing machine. Table 10 summarizes the knot tie-down resistance and roughness as well as the knot security of the four tested sutures. The two monofilament sutures (Gore-Tex and UHMW-PE) as a group had a much lower knot tie-down resistance than the braided sutures (Surgical Silk and Ethibond). A higher contact surface area among braided suture strands may be responsible for the high resistance to knot sliding. Silk suture was found to have the largest difference between static (for knot security) and dynamic (for knot tie-down) resistances. These silk data are consistent with their well-known excellent handling characteristics.

The high knot tie-down resistance of braided sutures also led to their higher knot security as evident in the lower number of throws that was required to achieve a secure knot (defined as one that broke without slipping >10 mm) in Table 10. Tomita et al. attributed the high knot security of these braided sutures not only to the surface friction force but also to the resistance resulting from cross-sectional deformity.

Tissue drag describes how easy it is to pull a suture through tissue during wound closure and suture removal. It hence gives an indication of the extent of tissue tear in needle holes. Obviously, tissue drag should be maintained at a minimum for easy passage of sutures through tissue, which is reflected in a surgeon's feel about a suture. Tissue

**Table 19.10** Knot Properties of USP Size 2 Sutures

Suture material	Knot security <sup>a</sup>	Tie-down resistance ( $\times 10^3$ N) ( $n = 3$ )	Tie-down roughness ( $\times 10^3$ N) ( $n = 3$ )

drag of a suture is closely related to both the surface physical roughness and the coefficient of friction. In general, coated or/and monofilament suture materials have less tissue drag than their uncoated or/and braided counterparts. This is because a coating material can smooth a rough surface and also change the coefficient of friction.

There are very few reported studies that examine the relationship between the structure/physical configuration of sutures and tissue drag (72,73). These published studies focus on the evaluation of suture withdrawal stress and work after predetermined periods of implantation. It is known that healing around a suture in a wound leads to ingrowth of fibrous connective tissues into the interstitial space of the suture. This tissue ingrowth can exert a significant resistance during suture withdrawal. Table 11 summarizes the maximum suture withdrawal stress (g/cm) and work (g-cm/cm) of six commercial sutures subdermally implanted in dogs for up to 14 days (72). Model II, which used the test sutures to close three 1 inch long cutaneous incisions via a short curved needle and a continuous stitch, was a better model for simulating clinical trauma proximal to the suture location. In general, monofilament sutures (e.g., nylon, polypropylene, and polyethylene) showed significantly lower maximum withdrawal stress values than multifilament braid sutures like silk (plain or silicone-coated) and Tevdek<sup>®</sup> (a PTFE-coated polyester). Plain silk had the highest maximum withdrawal stress (146.9 g/cm) among the six types of sutures. The duration of implantation appeared not to exert a strong ef-

fect. The data of withdrawal work were consistent with the maximum withdrawal stress. A subsequent detailed analysis of the withdrawal stress profile vs. the length of suture withdrawn in cutaneous tissues of pigs indicated a unique pattern (73). A sharp maximum withdrawal stress along the length of the suture withdrawn was the most characteristic pattern for silicone-coated silk sutures over all three periods of implantation (1, 2, and 3 weeks), while the synthetic monofilament polyethylene, polypropylene, and nylon as well as Tevdek<sup>®</sup> sutures showed relatively flat withdrawal stress curves (less profound maximum withdrawal stress) with the length of suture withdrawn.

## F. Biological Properties

Biocompatibility of suture materials describes how sutures, which are foreign materials to the body, affect surrounding tissues and how the surrounding tissues affect the properties of sutures. Thus biocompatibility is a two-way relationship. The extent of tissue reactions to sutures depends largely on the chemical nature of the sutures and their degradation products if they are absorbable. Sutures from natural sources like catgut and silk usually provoke more tissue reactions than synthetic ones. This is due to the availability of enzymes to react with natural biopolymers. Besides the most important chemical factors, physical form, the amount and stiffness of suture materials have been reported to elicit different levels of tissue reactions. For example, a stiff suture would result in stiff projecting

ends in a knot where cut. These stiff ends could irritate surrounding tissues through mechanical means, a problem associated with some monofilament sutures but generally not found in braided multifilament sutures.

Because the quantity of a buried suture relates to the extent of tissue reaction, it is a well-known practice in surgery that one should use as little suture material as possible, such as a smaller knot or a smaller size, to close wounds. The use of a smaller size for wound closure without the expenses of adequate support to wounds and cutting through wound tissue is due to the square relationship between diameter ( $D$ ) and volume ( $V$ ) ( $V = \pi D^2 \times \text{length}$ ), which suggests that a slight increase in suture size or diameter would increase its volume considerably.

There are two basic means to study the biocompatibility of suture materials, cellular response and enzyme histochemistry. The former is the most frequently used and provides information about the type and density of inflammatory cells at a suture site. The latter provides information on what these inflammatory cells would do and is based on the fact that any cellular response is always associated with the presence of a variety of enzymes and is particularly useful in the study of the mechanism of absorption of absorbable sutures. In the cellular response approach, histological stains with a variety of dyes like the most frequently used H & E are the standard methods of evaluation of cellular activity at the suture sites. Figure 4 is a typical example of histological photomicrographs of PDS and Maxon sutures at 35 days postimplantation in a variety of tissues (74). In addition to a qualitative description of cellular activities, tissue response could be graded by the most frequently used and accepted Sewell et al. method or its modification (75).

Most biocompatibility studies of suture materials have been performed in rat gluteal muscle. This implantation site has given a very consistent and reproducible cellular response for valid comparisons, even though it is not a common site for suture in surgery. However, Walton recently raised the question of using this common test procedure, particularly in orthopaedic surgery (76). His arguments were based on the observed inflamed nature of the postoperative synovial tissue and the mechanically stressed nature of the suture.

The second means for the study of suture biocompatibility is the use of enzyme histochemistry. It is a more objective, quantitative, consistent, and reproducible method than cellular response, which is based on a more subjective histological evaluation. Enzyme histochemistry is, however, more tedious and requires more sophisticated facilities and better experience. The data obtained provide additional insight into the functions of those cells that appear during various stages of wound healing. The enzy-

**Figure 19.4** Light histological photomicrographs of tissue adjacent to PDS and Maxon sutures 3 and 5 days after implantation in a variety of tissues of New Zealand White rabbits.  $\times 130$ . (A) Peritoneum/PDS, (B) Fascia/PDS, (C) Peritoneum/Maxon, and (D) Fascia/Maxon. (From S. A. Metz, N. Chegini, and B. J. Masterson. *J. Gynecol. Surg.* 5(1):37–46 (1989). With permission.)

matic activity of a suture implant site is quantified by microscopic photometry of a cryostat section of the tissue. Figure 5 is a typical finding of an enzyme histochemical study of suture biocompatibility (77–79). The high level of cellular response to silk suture observed from a histological study is confirmed in this enzyme histochemical study. Enzyme histochemistry is also useful for studying the biodegradation mechanism of absorbable sutures because not only natural absorbable sutures are degraded through the enzymatic route but also the degradation products must be metabolized via enzyme activity.

The normal tissue reaction to sutures has three stages, according to the time for the appearance of a variety of inflammatory cells (77,79–81). They are the initial infiltration of polymorphonuclear leukocytes, lymphocytes,

**Figure 19.5** Enzyme histochemical evaluation of macrophage hydrolase activity of monofilament polypropylene and braided silk and polyester sutures. (From W. van Winkle, and T. N. Salthouse. Ethicon, Somerville, N.J., 1976. With permission.)

and monocytes during the first 3 or 4 days (i.e., acute response); the appearance of macrophages and fibroblasts from day 4 to day 7; and the beginning of maturation of fibrous connective tissue formation with chronic inflammation after the 7th to the 10th day. During the first 7 days after implantation, there is virtually no difference in normal tissue reaction between synthetic absorbable and nonabsorbable sutures. However, a slightly higher inflammatory reaction to synthetic absorbable sutures could persist for an extended period until they are completely absorbed and metabolized, while synthetic nonabsorbable sutures, in general, are characterized with a minimal chronic inflammatory reaction with a thin fibrous connective tissue capsule surrounding the sutures usually by 28 days after implantation.

Due to this normal tissue reaction, fibrous and/or epidermic tissue ingrowth into sutures may pose a problem during the removal of the sutures, particularly for those sutures placed through the cutaneous surface due to the ingrowth of epidermis in addition to fibrous connective tissue. This problem is particularly profound in multifilament sutures because of the available interstitial space within

these sutures for tissue infiltration. The formation of a perisutural cuff due to a downward growth of epidermis along the suture path has been found to be responsible for 70 to 85% of the force required to remove the suture (72,73,80). Among the multifilament sutures, silk is the worst offender. A very recently reported U.S. patent disclosed the approach of using a composite suture to reduce tissue ingrowth into silk sutures through encapsulation of the silk suture with biocompatible polymeric resin (33).

Monofilament sutures are considered to be a better choice than multifilament ones in closing contaminated wounds. This is because not only do multifilament sutures elicit more tissue reactions, which may lessen tissue ability to deal with wound infections, but also multifilament sutures have a capillary effect, which could transport microorganisms from one region of the wound to another. The reason that multifilament sutures generally elicit more tissue reactions than their monofilament counterparts is that inflammatory cells are able to penetrate into the interstitial space within a multifilament suture and invade each filament. Such an invasion by inflammatory cells, well evident in histological pictures, does not occur in monofilament

sutures. Thus the available surface area of a suture to tissue should bear a close relationship to the level of tissue reaction that a suture could elicit.

In addition to the normal tissue reactions to sutures, there are several adverse tissue reactions that are suture and site specific. Some examples include urinary stone or calci formation, granuloma formation, thrombogenicity, propensity toward wound infection and recurrence of tumor after radical surgery, and allergy.

### G. Biodegradation and Absorption Properties

Absorbable sutures require consideration of their biodegradation and absorption, factors that are not relevant for most nonabsorbable sutures. This biodegradation characteristic is the reason that absorbable sutures do not elicit the permanent chronic inflammatory reactions found with nonabsorbable sutures. The most important characteristics in biodegradation and absorption of sutures are the strength and mass loss profiles and the biocompatibility of degradation products. Although there is a wide range of strength and mass loss profiles among the available absorbable sutures, they have one common characteristic: strength loss always occurs much earlier than mass loss, as shown in Fig. 6. This suggests that absorbable sutures retain a large portion of their mass in tissue, while they have already lost all their designated function to provide support for the wound tissue. Thus an ideal absorbable suture should have its mass loss and strength loss profiles synchronized. Such an ideal absorbable suture is not available due to the inherent relationship between strength and fiber structure.

**Figure 19.6** Time to complete loss in tensile breaking strength and mass profiles of five commercial absorbable sutures.

Biodegradation properties are usually examined *in vitro* or/and *in vivo*. In the *in vitro* environment, the most commonly used medium is physiological saline phosphate buffer of pH 7.44 at 37°C. However, other buffers, like Tris, or body fluids like urine, bile, or synovial fluids, have been used. Occasionally, microorganisms were deliberately incorporated into these media to examine the effect of microorganisms on biodegradation properties of absorbable sutures. In the *in vivo* environment, unstressed absorbable sutures are normally implanted in rat gluteal muscle for predetermined periods of implantation. As described above in Sec. B.6, Walton raised the point that the use of unstressed sutures in the gluteal muscle site may not represent the real clinical environment that absorbable sutures normally experience (76). The sutures retrieved at various periods of immersion or implantation are then subject to the evaluation of their mechanical and physical properties to assess their changes with time. The degree of absorption *in vivo* is evaluated by the change in suture cross-sectional area, while the level of tissue reaction is assessed by either the histological method or by the enzyme histochemistry method previously described.

The vast amounts of published information about the biodegradation phenomena of synthetic absorbable sutures since the 1970s show that these synthetic absorbable sutures can be degraded by a hydrolytic mechanism via the scission of ester linkages in the polymeric backbone (1,2). The observed wide range of strength and mass loss profiles of absorbable sutures is attributable not only to the chemical differences among the absorbable sutures but also to a variety of intrinsic and extrinsic factors, such as pH, electrolytes, stress applied, temperature,  $\gamma$ -irradiation, microorganisms, and tissue type, to name a few.

Very recently, an interesting study of the effect of superoxide ion on the degradation of absorbable sutures has been reported (82). Superoxide ion can act as an oxygen nucleophile agent to attack the ester linkage in absorbable suture polymers. In their study of five commercial 2/0 size synthetic absorbable sutures at 25°C (Dexon<sup>®</sup>S, Maxon<sup>®</sup>, Vicryl<sup>®</sup>, PDS II<sup>®</sup>, and Monocryl<sup>®</sup>), Lee and Chu (82) observed that there was a significant superoxide-ion-induced degradation effect on the mechanical properties, thermal properties, and surface morphology of these absorbable sutures. Among the five absorbable sutures and over the concentration range of that study, the monofilament Monocryl suture was the most sensitive toward superoxide-ion-induced degradation, followed by Maxon, Vicryl, Dexon, and PDSII sutures, which had relatively the least effect of superoxide-ion-induced hydrolytic degradation, as shown in Table 12. The amount of tensile breaking force loss ranged from as low as 3% to as high as 80%, depending

on the type of absorbable sutures, reaction time, and superoxide ion concentration. Regardless of degradation reaction time (up to 24 h), the measurement of tensile breaking force of these five absorbable sutures at the highest superoxide ion concentration (0.01 molar) was impossible because all absorbable sutures were so degraded that they completely lost their physical integrity as fibers and became almost invisible. For the purpose of comparison, none of these five absorbable sutures lost any measurable tensile strength in the presence of buffer medium within 24 h.

Along with the drastic reduction in mechanical properties, all these five absorbable sutures showed significant reductions in both peak melting temperature ( $T_m$ ) and glass transition temperature ( $T_g$ ). For examples, Dexon<sup>®</sup> suture showed the most significant change in  $T_g$  at both superoxide ion concentrations ( $\Delta T_g = 9.0^\circ\text{C}$ ,  $19.5^\circ\text{C}$ ) followed by Vicryl<sup>®</sup> ( $\Delta T_g = 12.6^\circ\text{C}$ ). Among the monofilament absorbable sutures, Monocryl<sup>®</sup> had the highest  $T_g$  reduction ( $\Delta T_g = 7.4^\circ\text{C}$ ,  $9.7^\circ\text{C}$ ), while PDS II<sup>®</sup> was the most resistant to superoxide-ion-induced  $T_g$  change with the smallest  $\Delta T_g$  among all five synthetic absorbable suture materials ( $\Delta T_g = 0.8^\circ\text{C}$ ,  $1.2^\circ\text{C}$ ).

Unlike the surface morphological change of the absorbable sutures in buffer solutions, the effects of superoxide-ion-induced degradation on the surface morphological change of the five absorbable sutures were unique and un-

usual (Fig. 7), particularly the moon-crater shaped impressions of various sizes and depth found in Monocryl and Maxon sutures that defied the anisotropic characteristic of the fibers.

Lee and Chu suggested that the cleavage of the ester bonds in the backbone of these absorbable suture materials was via a nucleophilic attack of superoxide ion. As shown in Scheme 1, this nucleophilic attack was predominantly an  $S_N2$  type of reaction yielding mainly anionic end groups of different chain lengths. These active anionic species could subsequently attack the main backbone chains via transesterification with a rapid reduction in molecular weight until thermodynamic equilibrium was reached. The resulting degradation products would eventually lead to cyclic and/or linear oligomers. The nucleophilic attack of the superoxide ion on polymers occurs primarily in Steps 1 and 2 of Scheme 1, which lead to the fragmentation of polyester chains and the formation of two different types of species: lower molecular weight macromolecules with peroxy radical chain end groups and anionic catalyzed chain end groups, respectively. Unlike the base catalyzed hydrolysis of simple aliphatic polyesters in an alkaline buffer solution in which the alcoholic anions were stabilized by hydrogen abstraction from the carboxylic end group to produce an alcohol group and a relatively stable carboxylic anion end group, the alcoholate end group from Step 2 may subsequently attack the main backbone chains

**Figure 19.7** The surface morphology of 2-0 Monocryl suture upon superoxide-ion-induced hydrolytic degradation at 25°C for 24 h. (A) Original control, (B) 0.0005 molar, (C) 0.0025 molar, (D) 0.005 molar superoxide ion concentration.

via intra- and intermolecular transesterification reactions as illustrated in Step 3 of Scheme 1. This additional chain scission in Step 3 not only reduces the molecular weight of linear aliphatic polyesters like Dexon, Maxon, and Vicryl further but also produces another anionic species that repeats Step 3 again to accelerate the degradation further. Step 4 is a typical electron transfer reaction from the superoxide ion to the peroxy radical that leads to the formation of the carboxyl anionic intermediates, which are expected to be stable. Therefore their reactivity towards the polyester chain as Step 3 is very low or unlikely. Any excess superoxide ion would react with water as shown in Step 5 to form a hydroxyl anion and other species. Although it appeared to have competitive reactions between the hydroxyl anion attacking the ester linkage of the polyester for additional chain scission and the hydroxyl anion reacting with the carboxyl peroxide anion end group of the

polymer chain (Step 6) to produce the carboxylic anion without chain scission, it was less feasible for the former (i.e., hydroxyl anion to attack ester linkages) because of the relatively low temperature (25°C). Step 6 was preferable during the final step of the termination reaction. Finally, it is possible to exchange potassium counter anions with hydrogen via diluted hydrochloric acid solution used for the termination reaction.

The biocompatibility of degradation products is usually not a problem because all existing absorbable sutures are made from the well-known biocompatible glycolide, lactide, and their derivatives. However, biocompatibility of degradation products also depends on the rate of their accumulation in the surrounding tissues. This implies that the ability of the surrounding tissues to actively metabolize degradation products is essential. Such a metabolism depends on the extent of blood circulation in the tissue. A

**Scheme 1** Reaction mechanism of superoxide-ion-induced degradation of aliphatic polyesters. (From K. H. Lee and C. C. Chu. The effect of superoxide ions in the degradation of five synthetic absorbable suture materials. *J. Biomed. Mater. Res.* 49(1):25 (2000).)

well vascularized tissue could remove degradation products as fast as they are released from an absorbable suture and subsequently metabolized, which could minimize tissue reactions to degradation products.

Due to their ability to release degradation products, absorbable sutures have recently been studied as a vehicle to deliver a variety of biochemicals like growth factors to facilitate wound healing or antibiotics to combat wound infection. This new approach will increase the value of absorbable sutures and extend their function beyond the traditional role of wound closure.

### III. SURGICAL MESHES

Another common medical textile product that has a long history of saving human lives is surgical mesh for body wall repair. Defects of the body's tissues are the direct result of the radical resection of a cancer tumor, congenital lesions, infection and subsequent necrosis and debridement, violent crimes, accidents, or large hernias. One in every 200 U.S. adults has experienced a hernia problem. Attempts to close these large defects are essential to save the patient's life, as well as to restore normal body func-

tions. For those large defects lacking adequate tissue to permit primary repair, it is highly desirable to use materials of either a synthetic or a natural origin to reinforce tenuous aponeurotic closures and/or to bridge large defects in the abdominal or chest wall.

A wide variety of biological and synthetic textile materials have been used to repair the defective body wall. Biological materials include autologous, homologous, and heterologous transplants of fascia lata, skin or dermis, and dura mater (83–86). Synthetic textile materials for mesh use include the metallic based (e.g., tantalum, stainless steel) and the polymeric based. The polymeric based meshes include the nonabsorbable type, which includes polyamide (nylon), polyester (Dacron<sup>®</sup>), polytetrafluoroethylene (PTFE) or expanded polytetrafluoroethylene (Gore-Tex<sup>®</sup>), and polypropylene (Marlex<sup>®</sup>), and the absorbable type, which includes PGA (chemically identical to Dexon suture) and polyglactin-910 (chemically identical to Vicryl suture) (87–106). Very recently, there are a few new mesh products introduced for a variety of biomedical applications. For example, Genzyme introduced two unusual absorbable surgical meshes that are not based upon synthetic absorbable suture materials. These two absorbable meshes, Seprafilm<sup>®</sup> and Sepramesh<sup>®</sup>, are made from carboxymethylcellulose and sodium hyaluronate (107,108). Klinge et al. (109) reported a new hybrid mesh (Soft Hernia Mesh) that consists of both nonabsorbable (i.e., polypropylene) and absorbable (i.e., polyglactin-910) components. They also introduced a polyglactin-910 coated polypropylene mesh for improving the handling property during surgery (110). Regardless of the nature and type of fibers used, all these synthetic surgical meshes are fabricated in either a woven or a knitted structure and exhibit various levels of porosity and strength.

In addition to the traditional use of surgical meshes for the repair of hernias and abdominal body wall defects, there are some innovative uses in many surgical areas, particularly for the protection of internal organs, that are worth of mentioning here briefly. They include pelvic floor reconstruction (108,111), isolation of the abdominal tissues from the denuded and possibly infected pelvis after radical pelvic surgery (112), the repair of the fractured orbital floor (113,114), the wrapping of severe traumatized hepatic tissues for controlling hemorrhage that otherwise would be a life-threatening problem (115,116), the management of the enlarged liver of an infant with stage 4S neuroblastoma that required decompressive laparotomy (117), transabdominal rectopexy in the treatment of rectal prolapse (118–120), wrapping of injured spleen during splenorrhaphy (121–126) or kidney during renorrhaphy (127) after blunt and penetrating trauma, mesh envelope

of en bloc pediatric kidneys to facilitate the handling and positioning of the kidney in renal transplantation (during vascular anastomoses) with minimal vascular complications and lower risk of torsion of renal pedicles (127), gaining better abdominal access in patients with necrotizing pancreatitis by the use of absorbable mesh (129), retropubic sling procedures in women with urinary stress incontinence (130), repair of defects of the right atrium of pigs (131), use as a dural substitute (132), use in the absorbable mesh/fibrin glue technique to prevent cerebrospinal fluid leakage via the suture line along ePTFE mesh as dural substitute (133), the repair of tracheal defects (134), the reconstruction of chest wall defects following en bloc resection of lung carcinomas (135), the surgical management of esophageal perforation by absorbable mesh and fibrin glue (136), as the implant for chin augmentation (137), and finally as the treatment for periodontal defects (138).

#### A. Nonabsorbable Surgical Meshes

To reach a better understanding of the failure modes of surgical meshes, in terms of their properties, and to aid the development of new and better surgical meshes, Chu et al. (139) conducted a systematical and quantitative evaluation of the physical, mechanical, and morphologic properties of three most widely used nonabsorbable synthetic mesh materials, Marlex, Mersilene, and PTFE. Tables 13–16 and Figures 8–11 summarize the textile characteristics of the three most commonly used surgical meshes. It is clearly evident that there is a wide variation in structure and performance among these three.

Tables 13 and 14 show that the three meshes have distinctively different yarn and fabric structures. PTFE meshes are the heaviest and thickest and have the highest filament count and the lowest stitch density. Mersilene meshes are the lightest and thinnest and rank second in terms of filament count and stitch density. Marlex meshes, in terms of weight and thickness, rank second; this monofilament yarn has the highest stitch density. Overall fabric weights of the three surgical meshes are different because of variations in the linear density of the constituent fibers and fabric structure.

Table 15 shows that marked differences exist in tensile properties, not only among the three tested mesh specimens but also between the wale and course directions of the same mesh material. The difference in bursting strength and breaking strength and elongation at the wale direction among the three mesh fabrics was statistically significant according to Student's *t*-test ( $p < 0.01$ ). However, the breaking strength and elongation at the course direction of Marlex and PTFE mesh fabrics were not statistically

**Table 19.13** Yarn Characterization of Three Commercial Nonabsorbable Surgical Meshes

Trade name	Chemical component	Type	Texture	Linear density <sup>a</sup> (Tex <sup>b</sup> )	Filaments per yarn	Filament linear density (Tex <sup>b</sup> )	Filament cross section	Filament diameter (cm)

significant. Marlex meshes have the highest tensile breaking strength among the three surgical meshes, particularly in the wale direction. In this direction the breaking strength of Mersilene mesh is found to be only about one-third of that of Marlex. Mersilene mesh also exhibits the least extensibility in both the wale and course directions, while PTFE mesh shows the highest breaking elongation. In terms of bursting strength a similar pattern was also observed. Marlex mesh exhibits the highest bursting strength,

almost twice that of PTFE mesh and more than three times that of Mersilene mesh.

Table 16 shows large differences in the flexural rigidities of the three surgical meshes. While Mersilene and PTFE meshes are both extremely flexible, Marlex mesh is found to be extremely rigid, particularly in the course direction. Its overall rigidity is about 70 times greater than that of Mersilene mesh. In terms of wrinkle recovery, as shown in Table 17, Marlex mesh shows the lowest recov-

**Table 19.16** Flexural Rigidity of Three Commercial Nonabsorbable Surgical Meshes (mg-cm)

Trade name	$G_w$ , wale rigidity <sup>a</sup>	$G_c$ , course rigidity <sup>a</sup>	$G_0$ , fabric rigidity <sup>a</sup>
Mersilene	16.07	3.58	30.40
Marlex	78.07	825.22	2242.68
Teflon	16.20	6.83	42.34

<sup>a</sup> Calculated from the following formula:  $G_w$  (flexural rigidity in the wale direction) =  $W \times (O/2)^3$ ;  $G_c$  (flexural rigidity in the course direction) =  $W \times (O/2)^3$ ;  $G_0 = (G_w \times G_c)^{1/2}$ ;  $W$  = weight per unit area in mg/cm<sup>2</sup>.  $O$  = length of overhang in cm.

Source: C. C. Chu, B. Pourderyhm, and L. Welch. Characterization of morphologic and mechanical properties of surgical mesh fabrics. *J. Biomed. Mater. Res.* 19:903–916 (1985).

ery in the course direction. In the wale direction, however, it exhibits a slightly higher wrinkle recovery than both Mersilene and PTFE meshes. PTFE mesh has almost identical wrinkle recovery in both wale and course directions when measured immediately.

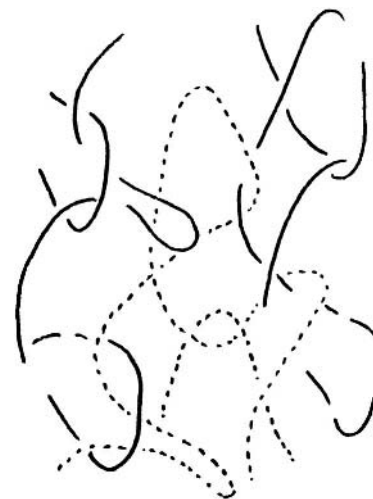

The wide range of observed characteristics and properties of these three surgical meshes is the combined result of both the constituent fibers and the yarn and fabric structure of each mesh. Based on fabric structure, all three surgical meshes examined are warp knitted; the yarns lie predominantly in the lengthwise direction. Knitted fabrics have a more open structure than woven. The size and shape of the pores are a function of the arrangement of the movement of needles or the fabric design and can therefore be easily controlled.

Figure 8 shows the way in which the yarns of the three mesh fabrics are interlooped around each other. Marlex mesh has a totally different structure from those of Mersilene and PTFE. The pores in Mersilene and PTFE meshes are mainly located between the two adjacent sets of yarns, while the pores in the Marlex are largely in the centers of the loops. The yarns in the Marlex mesh fabrics, however, are interlooped on almost every course. This would undoubtedly result in a higher strength but would also lead to a higher degree of stiffness as well as a reduced extensibility.

The shapes of the pores of the three surgical meshes are also different, as is evident in Figs. 9–11. The PTFE

mesh has nearly circular pores, the Mersilene mesh has hexagonal pores, and the Marlex mesh has irregular pores. The number of pores, as well as the pore size and shape, is important to the surgical mesh's ability to reinforce wounds. The porous area of the mesh serves as a scaffold for the subsequent ingrowth of a dense infiltrate of fibrous tissue, which, in turn, contributes to the strength of the wound (140). Arnaud et al. (141) used Wistar rats as models to show that porous mesh materials induced more than

twice the fibroblastic cell infiltration than nonporous fabric materials, therefore exhibiting higher bursting strength of the abdominal wound. Among the three surgical meshes tested, Mersilene has the highest porosity (or the lowest packing factor) and thus may induce more ingrowth of fibrous tissue than the other two meshes. Ingrowth of fibrous tissue, however, also depends on other factors, such as the pore size and shape, the chemical nature of the constituent fibers, and the mechanical force on a porous material–fibrous tissue interface. The pore sizes of the three surgical meshes are different; Mersilene has a pore size of 120  $\mu\text{m} \times 85 \mu\text{m}$  measured by taking the two longest perpendicular axes of the pore. PTFE has a similar pore size to that of Mersilene mesh, 157  $\mu\text{m} \times 67 \mu\text{m}$ , while Marlex has the smallest pores, ranging from 68  $\mu\text{m} \times 32 \mu\text{m}$  to as small as 23  $\mu\text{m} \times 23 \mu\text{m}$ . Bobyne et al. (142) have dem-

onstrated that the optimal pore size for the strongest mechanical attachment of ingrowth for fibrous tissues should range from 50 to 200  $\mu\text{m}$ , with an average pore size of 90  $\mu\text{m}$ . Chvapil et al. (143) also reported that a pore size greater than 100  $\mu\text{m}$  was needed for the rapid ingrowth of vascularized connective tissue. Smaller pore size is inadequate for the ingrowth of connective tissues, because of the lack of proper space for capillary penetration, as is discussed by Taylor et al. (144). These reported pore sizes for optimal fibrous tissue ingrowth are within the pore sizes of Mersilene and PTFE meshes but not Marlex mesh. Usher and Gannon (89) reported that PTFE meshes, however, stimulated less fibrosis than Marlex meshes in dogs and hence were not well bonded to the surrounding fascia. This lack of ingrowth of fibrous tissue in PTFE mesh, regardless of its porosity and pore size, is thought to be attributed to the chemical nature of the PTFE fibers. Because of a very low critical surface tension, 18.5 dyn/cm (145), it is difficult for fibrocytes to attach and spread on PTFE surfaces.

The observed wide range of mechanical properties of these three surgical meshes are no doubt the result of the distinct difference in yarn and fabric structure. Marlex has monofilament yarns, whereas Mersilene and PTFE have multifilament yarns with 12 and 52 filament counts, respectively. The linear densities and the sizes of the yarns are also different. These differences in fabric and yarn structure, together with differences due to chemical properties of the fibers, influence the tensile and bursting strengths, the flexural rigidities, and the wrinkle recovery properties of these fabrics.

Regardless of the magnitude of strength measurements, all three surgical meshes have one common characteristic—greater strength in the wale direction and more extensibility in the course direction. While this is a typical characteristic of a knitted fabric structure, this unique anisotropic property is important in determining the orientation of the mesh during implantation. The wale direction of the mesh implant should be parallel to the maximum physiological stress. Among the three tested materials, PTFE has the highest elongation at both wale and course directions. This property is not considered to be an advantage in hernia repair because too much stretch in a mesh material can either separate the underlying tissue before the mesh resistance can be brought into operation (93) or pinch the ingrowth tissue by a narrowing of the pore size, which can result in tissue necrosis. A certain amount of extensibility, however, is desirable, because it can act as a stimulant to orient the connective tissue parallel to the direction of the physiological force. Another common observation of the three tested surgical meshes is that the mesh with higher tensile strength also exhibits higher

bursting strength, because the force experienced by the mesh fabrics in bursting tests was of tensile mode. Marlex meshes exhibit the highest tensile and bursting strength, due mainly to the structure of the constituent yarn of this fabric.

A wrinkled mesh may cause more adhesion problems with viscera than a stretched mesh. Usher et al. (89) reported that there were adhesions of the bowel and omentum to the peritoneal side of the Marlex mesh in dogs, and that this might be due to the observed transverse wrinkling of the mesh. A wrinkled mesh can also result in the uneven distribution of stress on the mesh and cause an undesirable distortion and possibly, a premature weakening of the mesh. From the morphological point of view, a wrinkled mesh may result in bursas on the mesh material and hence predispose the wound to infection. The results of the wrinkle recovery test performed by Chu et al. (139) indicate that the recovery of a surgical mesh fabric depends on the direction of the mesh fabric (i.e., wale or course) and the time allowed for recovery. The exception was the PTFE mesh, which showed no difference of direction when measured immediately. Among the three surgical meshes, PTFE and Mersilene have better overall wrinkle recovery than Marlex meshes, and this can be attributed to different yarn and fabric structure.

Because of the difficulty of conforming to the topology of the surrounding tissues, a stiff and rigid mesh can cause the erosion or perforation of intraabdominal viscera, particularly with small children. Clinical cases of this complication have been previously reported (146). Moazam et al. (147) also reported that a pliable mesh will rarely develop problems with enteric fistulae, even when it is used over a prolonged period. Among the three types of meshes tested in this study, Marlex meshes have a significantly higher flexural rigidity than the other two. This is due to a high yarn stiffness and a bending modulus resulting from both the physical configuration of the monofilament yarn and the chemical structure of the high linear density polypropylene fiber. It is evident, therefore, that both the selection of the chemical nature of the constituents of the fibers and the selection of the yarn and fabric structures contribute to the properties of each mesh. These factors should be considered in the future design of surgical mesh fabrics to obtain the necessary balance between strength and properties such as porosity, stiffness, and wrinkle recovery. The availability of these characterization data can also serve as the foundation for a surgeon's selection of the appropriate commercial surgical mesh fabric for each particular case, and for its subsequent evaluation and comparison *in vivo*.

Among the synthetic nonabsorbable biomaterials, metallic meshes have been shown to become work-hardened, inflexible, friable, and fragmented with time (84,85,148,

149). They may protrude through the skin or erode into adjacent tissue or blood vessels.

The polymeric based meshes are far more successful than metallic ones, but they still exhibit various problems. Mersilene meshes produce good results in tissue repair but often produce seromas as the most common complication (150). Meshes made of PTFE are generally satisfactory, particularly in the presence of infection, but have “too much stretch” (93) and do not stimulate sufficient fibroplasia to be incorporated into the tissue (89). Meshes made of Marlex, the most commonly used, have the lowest frequency of related complications (151). However, they are relatively stiff and occasionally injure the underlying abdominal viscera (146). Long-term complications associated with Marlex, such as mesh extrusion and/or enteric fistulae following coverage by split-thickness skin, have been reported (152). Recently, a five-year follow-up study of the use of Marlex mesh for parastomal hernia by Morris-Stiff and Hughes (153) indicated poor results due to high recurrent hernia (29%), serious complications (obstruction and dense adhesion to the intra-abdominal mesh (57%), and mesh-related abscess (15%) (153).

The most recent comprehensive evaluation of biological tissue response to nonabsorbable meshes in animals was reported by Ortiz-Oshiro et al. (154). They found that polypropylene mesh in rats over a period of 15 weeks provoked higher acute inflammatory reaction (e.g., higher cell density and polymorphonuclear response) and connective tissue formation (e.g., fibrohistiocytic response) than Mersilene mesh, which induced higher foreign-body reaction. Similar findings were reported in the meshes retrieved from humans (106). In this study, Klinge et al. reported that polypropylene mesh had the highest partial volume of inflammatory cells (32%), followed by Gore-Tex (12%), Mersilene (8%), and “reduced” polypropylene mesh (7%). The extent of this inflammatory reaction correlated well with the level of connective tissue formation. They also concluded that these persistent foreign body reactions to nonabsorbable meshes could lead to chronic wound complications.

In order to reduce or eliminate the reported clinical disadvantages of nonabsorbable meshes, one approach was to reduce the amounts of nonabsorbable components in a surgical mesh to  $<30 \text{ g/m}^2$  via increasing mesh pore size. This reduced polypropylene mesh consists of multifilament yarn instead of the conventional monofilaments and has a larger pore size than nonreduced polypropylene mesh. This approach is based on the fact that tissue reaction to implants depends also on the amounts of the foreign materials presented in a biological environment. Thus the term “reduced” polypropylene mesh referred to a nonabsorbable mesh having smaller amounts of polypropylene

than conventional Marlex for the purpose of reducing tissue reaction. As reported by Klinge et al. (106), reduced polypropylene indeed showed the lowest partial volume of inflammatory cells and numbers of macrophages at the interface between meshes and tissues among Marlex, Mersilene, and Gore-Tex meshes.

Since this reduced polypropylene mesh was too soft and lumpy for proper surgical handling, polyglactin-910 absorbable biomaterial was either coated onto or/and blended (in multifilament form) with the reduced polypropylene mesh to increase its initial stiffness to facilitate its manipulation during surgery (110). The polyglactin-910-coated reduced polypropylene mesh, however, showed a remarkably different tissue reaction from the uncoated ones in rats over 90 days by the preferential formation of fibroconnective tissue capsule, surrounding the whole mesh. Such capsule formation prevents a proper incorporation of the mesh with the surrounding tissue.

Nonabsorbable meshes, particularly the polypropylene based, are known to have a strong tendency to form intra-abdominal adhesion between the mesh material and the intraperitoneal viscera. Such adhesion is due to the high integration of the surrounding tissues into the porous structure of the mesh and may lead to the obstructions of intestine and enterocutaneous fistulae. One promising reported approach to solve this intra-abdominal adhesion problem is to use absorbable meshes with or without the presence of nonabsorbable meshes. The details of this approach will be discussed in the next section.

In addition, all the above polymeric based meshes share one common disadvantage—they must be removed, in most cases, if infection develops. Absorbable surgical meshes have shown better chronic tissue tolerance because they are biodegraded completely so that no traces of a foreign body remain.

## B. Absorbable Surgical Meshes

Most absorbable surgical meshes are made from the same absorbable fibers as the absorbable suture materials. Among synthetic absorbable fibers, PGA (Dexon<sup>®</sup>) and polyglactin-910 (Vicryl<sup>®</sup>) are the two most popular fibrous biomaterials for making absorbable surgical meshes. The major advantage of absorbable surgical meshes over nonabsorbable ones is the absence of permanent foreign-body reaction, which could predispose to late complications like chronic infection, adhesion, mechanical irritation, drainage, erosion, and bleeding. The disadvantage of absorbable surgical meshes is the possible recurrence of hernia after the disappearance of the mesh.

Absorbable meshes are also particularly useful in closing contaminated abdominal wall defects. Dayton et al.

(101) reported that those patients who had prior infected polypropylene mesh or a chronically infected scar were treated by a single sheet of PGA mesh without the long-term complications of nonabsorbable meshes. However, six of the eight patients developed recurrent abdominal wall hernia at the site of the PGA mesh from 3–18 months follow-up. They suggested that this complication should balance against the more serious complications associated with nonabsorbable meshes, and the use of absorbable meshes as a temporary abdominal wall support in contaminated wound sites could lead to subsequent successful implantation of a nonabsorbable mesh after the infection was cleared. The recurrence of hernia due to absorbable meshes was also reported by Tyrell et al. (102) in their animal (rabbits) study and by Greene et al. (103) in their clinical study. Tyrell et al. found that all those rabbits repaired by either PGA or polyglactin-910 meshes exhibited ventral hernias by the 10<sup>th</sup> week after the operation, while those repaired by Marlex or PTFE showed no sign of hernias. In the Greene et al. study, PGA knitted meshes were used in 59 critically ill patients to bridge the abdominal wall defects after celiotomy; however, hernia defects were found in most patients 4 to 6 months after the operation. The time of hernia recurrence coincided with the complete disappearance of the PGA meshes (2 or 3 months). This suggests that the lack of proper mechanical support due to the complete biodegradation of the absorbable mesh was the cause for the hernia appearance. Since most trauma patients enrolled in emergency rooms have contaminated wounds, absorbable meshes were suggested as a better temporary alternative adjunct to fascial closure until the complete resolution of acute complications (105).

Absorbable meshes also have the advantage over nonabsorbable ones in terms of adhesion formation between prosthetic meshes and surrounding tissues. This advantage is supported by several reported studies (108,155–157). For example, Dasika and Widmann (156) implanted polyglactin-910 mesh alone or placed this absorbable mesh between Marlex mesh and the intraperitoneal viscera of rats for 1 to 3 months. Both polyglactin-910 mesh alone and the combination of polyglactin-910 and Marlex meshes showed a similar adhesion score (1.5), while the Marlex mesh had the worst adhesion score (2.75 with 3 the most severe). The control (midline laparotomy with suture closure only) had little adhesion and the lowest adhesion score (0.25 with 0 no adhesion). This difference in adhesion formation became the greatest at the longest implantation period (i.e., 3 months). The ability for absorbable meshes to reduce tissue adhesion also depends on the level of trauma. For example, Sondhi et al. (155) found that, in normal surgical trauma conditions, polyglactin-910 mesh could significantly reduce postoperative adhesion in the extraocular

muscle surgery of rabbits, but no significant reduction in adhesion was found in extensive trauma.

In addition to the synthetic absorbable aliphatic polyester based meshes, Genzyme's new Seprafilm has also been used along with nonabsorbable polypropylene mesh to prevent tissue adhesion problem (108,157). In their study, Alponat et al. (108) placed two Seprafilms over the abdominal viscera of an incisional hernia in rats before the surgical repair of the defect with polypropylene mesh, and fewer adhesion formations were observed than with polypropylene mesh only at the end of 30 days. Significant reduction in adhesion formation in rabbits by placing Seprafilms between tissues and polypropylene mesh was also reported by Dinsmore and Calton (157).

Although most reports of using absorbable mesh showed promising results toward the reduction of intra-abdominal adhesion, the findings were not unanimous. Using mice, Baykal et al. (158) recently demonstrated that, based on adhesion grading and tissue hydroxyproline levels, PGA mesh actually increased intestinal adhesion formation at 90 days after operation than the control (no mesh) and polypropylene mesh groups. They also found that tissue adhesion correlated well with the level of tissue hydroxyproline formation. They attributed these unexpected findings to the higher inflammatory and foreign-body reactions associated with the absorption process of PGA mesh.

There is one innovative use of surgical meshes that has nothing to do with their traditional function to bridge body wall defects. Surgical meshes, particularly absorbable ones, have been used in postoperative radiation therapy for gynecological (e.g., pelvic) and rectal-related malignant tumors. The function of surgical meshes in this application is to lift up patients' small bowels away from the radiation target region (e.g., pelvic or rectal) during postoperative radiation therapy to prevent the devastating radiation-induced small bowel injury that could predispose to infection, adhesion, and obstruction. There is a high frequency of this type of small bowel injury due to postoperative radiation therapy following pelvic cancer surgery (up to 50%). Because of this concern, postoperative radiation dosage cannot be raised to a more effective tumoricidal dosage level and is frequently limited to < 5,000 cGy. In this nontraditional application of surgical meshes, absorbable ones are better than the nonabsorbable because there is no need to remove the mesh afterwards and there is no permanent foreign-body reaction.

Several investigators have reported the use of absorbable surgical meshes like PGA or polyglactin-910 for such a nontraditional purpose in humans and animals with promising results (159–166). For example, Devereux et al. (159) used PGA mesh as an intestinal sling to elevate the

small bowel of 60 patents (18 with gynecologic malignancies and 42 with rectal carcinomas) away from the sites operated on and irradiated (a mean 5,500 rad dosage). After 28 months, there was no single case of radiation enteritis or complication associated with the implanted PGA meshes. Dasmahapatra et al. (163) reported the lack of incidence of clinical radiation-associated small bowel injury after a 12–53 months follow-up of the use of both PGA and polyglactin-910 meshes in 45 patients having rectal carcinoma, except for two patients with polyglactin-910 mesh that developed obstructions due to adhesions. Rodier et al. (165) reported that the PGA mesh was completely absorbed in such an application within 3 to 5 postoperative months. In a controlled animal study, Devereux et al. (161) found that cebus monkeys that had PGA mesh slings before irradiation showed normal small bowel function and histological data within 12 months, while the untreated 10 monkeys all died of small bowel necrosis upon 2,000 rads (single dose). PGA mesh disappeared completely by 6 months.

Therefore the use of absorbable surgical meshes to lift up small intestine bowels after surgical removal of tumors and before radiation therapy appears to be a promising technique to eliminate radiation-induced small bowel injury without significant mesh-related complications. Such application also permits the use of more effective radiation dosages for tumoricidal effect.

#### IV. VASCULAR GRAFTS

Vascular diseases have always been associated with human beings, as recorded history shows. They frequently result in either the loss of lives or limbs. The development of textile based vascular grafts of either synthetic or natural origin has been one of the most important biomedical applications. This development has made significant progress and allowed the reconstruction of obstructed or injured blood vessels with remarkable success. However, some serious problems still remain unsolved (167). While homografts are still considered to be the preferred arterial replacement for small-diameter vessels (below the knee), they are used in limited quantity and are insufficient to meet the increasing needs for vascular replacement, due mainly to an inadequate supply, nonuniform properties, and difficulty in preparation (168,169).

##### A. Introduction

In the long search for an ideal graft replacement, various synthetic materials have been experimented with. They include rigid nonporous tubes made of gold, silver, alumi-

num, glass, and polyethylene. However, these nonporous materials completely failed due to the lack of porosity and compliance. These two important requirements of an ideal vascular graft have been partially fulfilled by the use of fibrous based polymers and textile structure. The two most important polymeric biomaterials used for making vascular fabrics are poly(ethylene terephthalate) and expanded poly(tetrafluoroethylene). The former includes Dacron and has the largest market share. The latter is the same as Gore-Tex. In addition to these two common polymeric biomaterials as the major source for fabricating vascular grafts, the use of polyurethane based elastomeric fibers like Spandex has been tried for the purpose of improving the compliance of vascular grafts (170).

In contrast to a solid tube design, the inherent porous nature of textile materials has provided the required space for the fibrous connective tissue to grow into for achieving full-wall healing (defined by Sauvage as “incorporation of the entire graft within a fibrous tissue matrix whose flow surface is covered with endothelium”) (167).

Currently, there are three basic textile structures for vascular grafts: woven, knitted, and nonwoven. These three are different from each other in porosity, mechanical properties, and other properties. All woven and knitted vascular fabrics are made from poly(ethylene terephthalate), while the nonwoven vascular fabrics are made from expanded poly(tetrafluoroethylene), the same polymer for the non-absorbable Gore-Tex suture.

The woven structure provides strength with high dimensional stability and low permeability to blood, and it is less prone to kinking. It is used mainly in large-diameter vessels like the aorta and major arteries from which uncontrolled bleeding could lead to fatality. The main disadvantages of woven vascular fabrics are their very low healing porosity leading to poor healing, difficulty in suturing, fraying of cut edges, and poor compliance. In order to improve the healing porosity and compliance of woven vascular fabrics, velour woven vascular fabrics were introduced. These new fabrics were made by floating portions of the weft or/and warp yarns so that the numbers of intersections along both warp and weft directions were reduced considerably from the conventional  $1 \times 1$  woven structure. Since the numbers of intersections of both weft and warp yarns are closely related to the mechanical and physical properties of the resulting fabrics, a significant reduction in these numbers would make the fabrics more flexible and porous. The floated portions of the yarns have another advantage: they produce three-dimensional loose surface structures as the framework for tissue attachment and ingrowth that conventional woven fabrics do not have.

The knitted vascular fabrics have a much higher porosity than woven grafts and hence show better full-wall heal-

ing. However, due to their high porosity, they are difficult to preclot during the time of implantation and therefore impose the problem of blood leakage. As a result, knitted vascular fabrics are not normally used in large arteries where bleeding is a major problem. Knitted vascular fabrics are also softer and more flexible than woven vascular grafts and show better compliance. There are far more varieties of knitted than of woven structure. The current commercially available knitted vascular fabrics are mainly warp knitted with a single or double velour surface structure.

All woven and knitted vascular grafts have one common appearance, a crimped structure. A crimping process introduces “hills and valleys” along the longitudinal direction of the grafts. The purpose of crimping these vascular grafts is to prevent kinking of the graft at its bending site. A kinked graft would block the flow of blood at the point of bending. Since the crimped process would destroy the smooth and even flow surface of the fabric, the wells in the valley portions could be prone to thrombus deposits due to the stagnation of the blood flow in these regions.

The most nonconventional textile structure in vascular fabrics is Gore-Tex. It consists of nodes that are connected by fine fibrils. Because of this unique structure, it is highly porous. The details of Gore-Tex have been previously described in Sec. II.A.12.

## **B. Two Important Criteria for Designing Vascular Fabrics**

The two most important criteria in designing vascular fabrics are porosity and nonthrombogenic surface. These two criteria are closely related to each other because vascular fabrics require porous space for tissue ingrowth, which would ultimately lead to the formation of nonthrombogenic surfaces. The generation of a nonthrombogenic surface on synthetic vascular graft materials is one of the most important goals in the repair of damaged or diseased vascular systems. Incomplete healing imposes the continued risk of thrombotic occlusion, particularly in medium- and small-caliber blood vessels. There is only one reported case of a complete full-wall healing (defined by Sauvage as the incorporation of the entire graft within a fibrous tissue matrix whose flow surface is covered with endothelium) in humans at points distant from the suture line (171).

Because all of the existing commercial vascular grafts are constructed from a single type of nonabsorbable fiber (e.g., Dacron), their porosity is relatively constant and does not change with time. It is thus impossible to vary the porosity of these single-component fabrics so that they would be very tight during implantation (i.e., low bleeding porosity) to prevent the occurrence of blood leakage, and be

very porous during healing (i.e., high healing porosity) to promote fibrous tissue ingrowth for a full-wall healing.

There are several approaches to try to design ideal vascular fabrics that would meet these two most important criteria. Among them, the use of absorbable fibers as the sole component or as one of two components of a fabric and the theoretical prediction of the porosity of a fabric based on some mathematical formula are quite intriguing and appear to be promising for the design of the next generation of vascular fabrics.

The rationale of using absorbable fibers as components of vascular fabrics is threefold. First, since the absorbable component would eventually be biodegraded, the resulting vascular fabrics would have high healing porosity due to the new porous space generated from the disappearance of the absorbable components. This high healing porosity would induce the growth of an endothelial cell lining within the graft luminal surface. The formation of an endothelial lining within a vascular graft could be achieved through pannus ingrowth, capillary ingrowth, attachment and growth of blood-borne pluripotential cells, and the artificial endothelial cell-seeding at the time of implantation. All the ingrowth mechanisms would require adequate porosity of the fabrics, and the use of absorbable fibers appears to be the most promising approach to achieve such a goal without compromising bleeding porosity during implantation. Secondly, absorbable vascular grafts would not elicit permanent foreign-body reactions as nonabsorbable fibers do and hence are more biocompatible and less prone to chronic inflammatory reactions that lead to infection. Finally, absorbable vascular grafts could regenerate pseudoarterial tissues with nonthrombogenic surfaces during the biodegradation process of the absorbable grafts. This approach of tissue regeneration via absorbable scaffolds is being pursued with some very exciting and promising results.

## **C. Absorbable Based Vascular Fabrics**

Among absorbable based vascular fabrics, there are two kinds, totally and partially absorbable fabrics. The totally absorbable vascular fabrics do not have any nonabsorbable components, and the most representative researches are by Wesolowski et al., Bowald et al., and Greisler et al. (172–191). The partially absorbable vascular fabrics have both absorbable and nonabsorbable components, and the most representative researches are from Chu et al. (192–194).

### **1. Totally Absorbable Based Vascular Grafts**

Greisler et al. have used the same absorbable fibers as the synthetic absorbable suture materials for the completely

absorbable based vascular grafts, namely polyglycolic acid (PGA), polyglactin-910 (Vicryl), and poly-*p*-dioxanone (PDS). Their extensive *in vivo* and *in vitro* studies have documented active stimulatory or inhibitory effects of various absorbable materials on the regeneration of myofibroblast, vascular smooth muscle cells, and endothelial cells, and have shown a transinterstitial migration to be their source when lactide/glycolide copolymer prostheses are used (185). The rate of tissue ingrowth parallels the kinetics of macrophage-mediated prosthetic absorption in all polylactide/polyglycolide-based grafts (179,180,182, 183). Macrophage phagocytosis of these absorbable biomaterials is observed histologically as early as one week following implantation in the case of a rapidly absorbable material, such as PGA or polyglactin-910, and is followed by an extensive increase in the myofibroblast population and neovascularization of the inner capsules (179,180, 195). Autoradiographic analyses demonstrated a significantly increased mitotic index within these inner capsular cells, that mitotic index paralleling the course of the absorption of absorbable biomaterials (196). Polyglactin-910, for example, resulted in a mitotic index of  $20.1 \pm 16.6\%$  3 weeks following implantation, progressively decreasing to  $1.2 \pm 1.3\%$  after 12 weeks. The more slowly absorbable PDS based vascular grafts demonstrated a persistently elevated mitotic index,  $7.1 \pm 3.8\%$ , 12 weeks after implantation, a time in which the prosthetic material is still being biodegraded. The nonabsorbable Dacron vascular graft, however, never achieved greater than a  $1.2 \pm 1.3\%$  mitotic index (196). These mitotic indices correlated closely with the slopes of the inner capsule thickening curves, suggesting that myofibroblast proliferation contributed heavily to this tissue deposition. The labeled cells are found in the deeper zones of the inner capsule in proximity to the macrophages and prosthetic graft material (196) in the area in which the myofibroblasts demonstrate ultrastructurally synthetic phenotypes, a phenotype more commonly found in cells actively cycling (179).

Inner capsular collagen deposition similarly follows the kinetics of both myofibroblast proliferation and macrophage-mediated biomaterial absorption. Explanted inner capsule tissues within polyglactin-910, PDS, and Dacron grafts showed extensive deposition of collagen within the inner capsules of both polyglactin-910 and PDS absorbable graft biomaterials, more rapidly within the more rapidly absorbed polyglactin-910. Collagen contents at one month were  $35.5 \pm 9.9$  mg collagen/mg dry weight in polyglactin-910,  $25.6 \pm 5.0$  in PDS, and  $12.0 \pm 0.9$  in Dacron. By three months, PDS inner capsular collagen content had increased to  $44.6 \pm 6.3$  mg/mg, while the polyglactin-910 and Dacron exhibited little increase. A normal rabbit aortic collagen content was  $22.5 \pm 1.2$  mg/mg.

The research of Greisler et al. suggested that lactide/glycolide copolymer based absorbable vascular grafts could stimulate an extensive tissue ingrowth via their interactions with macrophages. Similarly, they showed that Dacron actively inhibited such tissue ingrowth (195). They reported that the presence of as little as 30% Dacron within a compound yarn could effectively abolish tissue ingrowth and inner capsule cellularity, resulting in inner capsules composed primarily of fibrin coagula. A compounded graft consisting of an absorbable yarn with the nonresorbable polypropylene, however, did not result in a similar blockade of the absorbable polymer induced tissue ingrowth (181,197).

Greisler et al. utilized this Dacron inhibitory activity to perform a study evaluating the source of regenerating tissues (185). Three 10-mm-long compound prostheses (30 mm  $\times$  4 mm I.D.) were constructed in such a fashion that Dacron segments were on both ends and polyglactin-910 between. These compounded grafts were implanted into adult NZW rabbit aortas. During the 4 month postimplantation period, all grafts showed 100% patency. Inner capsule thickness in the central polyglactin-910 segments increased from 2 weeks to 2 months, being significantly thicker than either Dacron segment at 1 and 2 months. By 1 month, inner capsules of polyglactin-910 segments were predominantly myofibroblasts and collagen, while the inner capsules in Dacron segments remained fibrin coagula beyond 2 mm from either anastomotic sites. This corresponded to the observations of capillary infiltration of inner capsules with capillary communication with regenerated aortic lumens (182) and suggested that a transinterstitial ingrowth rather than a transanastomotic pannus ingrowth would be the primary source of cells replacing absorbable vascular prostheses.

To demonstrate the humoral nature of the signal for cell proliferation, Greisler et al. reported that the freshly explanted polyglactin-910, PDS, and Dacron prosthesis/tissue complexes harvested 2–12 weeks following implantation were incubated in a physiologic salt solution (100 mg/mL) to elute growth factor activity from these tissues. The mitogenic activity of the eluates was then evaluated. The eluates prepared from the polyglactin-910 explants resulted in significantly more stimulation of DNA synthesis in the 3T3 cells than was seen in response to the Dacron or PDS prepared eluates (198). Radioimmunoassay for PDGF B chain in these eluates was negative, and likely other growth factors are the humoral mediators.

Greisler et al. have also demonstrated that the implantation of the same polylactide/polyglycolide vascular prostheses into rabbits with diet-induced arteriosclerosis results in a markedly attenuated regenerative response with significantly fewer endothelial cells and myofibroblasts in the

inner capsule tissues when these absorbable prostheses are implanted into rabbits previously made atherogenic by dietary manipulation (199). Histologically, 3-week explants showed only small areas of neointima with myofibroblasts and endothelial cells; the outer capsules were infiltrated by lipid-laden macrophages. This is in contrast to the thicker inner capsule with abundant myofibroblasts and collagen in polyglactin-910 grafts implanted into normal NZW rabbits by 3 weeks.

Based on the data from absorbable based vascular grafts, Greisler et al. suggested that the macrophage–biomaterial interactions are the basis for the observed vascular tissue regeneration over absorbable scaffolds. These interactions are expected to yield a differential activation of the macrophage resulting in a differential release of biologically active mediators that are both stimulatory and inhibitory to myofibroblast, smooth muscle cell, and endothelial cell migration and proliferation. Chu advanced this hypothesis by suggesting that different rates of absorption of absorbable biomaterials induce different levels of macrophage–biomaterial interactions and hence different degrees of vascular tissue regeneration.

Recent cell culture studies by Greisler et al. appeared to support the hypothesis that the macrophage–biomaterial interactions control the level of vascular tissue regeneration (200–202). They reported the greater ability of lactide/glycolide copolymers to induce macrophages to release growth factors, including bFGF, capable of stimulating DNA synthesis in cultured murine capillary lung endothelial cells, human umbilical vein endothelial cells, BALB/c 3T3 mouse fibroblasts, and rabbit aortic smooth muscle cells. On the contrary, by exposure the same macrophage population to nonabsorbable Dacron resulted in an inhibition of endothelial cell proliferation and a diminution in the stimulation of fibroblast and smooth muscle cell proliferation.

Smooth muscle cells of normal rabbit aortas (SMC) in the presence of the media consisting of normal diet macrophages that had been exposed to polyglactin-910 were stimulated to synthesize DNA significantly more (4–9×) when compared to the same macrophage media exposed either to Dacron or to neither biomaterial. The Dacron-exposed macrophage media yielded minimal mitogen release. It thus appears that the absorbable biomaterial conditioned macrophage media stimulated SMC proliferation. It further suggested that polyglactin-910 induced more mitogen release from the biomaterial conditioned macrophage media than did Dacron. These results are consistent with the *in vivo* observations of greater tissue ingrowth and mitotic indices following implantation of polyglactin-910 prostheses into normal rabbits as compared to Dacron prostheses. These data are also consistent with the greater

tissue ingrowth elicited by polyglactin-910 prostheses implanted into normal rabbit aortas as compared to arteriosclerotic rabbit aortas.

Bioassays utilizing quiescent LE-II endothelial cells similarly showed an increase in LE-II proliferation induced by the macrophage polyglactin-910 conditioned media, an effect not seen in response to Dacron exposure. Conversely, exposure of the macrophage Dacron conditioned media yielded less LE-II proliferation even than the PBS negative control, suggesting the release of a growth inhibitor due to the presence of Dacron. Greisler et al. suggested that the extensive transinterstitial ingrowth of myofibroblasts and endothelial cells following implantation of absorbable grafts in normal animals and the attendant elevated mitotic index of the myofibroblasts may be mediated by macrophage activation and release of growth factors promoting the mitogenic response.

## 2. Partially Absorbable Based Vascular Grafts

Because of the complete disappearance of the totally absorbable based graft materials, there is the common theoretical concern that the degradation of the component yarns in the totally absorbable vascular fabrics (i.e., loss of strength), before the regeneration of tissues becomes strong enough to withstand the pulsatile force, may make the totally absorbable vascular grafts more prone to aneurysmal dilation and subsequent failure. Aneurysmal dilation has been found in biological grafts like bovine heterografts (203). The current commercial remedy for the problem of aneurysmal dilation associated with degradable biologic grafts is the use of either a bioprosthetic (a combination of synthetic and natural materials) (204) or a better cross-linking process (203).

One solution to the aneurysmal dilation problem associated with synthetic vascular grafts before the arrival of ideal synthetic absorbable polymers is to use bicomponent fabric design. In this approach, absorbable yarns are blended with nonabsorbable ones with various compositions. The purpose is to provide minimal strength of the grafts (from nonabsorbable components) during and after the biodegradation of the absorbable components of the grafts. Theoretically, this type of design could take the advantage of the property of absorbable polymers (i.e., stimulating the regeneration of vascular tissue and reducing chronic foreign-body reaction by reducing the amount of permanent graft mass in a biologic environment) without the expense of making vascular grafts too weak to be useful in the clinic situation of delayed wound healing.

Chu et al. reported a comprehensive study of these bicomponent vascular fabrics (192–194) in terms of (1) how these bicomponent vascular fabrics hydrolytically de-

graded in the in vitro environment and hence the generation of porosity with time, (2) whether the use of partially absorbable vascular grafts in vivo would improve the non-thrombogenic performance of these grafts, (3) whether these partially absorbable grafts would be more prone to aneurysmal dilation and subsequent failure in vivo, and finally (4) to find out the relationships, if any, between these in vivo and the previously reported in vitro data with an emphasis on how the in vitro changes in fabric structure and properties related to the in vivo data.

The bicomponent vascular fabrics of Chu et al. consisted of polyethylene terephthalate (Dacron as the nonabsorbable component) and polyglycolic acid (PGA as the absorbable component). Two types of vascular graft fabrics were fabricated: woven and weft-knitted fabrics with different water permeability. In the woven type (the W group), Dacron yarns were used to make the framework

of the fabrics, while PGA yarns were incorporated in the warp, the weft, or both directions of the fabrics. Such a design would retain the structural integrity of the fabrics even after the complete absorption of PGA yarns. The composition of PGA yarns in the woven group ranged from 38% to 82% by weight. In the weft-knitted vascular fabrics (the K group), both Dacron and PGA yarns were fed through a circular knitting machine, and tubular bicomponent fabrics of various diameters could be made. The composition of PGA yarns ranged from 24 to 57% by weight. Tables 18 & 19 summarize the compositions of the eight types of bicomponent vascular fabrics. Depending on the type of vascular fabric construction, the location and composition of PGA yarns in the bicomponent fabrics, and the denier of Dacron yarns, bicomponent fabrics with a range of mechanical and physical properties could be made.

Compared with commercial vascular fabrics, the porosities of these bicomponent fabrics are controlled not only by the conventional means (e.g., the number of warp and weft yarns per unit length and the denier of the yarns) but also by the amount and location of the absorbable yarns incorporated into the fabrics. Figure 12 exhibits the most important advantage of these bicomponent vascular grafts: a significant increase in water porosity with time that none of the current commercial vascular fabrics could achieve. Almost all bicomponent vascular fabrics had final water porosity 10 times higher than their initial values, and reached the lower limit of the suggested optimum porosity (i.e., 10,000 mL/cm<sup>2</sup>/min of the graft suggested by Weso-

Res.* 27:1329–1340 (1993).)

lowski et al. (173). On the contrary, the water porosities of the two commercial woven vascular fabrics did not change with time and were significantly lower than the bicomponent fabrics at the end of 90 days. This suggests that the bicomponent fabrics may meet the two contradictory and mutually exclusive requirements of an ideal vascular graft: high healing porosity without the expense of low bleeding porosity.

The observed significant increase in water porosity with time in the bicomponent vascular fabrics is also confirmed by their morphological structure change upon immersion time as shown in Figure 13. Both W and K bicomponent fabrics became more porous and open as immersion (i.e., hydrolysis) time increased. This relaxation of the original tight fabric structure is due to the hydrolytic degradation of the absorbable component of the bicomponent fabrics and was the basic cause for the increasing water porosity and decreasing fabric weight and density with immersion time. The K group showed an isotropic and uniform structural change with time. The W group, however, exhibited unusual fabric surface morphology with time. Depending on the location of the absorbable component yarns, the tightness of the initial W fabrics would relax along the direction of a fabric without absorbable PGA yarns. The findings of Chu et al. suggest that the reduction in weft yarn size through the degradation and absorption of the PGA weft yarns is the primary requirement for generating a loose and velourlike surface morphology in bicomponent woven fabrics. The reduction in warp yarn size via the degradation of the PGA warp yarns, however, did not produce such a unique velourlike surface morphology. Therefore in addition to the advantage of increasing porosity with time, the generation of velourlike surfaces on woven vascular fabrics would provide a more open three-dimensional framework for tissue ingrowth.

Another important advantage of these bicomponent fabrics was their significantly lower initial and final stiffness than the corresponding commercial DeBakey woven vascular fabric. As shown in Fig. 14, the bending stiffness of all four bicomponent woven vascular fabrics decreased with time of immersion. Most of the final stiffness of these bicomponent vascular fabrics was only of the order of 1/10th of the values of the commercial woven grafts. A soft and compliant graft would certainly improve its performance and patency (205).

The knitted vascular fabrics made by Chu had the same textile structure as DeBakey Standard, DeBakey Ultralight Weight, and DeBakey Vascular D. They also consisted of both polyglycolic acid and Dacron fibers in various ratios (194). It was found that these vascular fabrics, in general, had lower initial water porosity than the commercial prod-

ucts and exhibited an increase in water porosity ranging from 22 to 116%, while the corresponding commercial weft knitted vascular fabrics showed no change in water porosity during the same period.

Did these bicomponent vascular fabrics provide adequate mechanical strength support to relieve the concern of the lack of mechanical strength of absorbable based vascular fabrics at a later period of implantation? Figure 15 shows that both W and K bicomponent fabrics still exhibit a minimal more than 30% retention of their original bursting strength at the end of 30 days immersion. Most of the reduction in bursting strength occurred during the first 14 days of immersion time, and no appreciable reduction in bursting strength was observed beyond 14 days, an indication that the absorbable PGA component yarns had already lost the majority of their strength and the remaining nonabsorbable Dacron yarns became solely responsible for the observed fabric strength remaining. Therefore a minimum bursting strength level was retained during the whole period of study (120 days), depending on the relative concentration of absorbable to nonabsorbable components. Along

with this reduction in bursting strength with time, the weight of these bicomponent vascular fabrics also decreased. Regardless of the composition ratio of the bicomponent fabrics, their biggest weight loss occurred between 14 and 60 days, depending on the polyglycolic acid composition.

An in vivo trial of these bicomponent vascular fabrics in dogs for 4 months was reported by Yu et al. (194). They found that these bicomponent vascular fabrics resulted in a full-wall healing in the thoracic aorta of dogs. All bicomponent vascular grafts in surviving dogs exhibited a 100% patency rate, free of thrombus and aneurysmal formation, no hematoma or seroma around the grafts, and free of fibrin coagula in the inner capsules. The gross morphology

of the regenerated tissues was visually very similar to the adjacent original arterial tissue. Histologically, the luminal surface was lined with a layer of endothelial cells with myofibroblasts, fibroblasts, and collagens underneath. The extent of the full-wall healing depended on the type of fabric structure, the concentration of absorbable yarns, the location of absorbable yarns (for the woven group only), and initial water permeability. It is believed that the concentration effect was related to the level of macrophage activation from the degradation products of the absorbable yarns, while the location effect was attributed to the various types of fabric structure change upon the degradation of the absorbable yarns. The knitted (K) group, in general, was better than the woven (W) group. The incorporation of absorbable yarns in the weft direction of the bicomponent fabrics resulted in a velourlike loose and porous fabric surface for facilitating tissue ingrowth. The placement of absorbable yarns in the warp direction, however, did not show this unique surface morphology. Calcification was, however, occasionally observed in the W samples with low initial water permeability. The observed in vivo performance correlated well with their in vitro study. This leads Chu et al. to conclude that the amount of an absorbable component in the bicomponent vascular graft appears to be the dominant factor for determining the healing characteristics of grafts consisting of absorbable components.

### 3. Mathematical Modeling of Porosity of Vascular Fabrics

In order to maintain a viable vessel after implantation, the vessel must be highly permeable to allow proper tissue ingrowth for full-wall healing and subsequent adequate fluid transport for minimizing the degeneration and calcification of the ingrown tissue in the pseudoneointima. At the time of surgery, however, the implant needs to be impermeable so that hemorrhage does not occur. The present commercial synthetic vascular grafts cannot achieve this dynamic nature needed for proper performance. Therefore an optimal balance needs to be determined for the porosity of the vascular fabric to allow healing of the vessel with tissue ingrowth, yet minimize blood leakage.

An industry standard to determine the “porosity” of vascular fabric is the water porosity test first developed by Wesolowski (206). However, Guidoin et al. recently pointed out that this term is incorrect in describing the relevant properties (207–209). They suggested that the permeability of a fabric describes how well a fluid passes through its fibers and gives an arbitrary parameter for surgeons to assess the need to preclot before implantation, while the porosity just describes the amount of void space within a fabric, and much of this space is not continuous throughout

the structure and inadequately characterizes the fabric's ability to allow fluid transport. Porosity, instead of water permeability, is thus approximately related to the capability of a fabric toward tissue ingrowth. Contrary to nonwoven fabrics, Guidoin et al. found no close relationship between water permeability and porosity of woven and knitted vascular fabrics (207).

The water permeability test, as it should be known, uses water as the fluid passing through the vascular grafts. Maintaining the pressure of a flow through a sample at physiological conditions (120 mm Hg), the flow rate measured can lead to a coefficient of permittivity (mL/cm<sup>2</sup> min/mm Hg) (207). This coefficient describes the water permeability of a graft and will be used as such. However, the testing procedures are lengthy and time-consuming.

Although water permeability data of vascular fabrics are critical to their successful performance in vivo, the standard practice in the designing of new vascular fabrics with proper water permeability is still based on trial and error, that is, one makes the samples first and then evaluates their water permeability. If the water permeability does not fall into the desirable range, manufacturers must go back to change the design and make new samples for the water permeability test. This is a very tedious and time-consuming process. There is a strong need to determine reliably the water permeability of vascular fabrics before they are made and to simulate the water permeability test of the vascular fabrics to be manufactured. The availability of such a theoretical prediction of the water permeability of vascular fabrics would allow vascular graft manufacturers to design their products intelligently with a desirable water permeability without tedious and time-consuming trial and error.

Chu et al. (210), with the help of mathematical formulae and a computer program that they developed, created a new means to predict instantaneously the water permeability of a hypothetical vascular graft design, given the material and geometric properties of the fabric. Any user can input the specified fabric and fiber parameters of a hypothetical vascular graft and obtain its computed water permeability. If the computed water permeability is outside the desirable range, the user can adjust the input fiber and fabric parameters until the desirable water permeability is obtained. These desirable fiber and fabric parameters could then be used to construct real vascular fabrics, and their water permeability would be experimentally determined. This approach would save considerable resources and time by eliminating the need to run lengthy experiments to determine the correct fiber and fabric specifications for achieving a desirable water permeability of any given surgical fabric.

The mathematical formulae of Chu et al. for predicting

water permeability of both woven and knitted vascular fabrics are

$$Q_w = \frac{A^{0.5}}{V_w} (-302.715 - 4.782\pi_2 + 28.062\pi_3 - 10489.354\pi_4 - 2.701\pi_6)$$

$$Q_k = \frac{A^{0.5}}{V_w} (851.694 - 70.644\pi_2 + 81.555\pi_3 - 23417.858\pi_4 + 292.568\pi_6)$$

where  $\pi_2 = \eta A^{0.5}$ ,  $\pi_3 = \delta A^{0.5}$ ,  $\pi_4 = T_f/A^{0.5}$ ,  $\pi_6 = D_i/D_f$ ,  $D_i$  = fiber density,  $D_f$  = fabric density,  $A$  = fabric cross-sectional area,  $V_w$  = water viscosity,  $Q_w$  = water permeability of woven fabrics, and  $Q_k$  = water permeability of knitted fabrics.

The above formulae,  $Q_w$  and  $Q_k$ , were then used to calculate the predicted water permeabilities,  $Q_{prd}$ , of all 25 vascular fabrics, and they were compared with their corresponding experimental water permeabilities,  $Q_{exp}$ . Table 20 summarizes  $Q_{exp}$ ,  $Q_{prd}$ , and the percentage of error,  $\Delta = \{|Q_{prd} - Q_{exp}|/Q_{exp}\} \times 100$ , for determining the accuracy of the mathematical formulae of Chu et al. to predict the water permeability of various types of vascular fabrics. A close match between  $Q_{prd}$  and  $Q_{exp}$  was defined as those whose  $\Delta$  were less than or equal to 10%.

In general, the accuracy of the predicted water permeability,  $Q_{prd}$ , of Chu et al. to the experimental water permeability,  $Q_{exp}$ , depended on the type of vascular fabrics (i.e., woven vs. knitted) and the source of  $Q_{exp}$ . The difference between  $Q_{prd}$  and  $Q_{exp}$  ranged from as small as 0.27% to as high as 74.2%. As a group, woven vascular fabrics, particularly those not commercially available (i.e., experimental), appeared to have a better match between  $Q_{prd}$  and  $Q_{exp}$  than knitted fabrics. If proper sources of  $Q_{exp}$  were chosen for comparison, we found that 86% of woven fabrics (6/7) and 77% of knitted fabrics (14/18) had their  $Q_{prd}$  within 10% of their  $Q_{exp}$ . This high percentage of close matches (within 10%) between  $Q_{prd}$  and  $Q_{exp}$  should be considered satisfactory, because the experimental error for obtaining  $Q_{exp}$  is generally higher than 10%. All experimental woven (4/4) and 63% (5/8) of knitted vascular fabrics exhibited less than 10% difference between  $Q_{prd}$  and  $Q_{exp}$ .

The data in Table 20 illustrate that mathematical modeling of water permeability of surgical fabrics for a reasonable prediction of their water permeability is feasible and that its level of reliability depends on many factors that are not fully understood at this time. The source of  $Q_{exp}$  had a big influence on the percentage of accuracy of our predicted water permeability formulae. For example, several knitted vascular fabrics like Weaveknit and Vasculour II had  $Q_{prd}$  within 1% of  $Q_{exp}$  if one set of  $Q_{exp}$  (211) was

used for comparison, while a difference as large as 74.2% (Weaveknit) was observed if a different set of  $Q_{\text{exp}}$  (208) was used. In the commercial knitted vascular fabrics, only two (Lopor and Rhodergon) were not affected by the source of  $Q_{\text{exp}}$  on the accuracy of our predicted water permeability formula. Both of them are velour, but Lopor is a weft knit while Rhodergon is a warp knit. These two different sets of  $Q_{\text{exp}}$  data were reported by the same authors (207,211). It is not known why the two sets of  $Q_{\text{exp}}$  data from the same lab are different from each other. The time dependence of  $Q_{\text{exp}}$  might be one of the factors contributing to this discrepancy. In their published study of water permeability of 34 commercial vascular fabrics, Guidoin et al. (207) reported that  $Q_{\text{exp}}$  decreased with time, irrespective of fabric construction type. The rate of reduction in  $Q_{\text{exp}}$ , however, was found to be less with woven structures than with knitted ones, presumably due to the rigid, compact, and dense packing of yarns and fibers in woven structures, which leaves very little room for them to swell with time under hydrostatic pressure. On the contrary, the loose knit structure provides plenty of interstitial space for the swelling of constituent fibers and yarns during water permeability tests. This higher degree of swelling would subsequently reduce the amount of water flowing through the fabric during the later stage of the water permeability test. This time dependence of  $Q_{\text{exp}}$  suggests that the  $Q_{\text{exp}}$  data from Guidoin et al. (207) (without \* in Table 20) are the water permeabilities of virgin vascular fabrics estimated from the linear extrapolation of experimental water permeabilities obtained at time  $t$  to  $t = 0$ . If these estimated  $Q_{\text{exp}}$  of virgin vascular fabrics were used for determining the accuracy of the formulae of Chu et al., half of the tested commercial knitted vascular fabrics (DeBakey Ultralight Weight, Milliknit, Cooley Double Velour, Microvel, and Rhodergon) and one woven commercial fabric (Woven DeBakey) showed considerable improvement. For example, DeBakey Ultralight Weight showed a considerable reduction in the difference between  $Q_{\text{exp}}$  and  $Q_{\text{prd}}$  from as high as 42% to 7.78%. However, the time dependence of  $Q_{\text{exp}}$  is not the sole factor contributing to the dependence of the formulae on the source of  $Q_{\text{exp}}$ . This is because most of the remaining commercial woven and knitted vascular fabrics (i.e., those fabrics showed very poor agreement between  $Q_{\text{exp}}$  and  $Q_{\text{prd}}$  using estimated  $Q_{\text{exp}}$  at  $t = 0$  or virgin  $Q_{\text{exp}}$ ) exhibited a close match between  $Q_{\text{exp}}$  and  $Q_{\text{prd}}$ , if the data set of  $Q_{\text{exp}}$  from King et al. (211) was used. It is not clear whether this  $Q_{\text{exp}}$  data set (211) took into consideration the time dependence of experimental water permeability. Assuming this set of  $Q_{\text{exp}}$  represented the water permeability after  $t$  minutes of testing, then the observed close match between  $Q_{\text{prd}}$  and  $Q_{\text{exp}}$  found in Woven Cooley Verisoft, DeBakey Standard, Weaveknit, and DeBakey Vasculour

lour D could not be attributed to the time dependence of  $Q_{\text{exp}}$  alone.

Although woven fabrics as a group showed relatively good agreement between  $Q_{\text{prd}}$  and  $Q_{\text{exp}}$ , Woven DeBaKey was the only one of the commercial woven vascular fabrics that neither estimated  $Q_{\text{exp}}$  at  $t = 0$  nor  $Q_{\text{exp}}$  at  $t > 0$  min could narrow  $\Delta$  to less than 10%. There must be some fabric and/or yarn characteristics in Woven DeBaKey that the formula of Chu et al.,  $Q_w$ , fails to take into consideration. An examination of the published fabric characteristics of the three tested commercial woven vascular fabrics (211) indicates they all have taffeta construction with 1/1 plain weave. However, Woven DeBaKey has the lowest packing factor (47%) and highest thickness (0.25 mm). In addition, Woven DeBaKey fabric is the only one in these commercial groups that uses textured yarns. This may suggest that the water permeability formula developed by Chu et al. for woven fabrics has its limitation and cannot accurately predict water permeability of those woven fabrics having a low packing factor and high thickness and is made from textured yarns. Whether it is the combination of all three of these differences in fabric and yarn characteristics, or whether it is one or two of them, that results in the larger discrepancy between  $Q_{\text{prd}}$  and  $Q_{\text{exp}}$  is not known at this time.

In the case of the commercial knitted fabrics, Lopor fabric was the only one that exhibited a close match between  $Q_{\text{prd}}$  and  $Q_{\text{exp}}$ , irrespective of which  $Q_{\text{exp}}$  was chosen. On the other hand, Rhodergon was the only knitted commercial vascular fabric that neither  $Q_{\text{exp}}$  would result in a  $\Delta < 10\%$ . An examination of their fabric and yarn characteristics did not reveal any apparent fabric and/or yarn characteristics that are responsible for the successful (i.e., Lopor) or failed (i.e., Rhodergon) prediction of their water permeability by our formulae.

Because of the lack of other sets of  $Q_{\text{exp}}$  for the experimental vascular fabrics, the above-mentioned  $Q_{\text{exp}}$  source problem does not apply. The  $Q_{\text{exp}}$  of these experimental fabrics were obtained after water flowed through the fabrics for one minute. Hence the reported accuracy of the predicted water permeability formula was not based on the estimated  $Q_{\text{exp}}$  of virgin fabrics like those that Guidoin et al. studied (207). Since the estimated  $Q_{\text{exp}}$  at  $t = 0$  is always greater than the  $Q_{\text{exp}}$  obtained at  $t$  minutes, Chu et al. thus predict that the accuracy of their formulae would change if  $Q_{\text{exp}}$  at  $t = 0$  were used, and the direction of change would depend on the relative magnitude of  $Q_{\text{exp}}$  to  $Q_{\text{prd}}$ . If  $Q_{\text{prd}} > Q_{\text{exp}}$  at  $t = 1$  min as with W2 and W4 (i.e., positive  $\Delta$ ), the use of estimated  $Q_{\text{exp}}$  at  $t = 0$  would further narrow the difference between the predicted and the experimental water permeability. On the contrary, those experimental woven fabrics that showed initial negative difference

( $Q_{\text{prd}} < Q_{\text{exp}}$ ), like W1 and W3, would exhibit a larger difference than the  $\Delta$  based on  $Q_{\text{exp}}$  at  $t = 1$  min. In the experimental knitted fabrics, it is interesting to know that most of the close match between  $Q_{\text{prd}}$  and  $Q_{\text{exp}}$  occurred in those experimental knitted fabrics ranging from K5 to K8. The main difference between these (K5–K8) and other (K1–K4) groups was the size of Dacron yarns (193). The K5 group had 200 denier Dacron yarn, while the K1 group had 250 denier Dacron yarn. It is known that heavier denier yarns are thicker and result in fabrics with more coverage for a given loop length. Thus the K1 group exhibited generally a higher packing factor than the K5 group. Whether this difference in yarn size really contributed to the observed larger error found in the K1 group is not known.

As with any mathematical formula for the purpose of prediction or forecasting, there is a limitation on what it can do. The less than completely satisfactory prediction of water permeability by the formula of Chu et al. in the knitted grafts, particularly in the commercial ones, would be expected with the lower  $R^2$  value (0.492). This finding suggests that a nonlinear, and more complex, relationship among the Buckingham  $\pi$  groups must exist in the knitted fabrics. In addition, the far more complex fabric structure found in the commercial knitted vascular grafts than woven ones could result in additional parameters that have not been included in our modeling. Some examples of such new parameters will be the mathematical description of the surface morphology of velours and textured yarns. Obviously, future refinement of these formulae is required for improving their accuracy in predicting water permeability of various types of medical textiles.

It is important to know that the water permeability formulae of Chu et al. will not replace the experimental water permeability test. The formulae, however, will help investigators or manufacturers in their R/D of medical fabrics by providing some meaningful guidelines for them to work with. With the help of a personal computer, scientists could use the formulae to find out instantaneously how changes in fabric and fiber parameters could affect the water permeability of the resulting fabrics without actually manufacturing and testing them. The formulae also allow scientists to study the effects of a wide range of fabric and fiber parameters on water permeability before they choose a few of them for actual experimental trials. This would save considerable time and resources.

## Bioabsorbable Polymers for Medical Applications with an Emphasis on Orthopedic Surgery

**Pentti U. Rokkanen**

*Helsinki University Central Hospital and University of Helsinki, Helsinki, Finland*

### I. INTRODUCTION

Synthetic materials used for biological applications (biomaterials) can be classified as metals, ceramics, polymers, and composites. Polymeric materials and their composites have been used for years, typical applications being tissue replacement, augmentation and support of tissues, and the delivery of drugs. Based on their behavior in living tissue, polymeric biomaterials can be divided into biostable, bioabsorbable (biodegradable or bioresorbable), and partially bioabsorbable materials. Biostable polymers are inert, cause minimal response in the surrounding tissue, and retain their properties for years. Biostable polymers, e.g., polyethylene and polypropylene, are used as endoprostheses and sutures.

In many cases biomaterial needs to be in place only temporarily, and in such cases bioabsorbable or partially bioabsorbable polymeric materials are more appropriate than biostable ones. Bioabsorbable surgical materials are therefore most suited for temporary internal fixation when the tissue has been traumatized, as the bioabsorbable implant preserves the structure of the tissue at the early stage of the healing of, for example, bone, tendon, or skin. After that, the implant gradually decomposes, and stresses are gradually transferred to the healing tissue. The time taken depends on the material, its molecular weight and structural properties, and the place where it is inserted. Bioabsorption of a material means degradation induced by the

metabolism of the organism. Therefore bioabsorbable surgical devices need no removal, which substantially benefits the individual and produces social savings.

This chapter deals mainly with the properties of bioabsorbable synthetic polymeric materials and their present and possible future surgical applications. It is based on the research work done by the research groups of Professor Pertti Törmälä and myself in traumatology and orthopedic surgery as well as on the published literature. Our investigations have, so far, led to 23 medical academic dissertations (1–23) and more than 1000 different papers (original scientific articles, reviews, patents, abstracts), books, or booklets.

This review deals with the bioabsorbable synthetic polyglycolide (PGA), polylactide (PLA), and polydioxanone (PDS) polymeric devices in the fixation of procedures in trauma or orthopedic disease mainly based on own investigations and experience in more than 3200 operations since 1984 (24).

### II. BIOABSORBABLE SYNTHETIC POLYMERS AND THEIR PROPERTIES

Many polymers have been found to be bioabsorbable in living tissue. The most important surgical bioabsorbable polymers are aliphatic polyesters (polymers and copolymers) of  $\alpha$ -hydroxy acid derivatives. Most of them are

thermoplastic, partially crystalline, or totally amorphous polymers.

Polyglycolid acid (PGA), with a high molecular weight, is a hard, tough crystalline polymer melting at about 224–226°C with a glass transition temperature of 36°C. Unlike closely related polymers such as polylactic acid (PLA) and poly-beta-hydroxybutyric acid (PHBA), PGA is insoluble in most of the common polymer solvents. Polylactic acid is a pale polymer melting at about 174–184°C with a glass transition temperature of 57°C. Such polymers can be processed using different manufacturing processes into fibers, films, rods, screws, plates, clamps, etc. Polydioxanone (PDS) is a colorless crystalline polymer produced by polymerizing para-dioxanone by a ring-opening method in the presence of a suitable catalyst (25). The melting and glass transition temperatures of PDS are 110°C and –16°C, respectively, which means that at room temperature PDS is very flexible and elastic. One advantage of polymeric materials compared to metals and ceramics is that they are easy and cheap to make.

Bioabsorbable materials should fulfill certain criteria and also specific requirements related to any special application of the material or implant. The bioabsorbable materials must be nonmutagenic, nonantigenic, noncarcinogenic, nontoxic, nonteratogenic, antiseptic, and tissue-compatible. They should not cause morbidity and must provide adequate mechanical stiffness and strength. The degradation products should be water-soluble, comprise small molecules, and be naturally occurring metabolites. The degradation should preferably occur by hydrolysis in aqueous media, though it is faster in the presence of certain enzymes (26). The products should dissolve in the extracellular fluid and be excreted via the kidneys and lungs. The breakdown products of polyglycolic acid, CO<sub>2</sub> and water, are examples. Accordingly, this is one mechanism of biodegradation for this major polymer. Another more common mechanism is phagocytosis by macrophages, neutrophils, and giant cells.

No macroscopic inflammatory foreign-body reactions have been seen in own animal experiments. Nevertheless, bioabsorbable implants elicit a histopathologically recognizable nonspecific foreign-body type of tissue response. This seems to be a phenomenon inherent to the degradation and absorption processes of these polymers in the tissues. With regard to the phagocytic and clearing capacity of the tissues, the most demanding phase is the decomposition stage, when the gross geometry of the implant is rapidly lost. At that time, the production rate of polymeric debris particles may exceed the critical limits of the tissue tolerance and transport potential of the anatomical site concerned.

No signs of toxic or teratogenic effects have been recorded with the use of bioabsorbable implants. Sarcomatous changes have been reported to develop at PLA implants placed in the soft tissues of rats, but in other studies no difference in the tumorigenicity was found between the implants made of PLA and those of polyethylene (27). Probably, such tumors merely represent nonspecific response to any foreign material known in rodents. It is even observed that PLA inhibits carcinoma cell growth *in vitro* (28).

### III. SURGICAL APPLICATIONS OF BIOABSORBABLE IMPLANTS

The bioabsorbable implants in current use are sutures and fiber constructions, porous composites, and drug delivery systems. Some are partially bioabsorbable devices, while the others are totally bioabsorbable. Although this review concentrates on bioabsorbable devices used in the fixation of fractures, osteotomies, and soft tissues, it will open with a short remark on other devices used in orthopedics.

#### A. Suture Materials

Suture materials provide support until the collagen is synthesized and woven into a scar. In 1954 Higgins (29) reported on the use of polyglycolide, and in 1967 Schmitt and Polistina (30) introduced PGA sutures, which three years later led to the first commercial synthetic biodegradable suture (Dexon®). Copolymerization of a small amount of lactide with glycolide (PGA/PLLA) led to the development of the second commercial synthetic bioabsorbable suture (Vicryl®) (31).

When bioabsorption occurs *in vivo*, PGA is hydrolyzed to glycolic acid (32). When exposed to glycolate oxidase, the glycolic acid molecules are transformed into glyoxylate, which reacts with glycine transaminase, thus producing glycine. Glycine may be used in protein synthesis or the synthesis of serine, which may be employed in the tricarboxylic acid cycle after transformation into pyruvate (33). PLA undergoes hydrolytic de-esterification into lactic acid, which is incorporated into the tricarboxylic acid cycle and subsequently excreted by the lungs as carbon dioxide (33,34).

Bioabsorbable sutures are widely used in the closure of soft tissue wounds. Several clinical studies have been published on the use of PGA, PGA/PLLA, PDS, and other sutures or bands that are manufactured for use in the repair of tendons and ligaments. Some studies have reported on the use of bioabsorbable sutures in the fixation of bone

fractures and osteotomies. Cutright et al. (35) used poly-lactide acid (PLLA) sutures for internal fixation of the symphysis disruption in *Macaca rhesus* monkeys. Roed-Petersen (36) described two cases in which bioabsorbable polyglycolic acid sutures were used in the fixation of severely dislocated mandibular fractures in young patients. The stability of the fixation was, however, secured by intraoral arch bars with rigid intermaxillary fixation. Vihtonen (5) studied the fixation of distal femoral osteotomy in rabbits with PGA sutures, and the results were satisfactory.

### B. Porous Composites

New possibilities for developing biomaterial for different purposes have been opened up by the technique of combining bioabsorbable polymers in porous or nonporous materials. Hydroxyapatite powders and blocks have applications in bone surgery, e.g., to fill in defects (37). Since porous ceramics are brittle, attempts have been made to increase their toughness by combining them with polymers. Tencer et al. (38) made coralline hydroxyapatite (CHAG)/polymer composites by coating porous CHAG externally or internally with PLA and polymethylmethacrylate (PMMA). Internal microcoatings of PLA and PMMA increased the strength of CHAG three- and tenfold, respectively.

### C. Drug Delivery Systems

Numerous studies have been done on the use of biostable and bioabsorbable polymers for releasing drugs (39). Polymeric devices for the controlled release of drugs and antibiotics have several advantages over traditional repeated dosage methods. For instance, a slow-release mechanism can provide continuous administration without the variable physiological factors associated with gastrointestinal absorption presystemic metabolism. It can save patients from being exposed to greater amounts of the drug than is necessary at the desired site of action.

### D. Partially Bioabsorbable Devices

The reinforcement of bioabsorbable polymeric matrices with biostable fibers yields strong, partially bioabsorbable materials. The first of such materials, plates, rods, ligaments, tendons, scaffolds, etc., were developed by Parsons et al. (40) and by Alexander et al. (41); they comprised PLA matrix reinforced with carbon fibers. Belykh et al. (42) developed partially bioabsorbable composites for bone surgery; they comprised a copolymer of methylmethacrylate and *N*-vinylpyrrolidone reinforced with polyam-

ide fibres. These materials had relatively good mechanical properties (43). Clinical studies have also been in progress for many years in various Soviet medical centers (44). The long-term response of living tissues to the biostable (slowly eroding) polyamide fibers of these materials has, however, not been reported.

### E. Totally Bioabsorbable Devices

The disadvantages of rigid plate fixation to bones, for example the reduction of mechanical strength owing to atrophy of bone and the risk of infection, prompted the experimental use of bioabsorbable devices in fixing fractures of the long bones, as suggested by Schmitt and Polistina (45). Despite some positive experimental results, the materials were not applied clinically. Early attempts to develop bioabsorbable devices were based on the use of implants manufactured with traditional melt-molding techniques, such as extrusion and injection molding. Secure fixation material for bone fractures must have a relatively high tensile strength, but these requirements are not fulfilled with non-reinforced bioabsorbable polymeric implants manufactured with melt-molding techniques. In the late 1970s another approach was made to the fundamental questions raised by bioabsorbable fixation. It was concluded that the requirements for high tensile strength of any fixation material could be best fulfilled by developing reinforced, bioabsorbable composites mostly of polyglycolic and polylactic acid (2). In fact, small PDS implants have been used also in the fixation of small fractures (46).

A review on the bioabsorbable implants was published eight years ago (47). Since then our knowledge has greatly increased, allowing new critical examinations. Many reviews have been published in journals or separately, e.g., on bioabsorbable implants in orthopedic surgery in 1992 (48), on applications in podiatry in 1995 (49), on PGA membranes in 1996 (50), on bioabsorbable polyglycolide devices in 1997 (51), on sports medicine in 1998 (52), and on the use of bioabsorbable implants in traumatology and orthopedics in 1996 (53), in 1997 (54–57), and in 1999 (58).

## IV. DEVELOPMENT OF SELF-REINFORCED BIOABSORBABLE COMPOSITES AND THEIR PROPERTIES

Experimental background. Many macromolecular compounds are bioabsorbable, but only a few possess the prop-

erties necessary for an internal bone fixation device. Some of the most suitable materials have been PGA, PLA, and PDS. In addition to these homopolymers, various copolymers of PGA and PLA have been tested. PLA occurs in different stereoisomeric forms, including polylevulactic acid (PLLA) and various stereocopolymers of polylevulic and polydextrolactic acid (P(L/DL)LA). PGA:PLA copolymer in a ratio of 90:10 and polydioxanone are used as bioabsorbable sutures. Initially, the implants studied were prepared by casting the polymers into sheets or films, which permitted basic investigations on the biological behavior of the compounds in bone tissue but did not make the devices suitable for fracture fixation (47). The fabrication of implants was accomplished by melt-molding and extrusion into rods. The strength characteristics of implants (rods, screws, and tacks) have been improved by the fiber-reinforced composite texture in which the polymer matrix is reinforced with the same material (self-reinforced, SR) (59–62).

In our own early studies, different types of partially or totally bioabsorbable (biodegradable) fiber-reinforced composites were developed, mainly based on different poly- $\alpha$ -hydroxy acids. The most promising results were achieved using self-reinforced (SR) bioabsorbable polymeric composites. These are polymeric materials in which the reinforcing elements and matrix material contain the same chemical elements. The following paragraphs will deal with the technical and medical properties of self-reinforced bioabsorbable polymeric composites.

One method of manufacturing SR composites is based on sintering and/or partial melting of polymer fibers and on shaping the sample under pressure. When the temperature profile of the process is carefully controlled, an SR structure comprising strong fibers embedded in polymeric matrix is obtained. According to Törmälä, the most effective way to create the self-reinforced structure into the bioabsorbable polymer is the mechanical deformation of nonreinforced material. Different models of deformation like free drawing, die-drawing, shearing, rolling, etc. are possible and result in different kinds of microstructures. However, a common feature in all deformation processes is the induction of oriented, self-reinforced structures into the polymeric matrix (63). Our own data on the initial strength of SR-PGA and SR-PLLA rods 3.2 mm in diameter were, respectively, 430 and 300 MPa (bending strength) and 255 and 200 MPa (shear strength). The implants lose most of their strength after 30 to 120 days and are resorbed, respectively, during 6 to 12 months (SR-PGA) or 2 to 5 years (SR-PLLA) *in vivo* depending on the size and composition of the implant. Certain experiments suggest an osteostimulatory potential of bioabsorbable polyester im-

plants, but transient local osteolytic lesions also occur (64,65). The degree of the final restoration of the original tissue architecture within the implant track varies for reasons not yet fully understood (66). The degradation of these polymers occurs mainly by hydrolysis and, to a lesser extent, through nonspecific enzymatic action (67). The degradation rates vary, PLLA having the longest degradation time. The molecular weight, the crystallinity, the thermal history of the sample, as well as the geometry of the implant influence the degradation. In experimental studies by light microscopy, PGA totally disappears from the tissues within 36 weeks (64). For copolymers the degradation rate is dependent on the ratio between the constituent homopolymers. It is stated that PLLA implants can be visualized in the bone with magnetic resonance imaging (68,69), though histologic examination is the most reliable method in this respect.

Prior to and parallel with the clinical studies of the bioabsorbable fracture fixation implants, more than 6200 animals were operated on in our experimental studies (e.g., 2–5,7–10,12,13,15–17,21,23). In these studies, macroscopic, radiographic, microradiographic, histologic, histomorphometric, oxytetracycline labeling, computed tomography, quantitative computed tomography, and magnetic resonance imaging studies were done, and the strength measurements of the implants and fixations were performed in different situations. These studies have made the basis for our clinical investigations and use of self-reinforced implants in the clinical trials and praxis. Osteotomies of the distal femur in 19 rabbits were operatively fixed with totally biodegradable implants, and the experimental operations were started on January 15, 1982 (2).

The use of PGA/PLA rods, SR-PGA, and SR-PLLA rods, screws, and other devices (Figs. 1 and 2) in fixing cancellous bone fractures has been documented in more than 3200 patients during the past 15 years at our department (e.g., 24,70,54) (Tables 1 and 2). The healing results are comparable or even better than those obtained with metallic fixation. SR-PGA rods and screws (Bionx devices) are routinely used nowadays or are being studied in clinical research in about 20 countries, Western European countries, the USA, Japan, etc., or have been used in more than 300,000 cases.

Since living cells help to absorb biomaterials, an important question is which factors affect the intensity and duration of the cellular response. Clinically it is desirable to keep any reaction as mild as possible so as not to delay healing. As with the clinical use of bioabsorbable PGA and PGA/PLA sutures (71), macroscopic symptoms of foreign-body reaction, such as local fluid accumulation (LFA) and transient sinus formation (TSF), sometimes occur but

**Figure 20.1** Self-reinforced poly-L-lactide (SR-PLLA) rods (a) and screws (b) routinely used in bone fixations.

without any adverse affect on the healing of the fracture (6,11).

SR-PGA is a widely used bioabsorbable fixation material about which qualitative conclusions can be drawn regarding factors contributing to LFA or TSF reactions and their treatment (Table 3). A general hypothesis, based on the above observations and on the experience of other research groups, is that this reaction is correlated to the relation between the local accumulation of polymer debris from the implant and the capacity of the surrounding tissues to eliminate the debris. If this capacity is low, e.g., due to poor circulation or low metabolic activity, the polymer debris may accumulate locally, leading to local transient disturbances, such as an increase of osmotic pressure, with subsequent manifestations of LFA or TSF. The correct surgical technique, including the use of the right implantation depth (21), is important to prevent sinuses.

**Table 20.3** Treatment of Transient Fluid Accumulation

Small and painless fluid accumulation can be observed.  
Large or painful accumulations must be aspirated with a needle.

The first experimental operation with a PGA/PLA implant was done at our department on January 15, 1982, the first clinical operation on November 5, 1984 (Rokkanen-Böstman), and the first operation with the use of an SR-PLLA implant on July 27, 1986, and on August 19, 1988, respectively.

## V. BIOABSORBABLE FIXATION IN FRACTURE TREATMENT

Bioabsorbable fixation (Table 4) has been used in several kinds of fractures in adults: glenoidal rim fractures, fractures of the proximal humerus, fractures of the lateral humeral condyle, fractures of the medial condyle of the humerus, fractures of the olecranon, fractures of the radial head, fractures of the distal radius, fractures of the hand, fractures of the femoral head and neck, fractures of the femoral condyles, fractures of the patella, fractures of the tibial condyles, malleolar fractures, fractures of the talus, fractures of the calcaneus, and fractures of the metatarsal bones and phalanges of the toes (72).

The correct surgical technique with bioabsorbable rods is essential. The fracture should be reduced exactly and fixed with clamps or fingers. Holes are drilled for implants, and the channel is flushed and measured. The rod is inserted into the drilled, measured, and flushed hole with an applicator. The rod is introduced into the channel by hammering at the piston of the applicator. Using this surgical technique, polyglycolide rods were clinically used in the fixation of several types of cancellous bone fractures and osteotomies of the upper and lower limbs. In these studies,

<sup>a</sup> The clinical course was uneventful in 82% of the patients.

for example, 289 patients were operated on using mainly SR-PGA rods in the fixation of displaced ankle fractures (6). Other research groups have used PLA implants for the fixation of ankle fractures (73–75) and of several kinds of small-fragment fractures (76,77). In radial head fractures the first prospective study of 24 patients showed encouraging results (6). These results were confirmed (19). Eight patients with radial head fractures were also successfully treated with PDS pins (78). Similarly, the retention properties of bioabsorbable pins by transarticular fixation seemed to be successful in the treatment of fractures of the humeral capitellum (79). In fractures of the olecranon the use of both bioabsorbable pins and screws showed equal and favorable results (11). Open reduction and internal fixation with bioabsorbable SR-PGA or SR-PLLA devices were used in the treatment of 32 fractures of the hand at our department and also at another department in 46 cases (80). Promising results were obtained, with the exception of the Bennett's fractures, where the outcome was less favorable in our series. The same conclusion can be drawn from the fixation of scaphoid delayed union or nonunion at Matti-Russe operation (19). Promising clinical reports have been published on the use of PDS rods for fracture fixation in the hand (81).

An increasing number of clinical reports have been published on the growing use of polylactic acid implants. Thirty-five successful operations out of 40 were performed using PLA 98 rods or screws for osteosynthesis in cancellous bone fractures or orthopedic conditions (82). In one multicenter study, nonreinforced Poly-L/DL-lactide 70/30 pins were used in small fragment indications, but resulting in 4/57 redislocations (83). SR-PLLA pins were studied in 27 patients with small-fragment fractures or osteotomies treated by internal fixation without redisplacements (84).

The correct operation technique with bioabsorbable screws and with drill bit, tap, countersink, screwdriver, and screws is essential. The fracture should be reduced exactly and fixed with clamps. Holes are drilled and tapped with a special tap. The hole is countersunk for the screw head, and the channel is measured and flushed. The screw is placed in a screwdriver and inserted into the screw hole. The screw is tightened. The implants can be shortened during the operation with a small oscillating saw. The excess part of the screw head is removed with a small oscillating saw.

In a prospective study, 319 operations were performed between 1987 and 1991 (11). SR-PLLA screws alone were used in 38 fixations, SR-PLLA and SR-PGA screws in 14 fixations, and SR-PGA screws in 247 fixations (Fig. 3). SR-PGA rods were used as controls in 20 fixations. The trauma indications were 41 olecranon fractures and 259 ankle fractures. The method showed subjectively excellent

**Figure 20.3** Displaced fracture of the ankle in a 59-year-old female. Radiographs taken on admission (a, b). Radiographs after open reduction and internal fixation with two SR-poly-L-lactide screws three and a half year later (c, d).

or good results in more than 90% of the patients with a fracture. SR-PGA screws can also be used in osteoporotic bone (22), but they are not recommended for fixation of displaced ankle fractures in alcoholics because of the risk of poor cooperation and redislocation (6/16 reoperations in our series) (22). Six patients with displaced split-depres-

sion-type tibial condylar fractures were treated with SR-PGA screws. One patient underwent reoperation due to an unacceptable primary fracture reduction unrelated to the implant material. The others healed well (22). In 4/28 patients with proximal tibial osteotomies and fractures, redisplacement was noted (85). Good indications for bioabsorbable fixation are also fractures of the talus (22) and calcaneus (22).

In one clinical study, 19 ankle fractures were fixed by plates and screws made of bioabsorbable polylactic acid (86). Fracture union was achieved within 6 weeks, though several fractures demonstrated an aseptic soft tissue problem. In seven patients, volume-reduced plates and screws with flat heads were applied without any soft tissue reaction (86). Patients with a closed, displaced fracture of the ankle were managed with medial malleolar fixation using either 4.0-millimeter orientruded polylactide screws (83 patients) or 4.0-millimeter stainless steel screws (72 patients) (87). It was concluded that polylactide screws are safe and effective. Bioabsorbable screws, pins, and nails of orientated polylactide were developed for fixation of bone grafts, fractures, and osteotomies, and their use was evaluated in 143 patients with bony union in all except one (88).

The SR-PLLA screw 6.3 mm in diameter was found as good as the metal screw to fix a bone-patellar tendon-bone graft for the anterior cruciate ligament in a bovine experimental model (89). SR-PLLA lag screws 6.3 mm in diameter can also be used safely to fix subcapital femoral neck fractures in Garden Stage I and II fractures and in younger patients with Garden III fractures (90).

## VI. BIOABSORBABLE FIXATION IN ORTHOPEDIC SURGERY

Bioabsorbable fixation of bone in osteotomies, arthrodeses, and in other reconstructive orthopedic surgery (Table 4) is valuable, as metallic fixation can never be an ideal fixation modality, due to corrosion, stiffness, and stress shielding. Mainly rods and screws are used in orthopedic procedures for bones.

The distal chevron osteotomy of the first metatarsal bone for hallux valgus is widely used. After osteotomy, lateralization of the distal part of the first metatarsal bone is performed. The drill channel is made for a rod 2.0 mm in diameter. The osteotomy is fixed with one rod (Fig. 4). Bioabsorbable SR-PLLA pins (84), SR-PGA pins (91), and PDS-pins (92) can be used reliably to fix distal chevron osteotomy and PLLA staples in Akin osteotomy (93) as well as widely in foot surgery (94,95). In proximal osteotomy of the first metatarsal bone for severe hallux valgus a wedge osteotomy is done one centimeter from the tarso-

(a)

(b)

**Figure 20.4** Hallux valgus of the left foot in a 45-year-old female. Radiography taken on admission (a). Radiography after chevron osteotomy fixed with one SR-polyglycolide rod one year later (b).

metatarsal joint distally. The osteotomy is fixed temporarily by a clamp. The tapped drill channel is made from the distal metatarsus to the proximal through the osteotomy. After countersinking the head one SR-PLLA screw (4.5 mm in diameter and 30–40 mm in length) is inserted to

fix the osteotomy or the first tarsometatarsal arthrodesis. By using proximal osteotomy, statistically slightly better results were achieved in the treatment of metatarsus primus varus and hallux valgus (96).

In talocrural arthrodesis the articular surface from all parts of the joint is removed. Tibia, talus, and fibula are compressed together with clamps. One drill channel is drilled from the fibula through the tibia into the talus, one from the medial side of the tibia into the talus, and one anteriorly from the tibia to the talus. The arthrodesis is fixed with three SR-PLLA screws. The union rate achieved has been over 90% (11). Using this technique one redislocation out of 25 operations was observed. In a study of 11 patients, 12 arthrodeses of the ankle joint were performed by using bioabsorbable SR-PLLA (or SR-PGA) screws (Fig. 5). Solid fusion was achieved in 11 of the 12 cases in nine weeks (11). In subtalar arthrodesis, due to malposition

after injury, osteoarthritis, or rheumatoid arthritis, the articular surfaces from the talocalcaneal, the talonavicular, and the calcaneocuboidal joint are removed. The surfaces are compressed tightly together and fixed with three SR-PLLA screws: one from the talus into the calcaneus, one from the navicular bone into the talus, and one from the calcaneus into the cuboid bone. The results, especially after subtalar arthrodesis, have been excellent (18). In severe destruction of the talocrural (TC) joint in osteoarthritis (or rheumatoid arthritis), operative fusion is required. In severe destruction of the subtalar joints in osteoarthritis (or rheumatoid arthritis), operative fusion is required for painless weight-bearing. The postoperative course was uneventful in all 21 cases operated at our department.

In the proximal tibial osteotomies for osteoarthritis of the knee joint the fixation has been done with three screws (54). Two screws are directed from the proximal tibia to

**Figure 20.5** Posttraumatic osteoarthritis of the ankle in a 55-year-old female. Radiographs taken on admission (a, b). Radiographs after arthrodesis fixed with one SR-polyglycolide and two SR-poly-L-lactide screws one and one-half years later (c, d).

the distal from the lateral side and one from the diaphysis to the medial condyle. The fixation should be done using either SR-PLLA screws of 4.5 mm in diameter or SR-PLLA lag screws of 6.3 mm in diameter.

In the fixation of osteochondritis dissecans (OCD) of the knee, bioabsorbable rods of 1.1, 1.5, or 2.0 mm in diameter are used as a fixation device. In earlier operations the open technique was used, and the OCD fragment was reduced and usually fixed with one or two rods in the knee. In the arthroscopic technique a rod, usually 30 mm in length, can be inserted to fix the fragment. In our series the results were excellent or good in 19/24 patients (97). In one series it is concluded that the poly-L-lactide pin is safe and useful in the fixation of three osteochondrites and two osteochondral fragments in the knee joint (98).

It is possible to prevent or delay the course of the rheuma disease, improve the function, and eliminate or diminish the pain with operations. Bioabsorbable devices can be used in the following operative procedures for rheuma patients when fixing bone, joint, or ligament: osteotomy, arthrodesis (especially PIP, DIP, IP, and base joint of the thumb, trapezio-, metacarpo-, scaphotrapezio-, wrist-, subtalar, and TC joint), and refixation (especially the ulnar collateral ligament of the I metacarpophalangeal joint). Polylactide (not polyglycolide) devices must be used in rheuma patients.

A destroyed wrist mostly caused by rheumatoid arthritis is an indication for arthrodesis. In this surgical technique the synovial membrane, cartilage, and sclerotic bone from the radiocarpal and midcarpal joints are removed. With a drill bit of 3.2 mm a channel is drilled in the capitate bone and radius. Some of the bone between the scaphoid and lunate bones is removed. An SR-PLLA rod 3.2 mm by 50–70 mm is inserted first in the radius with the other end pushed back in the capitate bone. The rod will retain the position until fusion has occurred. Fifty-three arthrodeses (18 in the wrist, 18 in the hand, 6 in the talocrural joint, and 11 in the subtalar-calcaneocuboid-talonavicular joint) were performed on 47 patients using SR-PLLA screws and rods with two nonunions in the TC arthrodeses (18).

Arthrodesis is indicated in the osteoarthritic or rheumatic destruction of the joint in the hand if it is painful and causes continuous inconvenience for the patient. In the surgery, the synovial membrane and the rest of the cartilage are removed until the proper angle is obtained. Refreshed and molded surfaces are compressed and held together with hands or clamps. The channels are drilled for two crossed SR-PLLA rods with drillbits of the same size, and the rods are inserted. In a study, 24 metacarpophalangeal arthrodeses fixed together with polylactide and metallic rods were performed with union in 22/24 cases (99).

A destroyed I metatarsophalangeal joint owing to the osteoarthritis or rheumatoid arthritis is an indication for operation. Resection arthroplasty and arthrodesis are the operative methods used. In a randomized study, the first metatarsophalangeal joint was fused in 39 patients with rheumatoid arthritis using either bioabsorbable SR-PLLA (3/20 nonunion) rods or Kirschner (0/19 nonunion) wires (100).

## VII. BIOABSORBABLE FIXATION IN TRAUMATOLOGY AND ORTHOPEDIC SURGERY IN CHILDREN

Certain fractures involving the growth plate need specific consideration due to a growth disturbance often related to them. Accurate reduction and internal fixation are essential especially in types 3 and 4 according to the classification of Salter and Harris (101). Metallic pins have been used in the fixation of physal fractures in children. In addition, osteotomies and arthrodeses have been fixed with metallic pins and with metallic screws. When bioabsorbable implants were experimentally used in young rabbits, it was found that the destruction of 7% of the cross-sectional area of the growth plate caused permanent growth disturbance and shortening at the femur but that of 3% did not (4). In one study, two SR-PGA pins 1.1 mm in diameter were used in the fixation of experimental distal femoral physal fractures in rabbits (102), giving sufficient stability for healing without any signs of impaired function of the growth plate. Accordingly, SR-PLLA pins 1.1 mm in diameter provided sufficient stability for healing of experimental distal femoral physal fractures of five-week-old rabbits (103). In addition to small-fragment fractures, osteotomies, and arthrodeses, the self-reinforced implants can also be used in the intramedullary fixation of growing bone fractures even in the diaphyseal area (54).

Most physal fractures and small-fragment fractures requiring open reduction and internal fixation are suitable for bioabsorbable rod fixation. Rod fixation with small-diameter (1.5–2.0 mm) SR-PGA rods appears to be safe even after transphysal placement of the fixation rods. The operation technique is partly the same as that with metallic fixation. Our own series of 140 fractures in children treated successfully with bioabsorbable rod fixation included mostly elbow fractures (Fig. 6), ankle fractures, and fractures of the phalanges and metacarpal bones (104). The complications recorded were loss of reduction (2.8%), inaccurate position of fixation or minor redisplacement (1.4%), and superficial infection (0.7%). Transient reactions (fluid accumulations, not sinuses) seem to be quite

(a)

(b)

**Figure 20.6** Displaced fracture of the lateral humeral condyle in a 7-year-old girl. Radiography taken on admission (a). Radiography (b) after open reduction and internal fixation with an SR-PGA rod one year later.

rare in children (2.1%) and always mild in character. There are many other investigations on pediatric fractures with successful results (105–108).

Bioabsorbable implants made of PGA and PLLA have been used in the fixation of metaphyseal osteotomies of small bones, such as the base and distal part of the first metatarsal bone in the treatment of hallux valgus. SR-PLLA screws are suitable for fixation of pelvic osteotomy

(Chiari), whereas ultra-high molecular weight PLA screws are well suited in rotational acetabular osteotomies to transfix the acetabulum to the grafted bone and the pelvis in children and adults (28 hips) (109) and in another 13 cases (hips, total 41) (110) in the treatment of congenital hip dysplasia. “There were four postoperative complications. A small subcutaneous abscess occurred around the nonabsorbable sutures in 2 hips within 1 year after operation that healed after removal of the suture material. Another hip had developed mild thrombophlebitis in the lower leg of the operated side, which healed with aspirin. A 55-year-old female patient developed itching local dermatitis of unknown origin, 3 cm in diameter, on the skin incision, 8 months after surgery. The result of the patch test was negative for each of the following materials: lactide, low-molecular weight poly-L-lactide and extract of poly-lactide.” In addition, SR-PLLA screw fixation has been successfully used to stabilize subtalar extra-articular arthrodesis in the treatment of severe flatfoot and hindfoot valgus deformity (111).

#### VIII. BIOABSORBABLE FIXATION IN SUPPORTING SOFT TISSUE INJURIES

The common injury of skiers is the total rupture of the ulnar collateral ligament of the first metacarpophalangeal joint of the thumb. The fixation of ruptures of the ulnar collateral ligament of the thumb is important (112). It offers a fast, simple, and safe possibility to treat this common sports injury. Seventy patients with clinically total rupture were treated fixing the ligament with SR-PLLA minitacks. Sixty-nine out of 70 patients healed without complications. The results of this method were confirmed in another study, which included 140 patients (113). Late ligament instability in the ankle can be treated safely also by using bioabsorbable tacks as a fixation device.

Another indication, the fixation of knee meniscus bucket-handle lesions with SR-PLLA arrows, has presently gained more importance (114). The arthroscopic technique has made it possible to fix a certain type of meniscal tear instead of using the former suturing technique. The method to fix meniscus bucket-handle ruptures with SR-PLLA arrows was developed (114,115) and proved to be safe and the fastest way to treat these injuries (116). In the operation, standard arthroscopic portals are used for meniscus fixation in the posterior 2/3 of the meniscus. In the anterior lesion (1/3), accessory portals may be necessary. The rupture is freshened with an arthroscopic rasp and reduced. The cannula with a blunt obturator inside is inserted. The obturator is removed. A channel is made

with a special needle through the meniscus. Irrigation fluid is retracted. The needle is retracted. The arrow is pushed to the surface of the meniscus with the obturator via the cannula. The implant is inserted by hammering into the meniscus. The T-shaped head is left on as the surface of the meniscus. The entire procedure is repeated at another site (distance 5–10 mm). Two to four arrows are needed.

A third indication is the use of SR-PLLA plugs in connection with reconstruction operations on the habitual dislocation of the shoulder (117) and the Bankart lesion with special tacks using the arthroscopical technique. There are many different procedures to prevent the recurrent dislocation of the shoulder joint. The Bristow–Latarjet operation is one of the techniques in which the top of the coracoid process is transferred. The fixation of the coracoid bone block conjoined the tendon of coracobrachialis and the short head of the biceps in the drill hole in the scapula neck through the subscapularis tendon was tested with SR-PLLA expansion plugs (117). In 33 patients, no dislocation of the coracoid bone blocks was noticed. For a Bankart lesion, it is possible to do the fixation with special tacks using the arthroscopical technique (118–120).

## IX. COMPLICATIONS OF BIOABSORBABLE IMPLANTS

The general complication rates with bioabsorbable fixation seem to be of the same magnitude as with metallic fixation. Several bioabsorbable materials form small debris particles during the last stages of degradation. Therefore it is important to know whether the resorption itself causes complications. Comprehensive studies of the complications associated with bioabsorbable orthopedic devices are limited, but extensive clinical experience with follow-up times of up to 15 years is available.

When wound infection associated with bioabsorbable or metallic devices used in the fixation of fractures, arthrodeses, and osteotomies was studied in 2114 operations, the infection rate was 0.7% with pure SR-PLLA implants but 4% with pure SR-PGA implants (121). When comparison of the infection rates was done between metallic (2073 patients) and bioabsorbable fracture fixation devices (1012 patients) in displaced ankle fractures, the infection rates were 4.1% and 3.2%, respectively.

The cytological analysis of the material aspirated from the effusion, which occasionally develops around a polyglycolic acid (PGA) osteosynthesis implant, showed a predominance of inflammatory monocytes and, in particular, lymphocytes (122). This suggested that PGA is an immu-

nologically inert implant material that induces inflammatory mononuclear cell migration and adhesion, leading to a slight nonspecific lymphocyte activation.

Out of 216 patients with displaced malleolar fractures operated on using bioabsorbable polyglycolide screws, 24 developed a transient local nonbacterial inflammatory reaction on average 3 months after the operation. Upon histopathologic examination, these tissue responses were found to be nonspecific foreign-body reactions. No deleterious effect of these tissue responses on the union of the fractures could be detected (123). A series of 286 patients with unimalleolar or bimalleolar fractures were treated by open reduction and internal fixation using cylindrical rods made of polyglycolide (124). Among them 18 nonbacterial inflammatory tissue responses (6.3% of the total) occurred, requiring surgical drainage. When Kirschner wires were compared to PGA rods in the treatment of distal radial fractures (Frykman types I, II, V, and VI) in 15 human cases, PGA was associated with more foreign-body reactions at 3 to 6 months; in these cases the technique could be a causative factor, as the rods were placed partly outside the bone (125). Nine out of 40 Colles fractures fixed with SR-PGA rods developed sinus formation (126). Frøkjær and Møller (1992) (127) could not recommend SR-PGA rod fixation for ankle fractures due to complications and osteolysis. However, osteolysis or decreased density is a transient phenomenon (70,128,129). Also, the cases of knee synovitis observed by Tegnander et al. (130) (1994) were too early to result from PLA degradation. Such complications can be explained with the rod insertion technique or with the lesion and operation itself. Tegnander et al. also found high levels of Csa des Arg in plasma incubated in the presence of polylactic acid with conclusions against the biocompatibility of polylactic acid. However, the test procedure has been found inadequately designed and the conclusion not justified (131). Two cases of severe aseptic synovitis of the knee were reported 8 and 13 weeks after fixation of a fracture of the intercondylar eminence with PGA rods (132). Both knees were treated by surgical revision and synovectomy. Histologic examination revealed a severe foreign-body type of reactive synovitis in the absence of infection. Local complication after fixation of displaced ankle fracture with PGA rods was reported in two cases (133).

Although complications with the use of bioabsorbable fixation are similar to those of any method of internal fixation, polyglycolide polymer may cause a clinical foreign-body reaction. This occurs 8–16 weeks after the operation but has nothing to do with bone healing. Aspiration with a needle of 1.1 mm is necessary in painful or reddish fluid accumulation and an incision and antibiotics in sinuses.

Complete healing is reached in a few weeks. The incidence of the fluid accumulation when using polyglycolide implants has been recently lower than 2% and has hardly ever occurred with the use of polylactide implants (58). To avoid this complication the accurate operative technique is essential, which is also emphasized in this article.

## X. THE FUTURE OF BIOABSORBABLE SELF-REINFORCED COMPOSITES IN ORTHOPEDICS AND TRAUMATOLOGY

The advantages of bioabsorbable implants are significant. Osteoporosis and other harmful consequences associated with rigid metallic implants can be avoided. The avoidance of implant removal procedures results in financial benefits and psychological advantages. The bioabsorbable devices are especially suitable for arthroscopical and other minimum-invasive surgical techniques. The advantages of these implants are not only limited to the mechanical function. They themselves have osteogenic potential. With these polymeric implants it is also possible to combine physiologically active components which accelerate or facilitate tissue healing and prevent or heal infections.

The application of bioabsorbable SR composites such as rods, screws, and tacks is expanding rapidly. The annual number of operations with devices manufactured from these materials has increased steadily over the past years. This means that surgeons have accepted the use of these implants in certain well-defined circumstances. The main goals are to improve the properties of implants and develop surgical techniques suitable for use with bioabsorbable implants. Research is continuing in several units where it has been started already years ago (134–137).

The latest SR composites are strong enough for fractures of load-bearing cancellous bones to be fixed without a plaster cast and with an early mobilization of the patient. Cortical bone osteotomies have also been securely fixed on an experimental basis and clinically in hand and foot surgery.

Bioabsorbable fixation devices have been in clinical use in orthopedic surgery for 15 years. The cumulative number of operations with self-reinforced bioabsorbable implants in surgery has exceeded 300,000. In addition, other bioabsorbable implants than SR bioabsorbable implants increase the total number operations performed. The number of surgical applications will continue to increase in orthopedics and also in other surgical specialties, so that in the future these implants will have a more significant part in modern surgical technique.

## ACKNOWLEDGMENTS

The studies of our research group have been financially supported by the Finnish Parliament, the Academy of Finland, the University of Helsinki, Helsinki University Central Hospital, Research Foundation of Orthopaedics and Traumatology, and Tampere University of Technology. The support has been of prime value to the investigations of our research group.

## Polymers for Artificial Joints\*

Naohide Tomita and Hiroshi Fujita

*Kyoto University, Kyoto, Japan*

Kazuya Nagata

*Industrial Technology Center of Okayama Prefecture, Okayama, Japan*

### I. ARTIFICIAL JOINTS

#### A. History of Artificial Joints

A typical view of a joint is shown in Fig. 1a; it is composed of bone, cartilage, a joint capsule, joint fluid, and ligaments. When the cartilage has large lesions as shown in Fig. 1b, some replacement or regeneration of the joint is required (1). Several regenerative treatments, including bone osteotomy, autograft, and cultured cell implantation, have been developed, but joint replacement with an artificial joint is the most common and effective treatment for the aged. The use of biological and inorganic materials for joint arthroplasty became popular in the early twentieth century. Deformed or ankylosed joint surfaces were contoured and an interpositional layer inserted to resurface the joint and allow motion, as shown in Fig. 2a. Fascia lata grafts, periarticular soft tissues, and gold foils were tried as the interpositional layer. Then cup arthroplasty and joint

\* Part I of this chapter is by Nagata and Tomita; Part II is by Fujita.

head replacement, as shown in Fig. 2c, were also used for hip and finger joints as shown in Fig. 2b and c. They became the standard operation for hip reconstruction until the advent of modern total hip arthroplasty. The artificial joint in the restricted sense should have an artificial articulating joint mechanism as shown in Fig. 2d. The modern total joint arthroplasty was pioneered by McKee (1951)

**Figure 21.1** Typical view of joints. (a) Normal joint; (b) arthrotic deformity.

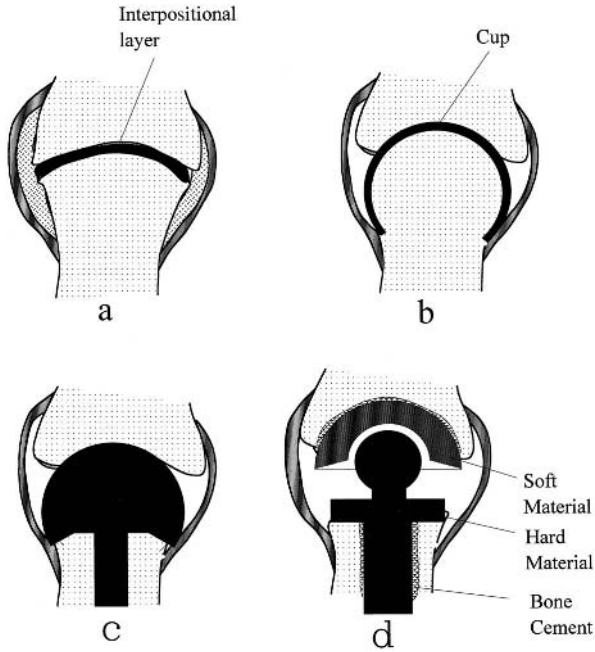

Figure 21.2 Typical view of arthroplasty for deformed joint.

and by Charnley (1961) (2,3,4) after several abortive attempts. Figure 2d shows schematics for modern total arthroplasty established by Sir John Charnley. The artificial joint has a sliding interface using a combination of a hard material against a soft material. He used a metallic femoral head as the hard material and a polytetrafluoroethylene shell as the soft material. He then cemented the stem and cup with cold-curing acrylic cement (polymethylmethacrylate) to fix the components securely in the bone and to transfer stress more uniformly. The polytetrafluoroethylene was replaced by high-density polyethylene (HDP) and later by ultrahigh molecular weight polyethylene (UHMWPE) because of its excessive wear and tissue reaction. The metal-on-metal total hip arthroplasty did not prove satisfactory at that time because friction and metal wear could not be prevented.

Typical shapes for artificial hip and knee prostheses are shown in Fig. 3 and Fig. 4. Motion in hip prostheses is universal but there is only one center for bending and rotating, whereas knee prostheses should bear more complicated motion, including flexion, rotation, and anterior-posterior sliding. The contact area on the sliding surface of knee prostheses is narrower than that of hip prostheses because of the difference in movement.

Figure 5 shows a rough estimation for the prognosis of total hip replacement. Incidence of infection has been diminished because of improvements in surgical equipment and technique. Obviously, loosening is the most seri-

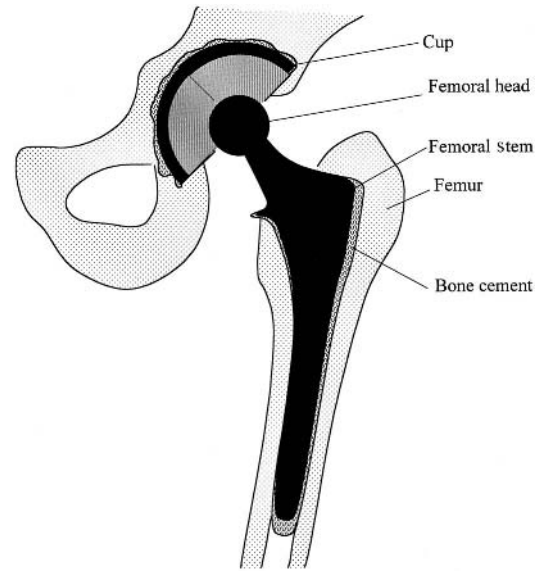

Figure 21.3 Schematic drawing of a typical artificial hip joint.

ous problem in modern total joint replacement. Loosening is caused by mechanical loading, but the UHMWPE wear particles generated at the articulating surfaces are thought to accelerate the loosening process.

**B. Ultra-High Molecular Weight Polyethylene for Articulating Surfaces**

Ultra-high molecular weight polyethylene (UHMWPE) has been used as the bearing material in total joint prostheses (hip, knee, ankle, shoulder, elbow, and wrist) implanted since the 1960s. UHMWPE was chosen because of its unique material properties, such as a low friction coeffi-

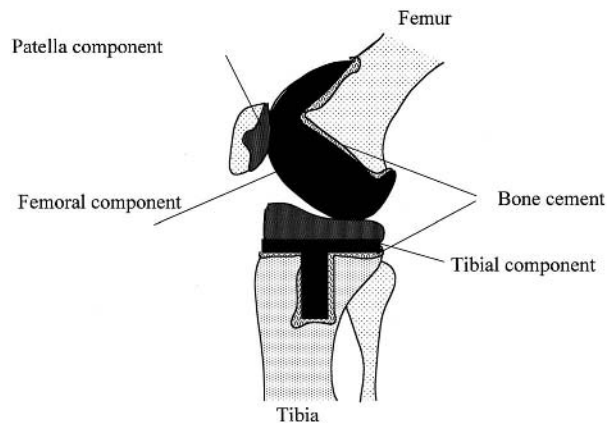

Figure 21.4 Schematic drawing of a typical artificial knee joint.

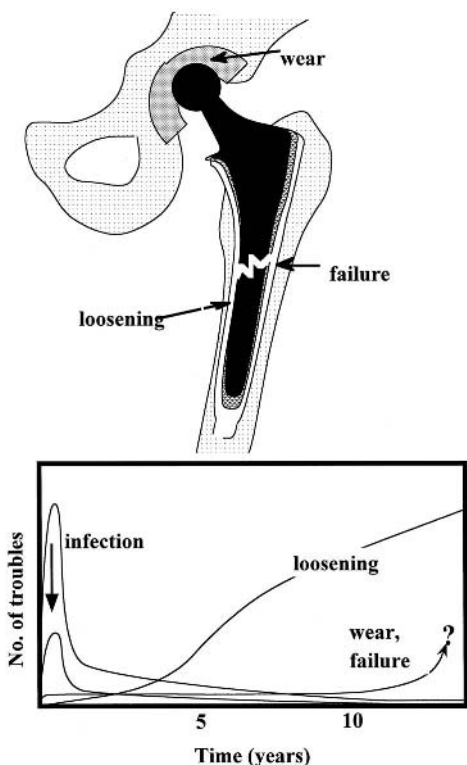

Figure 21.5 Rough estimation for prognoses of total hip replacement.

cient, high resistance to wear, high impact resistance, high ductility, and stability in the body (5). However, producing the UHMWPE implant is complicated due to its high molecular weight. Research and development efforts in the manufacturing process of UHMWPE are the key points for improvements in quality.

1. Structure and Properties of UHMWPE

UHMWPE is a linear type of polyethylene that has a branching chain loosely contained in one chain (Fig. 6). The molecular weight of UHMWPE is extremely high, normally in the range of two to six million. These values are in contrast to 20,000 to 300,000 for regular polyethylenes such as high-density polyethylene (HDPE), low-density polyethylene (LDPE), and linear low-density polyethylene (LLDPE) (6). The UHMWPE molecular chain arrangement in the solid state is HDPE, which consists of highly ordered chain-folded crystallite regions and a relatively unoriented amorphous region. Long tie molecules in the amorphous region connect the crystalline with the surrounding crystalline. The major difference between the morphology of UHMWPE and that of HDPE is that the

Figure 21.6 Chemical structure of UHMWPE.

number and chain length of the tie molecules in UHMWPE is much higher than that in HDPE (7). This is the reason that UHMWPE exhibits superior physical properties and resistance to wear in regular polyethylene and various types of polymers (Table 1, Fig. 7) (7,8). UHMWPE also exhibits superior impact strength. Figure 8 shows a characteristic curve correlating impact strength with the molecular weight of polyethylene. The impact strength increases with increasing molecular weight initially, reaches a maximum, and decreases slightly upon a further increase in molecular weight in the ultra-high molecular weight region (9,10).

The density of polyethylene decreases with the increasing molecular weight of polyethylene as shown in Fig. 9.

Table 21.1 Physical Properties of Polyethylene

Property	High-density polyethylene	Ultra-high molecular polyethylene
Molecular weight/millions g · mol <sup>-1</sup>	0.05–0.2	2.6
Melting point/°C	130–137	125–135
Density/g · cm <sup>-3</sup>	0.952–0.965	0.930–0.945
Tensile yield/MPa	26.2–33.1	19.3–23
Elongation at break/%	10–1200	200–450
Tensile modulus/MPa	400–4000	600–1500
Izot impact/J · m <sup>-1</sup>	21–210	<1070–no break
Shore-D hardness	67–73	60–65

Figure 21.7 Izod impact strength of various polymers.

There always exists a correlation between crystallinity and density for crystalline polymers. The crystallinity and density of UHMWPE are lower than that of HDPE, due to the high molecular weight and chain structure. The crystallinity of UHMWPE, estimated with the use of differential scanning calorimetry, lies in the range of 45 to 65%, while that of HDPE is 70% or higher (10,13).

2. Synthesis of UHMWPE

Figure 10 shows the manufacturing process of UHMWPE for artificial joints. The synthesis of UHMWPE is conducted with use of a Ziegler and Natta coordination catalyst under low pressure. The catalyst is made from titanium chloride and an aluminum alkyl compound. The polymerization reaction is a heterogeneous system involving a hy-

Figure 21.8 Relationship between molecular weight and impact strength of polyethylene.

Figure 21.9 Relationship between molecular weight and density of polyethylene.

drocarbon solvent (hexane), ethylene gas, and the catalyst. The polymerization is typically conducted at pressures between 0.4 and 0.6 MPa, at a temperature between 66 and 90°C (6,8). The polymerization results in a fine granular white powder. In some grades, a very fine calcium stearate powder is added after isolation and drying of the reactant powder. There are mainly two companies manufacturing UHMWPE for medical applications: Ticona (Hoechst, Hostalen GUR) and Montell (Himont, HiFax). The powder properties of typical grades of UHMWPE are shown in Table 2.

3. Processing of UHMWPE

When UHMWPE is melted, it does not flow easily, as low molecular weight polyethylenes such as LDPE and HDPE

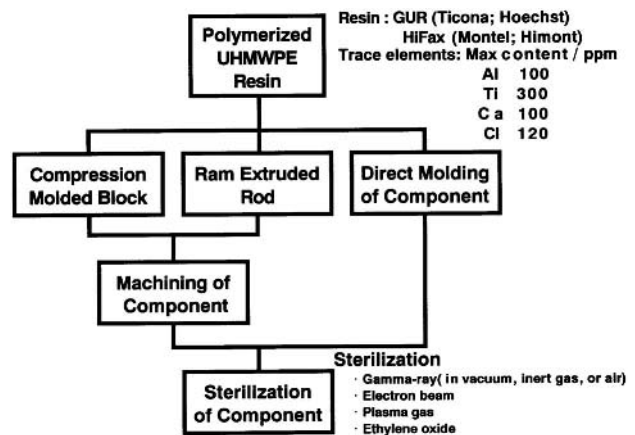

Figure 21.10 Manufacturing process of UHMWPE for artificial joints.

**Table 21.2** Powder Properties of Typical UHMWPE Grades (Ticona; Hoechst, Hostalen GUR)

Grade	Mean particle size/ $\mu\text{m}$	Intrinsic viscosity $\eta/\text{dl} \cdot \text{g}^{-1}$	Molecular weight <sup>a</sup> $\times 10^4$	Calcium stearate
GUR1120	120	1920	308	<50 ppm
GUR1150	120	2700	490	<50 ppm
GUR1020	120	1920	308	<5 ppm
GUR1050	120	2700	490	<5 ppm

<sup>a</sup> ASTM method: Molecular weight =  $5.37 \times 10^4 \times [\eta]^{1.37}$

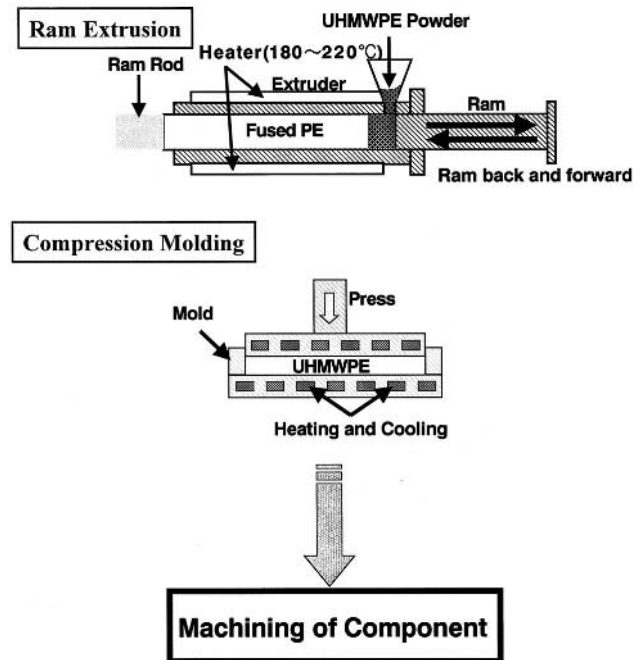

do, owing to its high molecular weight and excessive entanglement (Fig. 11) (9). When UHMWPE is heated above its crystalline melting temperature (125–135°C), the resin becomes rubbery but does not flow. Scanning electron microscopy (SEM) images of UHMWPE powder heated at 160, 180, and 200°C are shown in Fig. 12. A specimen heated to 200°C shows a highly granular structure in which the original powder particles are clearly evident. The method of fabricated forms for commonly used thermoplastics cannot be applied to process UHMWPE due to this extremely high melt viscosity. The processing of UHMWPE requires a proper combination of temperature, high pressure, and time to achieve complete plastification. Three methods are currently used to make artificial joints with UHMWPE. These methods are ram extrusion, compression molding, and direct compression molding (Figs. 13, 14, and 15). For each method the goal is to apply enough temperature and pressure to UHMWPE powder to insure that the particles are fully sintered.

**Figure 21.12** Scanning electron micrograph of UHMWPE particles at various temperatures.

**Figure 21.11** Relationship between molecular weight of polyethylene and melt flow rate.

**Figure 21.13** Manufacturing process of ram extrusion and compression molding for UHMWPE implants.

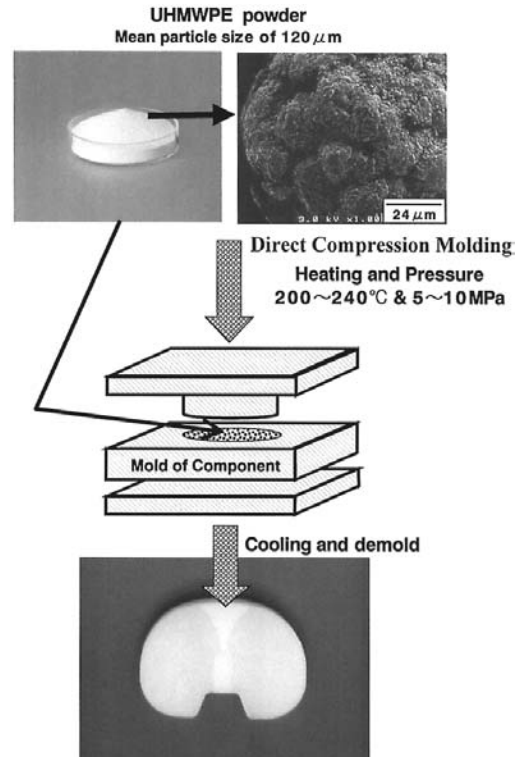

**Figure 21.14** Manufacturing process of direct compression molding for UHMWPE implants.

#### a. Ram Extrusion

Ram extrusion of UHMWPE is essentially a continuous compression. A ram extruder consists of a hydraulic ram and a heated die. Rods are produced by feeding UHMWPE powder into an electrically heated die (from 5 to 15 cm in diameter, 180–220°C), in which a plunger driven by an oil hydraulic mechanisms is moved backward and forwards for compression (8,9). Following ram extrusion, the rods are annealed at a temperature slightly above the melting temperature of UHMWPE in order to improve the material dimensional stability. The implant is then machined from this bar stock. Over 90% of all the UHMWPE fabricated forms for surgical implants are prepared by this method.

#### b. Compression Molding

Compression molding is used to manufacture sheets or blocks. A metal mold, made of steel, stainless steel, or aluminum, is filled with UHMWPE powder. The mold is then inserted into a press that has heating and cooling capabilities. Heating at temperatures of 200 to 230°C is continued under pressures of 2 to 10 MPa until the powder has plasticized completely. After plastization is completed, the hot

**Figure 21.15** Manufacturing process of the flow of direct compression molding for UHMWPE knee implants.

mold is cooled gradually at a controlled rate. The sintered UHMWPE sheet or block is demolded. The implant is then machined from the sheet or block.

#### c. Direct Compression Molding

UHMWPE can also be directly compression molded into final inserts. Direct compression molding results in a sintered insert that is fully consolidated and exhibits largely uniform properties. A metal mold designed for surgical implants is filled with UHMWPE powder. The powder is then heated under pressure until the powder has plasticized completely. After plastization is completed, the hot mold is cooled gradually at a controlled rate. The sintered implants are demolded.

In direct molding, the UHMWPE powder is usually heated at temperatures of 200 to 240°C under pressure from 5 to 10 MPa (Fig. 16). There are manufacturing defects such as fusion defects, macro voids, and grain boundary in sintered implants that were fabricated under insufficiently plastized conditions such as inadequate temperature, pressure, or time (Fig. 17). The defects are formed by incomplete particle consolidation between some adjacent powder particles. The scanning electron micro-

graph of the fracture surface of an unused UHMWPE knee implant produced by a ram extruder is shown in Fig. 18. Several fusion defects, other than rigid surfaces that are fully consolidated between adjacent powder particles, are observed in the implant. The defects may lower the mechanical properties of UHMWPE implants and make them more susceptible to fatigue damage (14,15). Figure 19 shows a photograph of a retrieved knee implant. Damage

**Figure 21.20** Photograph of a microtomed thin section of a UHMWPE implant.

such as a delamination and breaking is likely due to fatigue correlated by material processing and oxidation of the UHMWPE implants. The defects may become a diffusion path for oxidants such as oxygen in the air or hydrogen peroxide in body fluids, causing oxidation of UHMWPE (Fig. 20).

#### d. Calcium Stearate

Calcium stearate is added to UHMWPE for neutralization of the catalyst, improvement of melt flow, and reduction of wear and tear of the tool dies used to shape the final implants. The grade containing calcium stearate is standard for industrial use. However, it has been reported that fusion defects are associated with the presence of calcium stearate, and that use of UHMWPE source resin, which was free of calcium stearate results in improved material consolidation and wear resistance (16,17,18). Figure 21 shows the optical micrographs of microtoming thin sections of a plate prepared by direct compression molding using UHMWPE source resin of different calcium stearate contents. The visible grain boundaries in the plate become obvious with an increase in calcium stearate content. In spite of the high molecular weight, the plate prepared with calcium-stearate-free resin has no visible grain boundaries or fusion defects.

#### e. Sterilization

Sterilization is performed after packaging. There are several sterilization methods for surgical implants, such as dry heat, steam under pressure, steam-formaldehyde, ethylene oxide (EtO) or other chemicals, and irradiation ( $^{60}\text{Co}$ ,  $^{137}\text{Cs}$ , accelerated electron). Some of these procedures including steam autoclave are not recommended because the high

**Figure 21.21** Photograph of a microtomed thin section of a plate fabricated by direct compression molding using various grades of UHMWPE powder.

temperature may affect UHMWPE properties and product dimensions. Currently,  $\gamma$ -ray irradiation from a cobalt source and EtO sterilization are commonly used as the sterilization methods for UHMWPE. The FDA requires that a minimum dose of 2.5 Mrad be used for  $\gamma$ -ray sterilization. The sterilization of EtO does not affect the mechanical properties or wear resistance of UHMWPE implants.  $\gamma$ -ray sterilization, in the presence of oxygen, can result in property changes in UHMWPE implants.  $\gamma$ -ray energy that destroys microbes on the implant surfaces also causes chemical reactions, such as oxidative chain scission, recombination, and cross-linking, to occur within the polyethylene (15). It is reported by many researchers that the oxidation of UHMWPE implants from  $\gamma$ -ray sterilization, in the presence of oxygen, may reduce the mechanical properties and wear resistance of UHMWPE implants (8,20,21).

#### f. Oxidation

It has been reported that UHMWPE oxidizes after  $\gamma$ -ray sterilization and that the process of oxidation continues after implantation (8,19,21–27,29–31). The  $\gamma$ -ray energy causes a chemical reaction from the breaking of carbon–hydrogen and carbon–carbon bonds, which results in the production of free radicals in the polyethylene molecule. These free radicals react with oxidants, such as oxygen in the air or hydrogen peroxide in body fluids. The free radicals also undergo reactions of recombination and cross-

Figure 21.22 Predictive model of UHMWPE oxidation.

linking to other polyethylene molecules (19,27) (Fig. 22). During heating at temperatures exceeding the crystalline melting point of UHMWPE, particle fusion and cross-linking to other chains and chain scission occur simultaneously. These chemical cause changes in the physical properties of the UHMWPE implant.

Oxidation of polyethylene is a chemical attack that leads to a combination of chain scission and the introduction of oxygen containing groups, such as ketone, alcohol, ester, and hydroxylic acid, into the molecules. Chain scissions, which take place during oxidation, lead to a relevant reduction of molecular weight. When the original UHMWPE has a molecular weight of 4 million, five chain scissions depress the molecular weight to 70,000, which is the typical molecular weight of regular polyethylene (HDPE, LDPE, and LLDPE). Figure 23 shows optical micrography of a UHMWPE knee component. The knee component was fabricated by ram extrusion, sterilized by  $\gamma$ -ray irradiation in air, and then stored for 7 years. A white area, a so called white band, can be seen along the edges of a section about 0.5 mm in depth and 2 mm in width. The chemical results of oxidation are the formation of carbon-carbon double bonds and the introduction of oxygen-containing groups such as ketone, ester, or hydroxylic acid into the polymer. Fourier transform infrared spectroscopy (FT-IR) has been shown to be a convenient and effective method for the direct detection and determination of relative amounts of these types of chemicals (30) (Fig. 24). The IR peaks of oxygen-containing groups appear in the range of  $1600\text{ cm}^{-1}$  to  $1800\text{ cm}^{-1}$  (19,23). The integrated peak area in this range is proportional to the amount of oxidized UHM-

Figure 21.23 Photograph of a microtomized thin section of a UHMWPE knee implant fabricated by ram extrusion and sterilized in air.

WPE and can be used to quantify the extent of oxidation. The oxidation index—the oxidized peak area is divided by the peak area of  $1464\text{ cm}^{-1}$  assigned to the  $\text{CH}_2$  group—is often used (10) in order to have a valid comparison from sample to sample. Figure 25 shows a typical oxidation profile for a knee implant fabricated by ram extrusion after  $\gamma$ -ray sterilization in air and shelf aging for 7 years (30). The oxidation index shows a maximum at the subsurface area, which corresponds to the depth of the white band area seen in the section of oxidized UHMWPE implant. UHMWPE implants sterilized with  $\gamma$ -irradiation are known to undergo oxidative degradation, both while being stored on the shelf and after implantation. The oxidative degradation of implants results in both changes in chemical properties and changes in physical properties such as density, mechanical properties, and wear resistance. Oxidation would be ex-

Figure 21.24 IR spectra of a microtomized thin section of a UHMWPE knee implant fabricated by ram extrusion and sterilized in air.

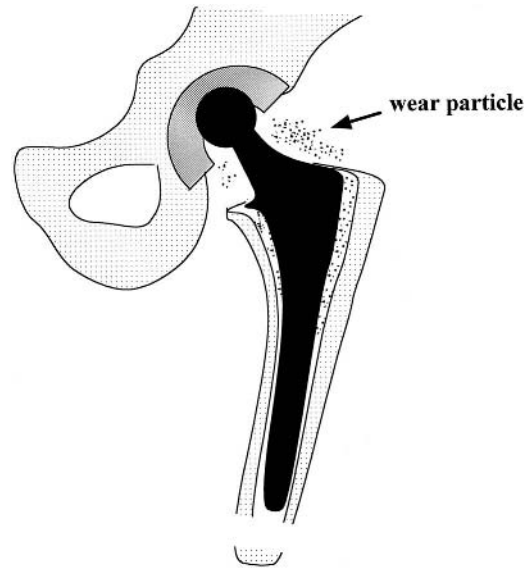

**Figure 21.25** Depth profile of oxidation index for a UHMWPE knee implant fabricated by ram extrusion and sterilized in air.

pected to increase the modulus and brittleness of polyethylene. Increases in density near surfaces (subsurfaces) of an implant cause major increases in the stress associated with wear damage (delamination) that occurs on and near the surfaces. The oxidative degradation of implants may lower the mechanical properties of UHMWPE and make them more susceptible to fatigue damage owing to chain scission, effectively turning them into regular polyethylene. In order to prevent the oxidative degradation, most manufacturers currently use  $\gamma$ -irradiation in a vacuum or inert gas to sterilize their products. The reduction of oxidative degradation leads to a minimum amount of chain scission and an increase in cross-linking, which preserves the mechanical properties associated with wear resistance.

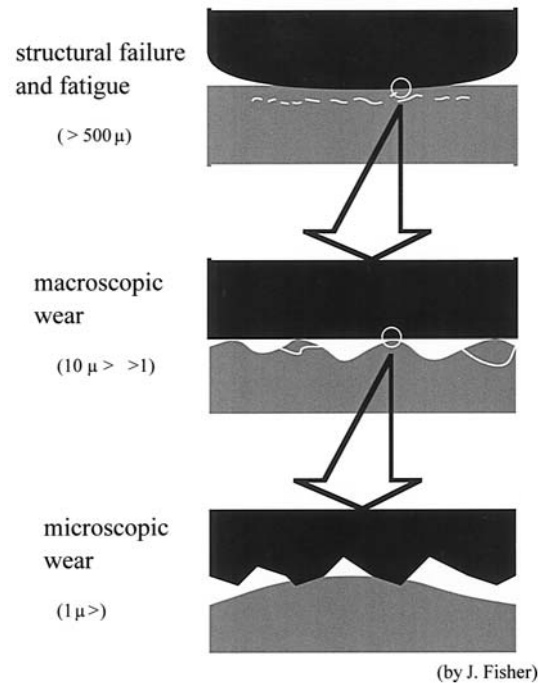

4. Wear Properties of UHMWPE

Medical grade ultra-high molecular weight polyethylene (UHMWPE) is the current material of choice for use as a bearing surface in artificial joints because it offers high toughness, a low friction coefficient, and low wear in the body. However, UHMWPE also remains as the limiting factor for the longevity of joint replacement. Artificial hip joints do not generally wear out, but UHMWPE wear particles generated at the articulating surfaces can enter the tissues surrounding the prosthesis and cause adverse cellular reactions as shown in Fig. 26. Since loosening of the stem is thought to be accelerated by the cellular reactions, tribological performance is one of the most important characteristics of UHMWPE.

Figure 27 shows a typical classification of polyethylene wear for artificial joints proposed by the Leeds University group (32). Microscopic wear of UHMWPE is caused by abrasion against hard material, such as the metal surface of a joint, and is associated with very small asperities or smooth counterfaces (less than 0.2 micrometers). The mi-

(by J. Fisher)

**Figure 21.27** Classification of wear for artificial joints.

Test Method of sand slurry abrasive wear

$$\text{Relative weight loss} = \frac{\text{loss weight of materials}}{\text{loss weight of UHMWPE}}$$

Figure 21.28 Comparison of abrasion properties between UHMWPE and other materials.

Macroscopic wear is characterized by the formation of particles with diameters smaller than 1 micron. Macroscopic polymer asperity wear processes are associated with stress concentrations under the much larger peaks in the UHMWPE surface (amplitude less than 10 micrometers). Structural failure and fatigue is called delamination wear. This failure is initiated by high stress at the subsurface of UHMWPE, followed by sudden explosive destruction and the formation of particles with diameters greater than 0.5 mm.

Generally, microscopic wear corresponds to abrasive wear and macroscopic wear corresponds to adhesive wear. UHMWPE shows high resistance against abrasive wear as shown in Fig. 28, where the sand slurry abrasive wear test for various materials was performed. The abrasion resistance of UHMWPE is the highest of the various materials (2,5). The abrasive wear resistance is seen to increase with linearly increasing molecular weight as shown in Fig. 29. It is reported that the abrasive wear rate for a variety of polymers increased with the inverse of the product of the ultimate tensile strength and the tensile elongation at break and toughness.

The mechanism for the macroscopic wear seen in the body has not been clarified yet. UHMWPE and polytetrafluoroethylene demonstrated very low coefficients of friction as shown in Table 3 (5). The low coefficient of friction can

Figure 21.29 Relationship between molecular weight of polyethylene and abrasion weight loss.

be explained by transfer film lubrication: a very thin film of polymer is transferred to the opposing surface and this leads to the resultant coefficient of friction being very low. However, the formation of the transfer film cannot be observed in the body or in wear testing using bovine serum as lubricant.

There has been no simple test device that would yield wear rates and wear mechanisms similar to those found in retrieved prosthetic joint components. The wear factors obtained for UHMWPE against polished Co-Cr alloy in serum are of the order of 10–8 mm<sup>3</sup>/Nm or almost negligible by pin-on-disk testing in which a polymer pin slides against a unidirectionally rotating or reciprocating plate. However, the clinical wear factors measured from retrieved acetabular cups of total hip prostheses are of the order of 10–6 mm<sup>3</sup>/Nm or more. Some of the joint simulator testing yields wear rates and mechanisms similar to those in clinical studies but were expensive and had poor reproducibility.

A simple testing method is required for wear and friction studies of prosthetic joint material. Recently, the effect

Table 21.3 Coefficient of Friction of Various Polymers (ASTM1894)

Polymer	Coefficient of kinetic friction
Polycarbonate	0.36

HDPE	0.12
Polytetrafluoroethylene	0.04–0.10
UHMW-PE	0.10–0.22

of multidirectional motion on the wear behavior of UHMWPE has been reported by several groups. Besong et al. reported that the number of wear particles produced in multidirectional wear testing was 26 times higher than that in unidirectional testing. Some of them advocated the importance of molecular orientation at the surface layer. Sambasivan et al. reported that unidirectionally rubbed UHMWPE shows higher average molecular orientation than in cross-shearing rubbed UHMWPE. Although the mechanisms for the effect of multidirectional sliding have not been clarified, multidirectional testing may open up a road to evaluating wear performance in the body.

5. Fatigue Properties of UHMWPE

Flaking type wear, so-called delamination, is often observed in polyethylene knee components as shown in Fig. 19. This wear can be classified as structural wear (32) caused by structural failure and fatigue. This failure will be initiated by high stress at the subsurface of the UHMWPE, followed by sudden explosive destruction accompanying the formation of particles with diameters greater than 0.5 mm as shown in Fig. 27. This destruction is thought to occur due to crack or defect formation and propagation and is accelerated by oxidation at the grain boundaries. However, this fatigue process has not yet been studied in detail, because the UHMWPE components have a complicated structure along with defects such as grain boundary and crystalline amorphous phase interface as shown in Fig. 30.

Figure 21.30 Structure of UHMWPE.

Figure 21.31 Schematic illustration of the scanning acoustic tomography (SAT) system 6.

Moreover, the methods available for fatigue study are quite limited, and detailed investigation of subsurface crack formation and propagation is obstructed by the difficulty of cleanly cutting UHMWPE products to produce a specimen suitable for outer surface and subsurface study. Scanning acoustic tomography (SAT, Fig. 31) is one possible method for estimating the crack or defect formation and propagation in UHMWPE (33–35). Figure 32 shows a photograph

Figure 21.32 Photograph (a) and SAT image (b) of retrieved UHMWPE knee component.

and SAT image of a tibial component that has neither apparent severe wear nor flaking on the surface. However, it is obvious that subsurface cracks or defects are represented in the SAT image as dots at the loaded site. The accumulated area of subsurface cracks or defects evaluated by SAT is shown in Fig. 33, where the delamination destruction was reproduced by sliding fatigue testing. Fatigue seems to develop slowly during the early and middle stages after implantation, followed by sudden explosive destruction. A cross-sectional view of the UHMWPE sample showed some amount of looseness at the grain boundary of UHMWPE.

Numerous studies have reported a significant influence of gamma-irradiation on the UHMWPE delamination (36–43). Sun et al. (44) found that the maximal subsurface oxidation level of gamma-sterilized UHMWPE components peaked at a depth ranging from 0.2 to 0.8 mm below the surface. This depth is almost identical to where maximal residual strain was stored, found by analysis using a constitutive equation for cyclic plasticity (45,46). Probably, oxidation caused by gamma-irradiation has accelerated the fatigue process of polyethylene. Indeed, our study on explants revealed that flaking-like destruction or apparent propagation of subsurface cracks occurred in UHMWPE components sterilized by gamma-irradiation.

Figures 34–36 (47) shows results obtained by a two-dimensional sliding fatigue testing machine, where UHMWPE specimens were fixed on a computer-controlled X–Y table and loaded by a round rod. The end of the rod

Figure 21.33 Cracks observed in UHMWPE loaded with Si3N4 balls (r = 5 mm) sliding on the specimen (load = 1000 N).

Figure 21.34 Cracks observed in UHMWPE loaded by a rounded rod (r = 3 mm) moving two different locis.

was made into a half ball with a curvature radius of 3 mm polished with cloth into a surface roughness value (Ra) of 0.3–0.4 μm. A pressure of 196 N was applied to the specimen through the rod. Twenty minutes was adapted as the stationary period before the start of the sliding movement. The end of the rod was sunk into the specimen during the 20-minute stationary period. Two simple patterns of sliding movement were adopted; simple reciprocating (pattern 1) or switched reciprocating (pattern 2), movement which consisted of two parallel lines at a distance of 1 mm and was switched at every other cycle of the reciprocating movement. Surrounding water in the chamber was maintained at 37°C, and the number of loadings in the observed area was 200,000 cycles. Subsurface cracks that formed in the middle portion of the loaded area were measured by SAT.

Figure 34 clearly demonstrates that complicated sliding motion (pattern 2) accelerates crack formation and/or propagation below the surface. This result suggests that the locus of the sliding movement is an important factor. It is likely that multidirectional fatigue loading causes tensile strain at grain boundaries to accelerate the fatigue process. Gamma-irradiated UHMWPE specimens demonstrated lower rates of crack formation than unirradiated specimens under pattern 1 movement as shown in Fig. 35, whereas flaking-like destruction was observed in the gamma-irradi-

Figure 21.35 Cracks observed in UHMWPE loaded by a rounded rod ( $r = 3$  mm) moving on pattern 1 locus.

ated UHMWPE under pattern 2 movement as shown in Fig. 36. One out of five gamma-irradiated UHMWPE specimens exhibited relatively low crack area, suggesting that the flaking-like destruction would occur suddenly from a low-cracked state. These results suggest that the gamma

Figure 21.36 Cracks observed in UHMWPE loaded by a rounded rod ( $r = 3$  mm) moving on pattern 2 locus.

irradiation reduces crack formation but increases crack propagation under multidirectional sliding.

### 6. New Processing of UHMWPE

The aim of many researchers in high performance implants has been to alter the properties of UHMWPE by changing its morphological characteristics by various manufacturing processes. It is reported that crystallinity in polyethylene can be increased without causing degradation by using temperatures greater than 250°C and pressure greater than 2,800 atmospheres (8,31,49). It is also reported that UHMWPE with crystallinity over 80% can be prepared by re-crystallization of solid UHMWPE with crystallinity of 50% without degradation of the original material.

#### a. Cross-Linking

UHMWPE is cross-linked by low-dose (2–5 Mrads)  $\gamma$ -ray sterilization in a vacuum or inert gas and then stored in an oxygen-free environment or heat-treated at a temperature below the melting point in a vacuum or inert gas owing to the inactivation of free radicals (50,51). UHMWPE sterilized by this favorable cross-linking has a low density, low crystallinity, and a higher insoluble fraction than UHMWPE that is  $\gamma$ -sterilized in air. It is reported that the increase in the favorable cross-linking of UHMWPE results in a significant improvement in wear resistance as compared to both  $\gamma$ -ray sterilization in air and EtO sterilization; hip simulator tests indicated a 49% decrease in wear rate for the samples irradiated in a vacuum relative to samples irradiated in air (Fig. 37), and a 36% decrease in wear rate

Figure 21.37 Direct compression molding in vacuum.

for samples irradiated in a vacuum relative to samples sterilized using EtO (52). The UHMWPE implants treated in a vacuum have the greatest wear resistance, presumably due to the increased cross-linking in the polyethylene.

UHMWPE is cross-linked by low-dose  $\gamma$ -ray irradiation (~2.5 Mrad) in a vacuum and then directly compression-molded into final inserts at a temperature of 200°C under pressure of 20MPa owing to orientation of the polyethylene chains and inactivation of free radicals. The wear factor of the samples significantly decreased with an increase in the degree of orientation of the UHMWPE (53). This suggests that the wear resistance of implants is improved by the cross-linked orientation of UHMWPE.

Many kinds of cross-linked UHMWPE have been developed and used in clinical applications (54–56).

*b. Vitamin E Addition*

The effect of vitamin E on crack formation and/or propagation in UHMWPE was evaluated using two-dimensional sliding fatigue testing and microindenter testing. Figure 38 (47) shows the effect of vitamin E on the delamination destruction. All the irradiated vitamin E-containing specimens did not demonstrate flaking-like destruction. Both crack formation and flaking-like destruction were significantly prevented by adding vitamin E. The amount of vita-

**Figure 21.38** Cracks observed in vitamin E added UHMWPE loaded by a rounded rod ( $r = 3$  mm) moving on pattern 2 locus.

**Figure 21.39** Dynamic hardness at the surface of a UHMWPE specimen.

min E at 0.1 and 0.3% demonstrated no apparent difference in this experiment. The effect of vitamin E on the delamination destruction is thought to be caused by many factors. However, it is possible that the presence of vitamin E prevents crack propagation in part due to reduced hardness at grain boundaries. Results of the microindentation testing are shown in Fig. 39 (47), where dynamic hardness at the grain boundary was higher than in the grain and was increased by gamma-irradiation. This hardening at the grain boundary was reduced by adding vitamin E in UHMWPE. The gamma-irradiated vitamin E-containing UHMWPE is a promising material to prevent flaking-like destruction of polyethylene joint components.

**II. BONE CEMENT**

Surgeons must thoroughly understand the background of self-curing acrylic cement to appreciate the mechanism of fixation and the biological interaction between bone and cement and to deal with problems arising from defective fixation of a total hip prosthesis. Space limits a complete account of self-curing cement; the reader is strongly urged to review Charnley’s original report and the appropriate references (57,58) at the end of this chapter. The goal of

this chapter is to review the general aspect of the available acrylic cements as well as modern cementing techniques. Our new challenges of improving the bone cement and intramedullary plug are also discussed.

### A. History of Bone Cement

The successful use of acrylic cement for fixation of total hip implants was one of Sir John Charnley's major contributions. At the suggestion of Dr. Dennis Smith of the materials laboratory of the Manchester University Dental School, he began to work with polymethyl methacrylate (PMMA), which was being used for the construction of temporary dentures.

The industrial form of polymethyl methacrylate is familiar as Plexiglas or Lucite. The material was developed in the years before and during World War II when it could be substituted for glass as a clear material. It was originally used as a denture base material in 1937 and it subsequently found use in a wide variety of medical applications, especially for cranioplasties. In 1946, the Judet hip was introduced with a heat-cured acrylic substitute for the femoral head (59). Although a number of applications were found in orthopedics, Charnley was the first to utilize the material in a self-curing form for fixation of an intramedullary stem in 1958 (60).

Our current understanding of acrylic bone cement stems from much of the original investigative work done by Charnley and other workers in the 1960s and 1970s when bone cement was first introduced. Charnley (61) first identified such issues as the porosity of bone cement and the effect of air and blood inclusions. Building on the extensive experience with PMMA in dental biomaterials, the essential properties and limitations of the material were identified as applied to orthopedics. After over 40 years of clinical use, acrylic cement is still the most frequently used method and material for the fixation of total joint prostheses.

### B. Chemical Composition

Polymethyl methacrylate is one of a group of widely known polymers such as polyethylene, polyvinyl chloride (PVC), and polystyrene. These are all repeating carbon-based units of varying chain length. The methyl methacrylate molecule, which has a molecular weight of 100, is seen in Fig. 40. The polymer consists of repeating units of the basic molecule with the double carbon bond broken and replaced with single carbon bonds to the adjacent subunits. The ultimate chain length of the polymer is dependent on the manufacturing process as well as the initiators and activators that cause the reaction to occur when the mixture

**Figure 21.40** Chemical formula of acrylic bone cement. (a) methyl methacrylate, (b) bisphenol-A-glycidyl dimethacrylate (bis-GMA), and (c) triethylene-glycol dimethacrylate (TEGDMA).

is prepared in surgery. A longer ultimate chain length will be reflected in a higher molecular weight and increased material properties and will cause a greater degree of viscosity during the mixing and curing process. While the PMMA used in orthopedic surgery is an example of a single-link polymer chain, much stronger materials are available in dentistry, such as bisphenol-A-glycidyl methacrylate (BIS-GMA), where significant cross-linking occurs between the subunits of different chains (62).

The cements used in orthopedic surgery rely on combining prepolymerized solid particles (powder) and the liquid monomer (liquid). A process of suspension polymerization that allows the manufacturer to control both particle size and the molecular weight or mean polymer chain length of the polymer produces the prepolymerized powder. The powder particles are generally spheres from 30 to 150  $\mu\text{m}$  in diameter. There is a wide distribution of the molecular weight in a range from 20,000 to 2 million with a mean weight of 172,000 g/mol (63).

Whereas the methyl methacrylate monomer will polymerize on its own if exposed to light or heat, the self-curing process relies on chemical agents for the polymerization. The liquid monomer also generally contains the activator *N,N*-dimethyl-*p*-toluidine (DMPT). For the reaction to occur, the powder component of prepolymerized PMMA beads needs to contain an initiator, which is most commonly dibenzoyl peroxide (BP). To prevent the monomer from polymerizing, the liquid generally contains an inhibitor or retardant, hydroquinone, which functions by absorbing any free radicals that may occur and causing the breakup of the double carbon bonds and initiating the polymerization.

When the liquid monomer and prepolymerized powder are mixed together, a chemical reaction begins with the activator (DMPT) and the initiator (BP) combining and releasing a benzoyl peroxide free radical, which reacts with

the methacrylate monomer molecule to begin the polymerization process. Chains are then formed of repeating subunits in the range of 20–20,000 (63). As the chains form with the double carbon bonds being converted to single carbon bonds, heat is generated as an exotherm of 130 calories/g of liquid monomer, which further accelerates the reaction as the cement cures into a hard mass.

In addition to these basic components, many of the cements also contain copolymers (polymers derived from more than one type of monomer) that can influence the mixing and handling characteristics of the cement. Simplex P cement, for example, includes a styrene copolymer in its composition. All of the cements also have an opacifier, usually barium sulfate ( $\text{BaSO}_4$ ) or zirconium oxide ( $\text{ZrO}_2$ ).

The exact composition and relative proportions of the components of the individual orthopedic bone cements influence both the final physical properties and the handling and flow characteristics of the cement during its preparation and application. Variations in the composition as well as the mixing method will affect total set time, amount of heat generated, expansion and shrinkage during the curing, the flow characteristics over time (liquid phase through dough phase), and the degree of polymerization or amount of residual monomer that may be present after the reaction has finished.

### C. Problems of PMMA Bone Cement

Since the introduction of polymethylmethacrylate (PMMA) bone cement (60), PMMA bone cement is considered to have become one of the most effective means for the fixation of hip prostheses. Aseptic loosening, however, remains the most serious long-term drawback on a multifactorial basis. Biochemical (64–66) and mechanical (67, 68) factors are considered to be responsible for the loosening of hip prostheses. In the acetabular component, particulate polyethylene may invade the interfacial membrane between the bone and the cement, where phagocytosis by macrophages and foreign body giant cells leads to release of bone resorbing factors, resulting in osteolysis (66). In the femoral component, the mechanical (67,68) and biochemical factors mentioned above are thought to be responsible.

### D. Bioactive Filler–Impregnated Bis-GMA-Based Resin

#### 1. Introduction

To improve the mechanical properties of PMMA bone cement (69) and to avoid cement fracture, centrifugation (70) and pressurization of the cement (71) are now used. To

improve the biochemical properties of PMMA bone cement, bioactive glass ceramic particles have been added (72). However, the mechanical properties of these composites have been shown to be inferior to the mechanical properties of PMMA bone cement, resulting in failure. Taken together, these problems warrant the development of a new bioactive bone cement (BABC) that has better mechanical and biochemical properties than those of PMMA bone cement. One important type of BABC is made by mixing bioactive powder with resin (72–76).

The apatite and wollastonite-containing glass ceramic (AW glass ceramic) developed at Kyoto University (77–80) is one of the most promising bioactive glass ceramic materials (81) and is now used clinically (82). The mother glass of AW glass ceramic (83) before crystallization is thought to have high bioactivity because of its glass phase. In 1993, Kawanabe et al. reported on a BABC consisting of  $\text{CaO-SiO}_2\text{-P}_2\text{O}_5\text{-CaF}_2$  glass powder and a bisphenol-A-glycidyl dimethacrylate-based resin (Bis-GMA-based resin) (84). This new BABC showed direct contact with living bone through a calcium and phosphorous-rich layer and a higher mechanical strength than PMMA bone cement. To achieve better clinical results for fixation of orthopaedic implants, we have developed new BABCs consisting of  $\text{CaO-MgO-SiO}_2\text{-P}_2\text{O}_5\text{-CaF}_2$  glass or a glass ceramic powder and Bis-GMA-based resin (85–88). These cements also showed direct contact with living bone through a calcium phosphorous rich layer and had improved mechanical strength.

However, these BABCs may demonstrate different characteristics when used for implant fixation and when subjected to greater mechanical stress. Senaha et al. (89) worked with dog femora and reported that a BABC consisting of bioactive glass powder and a Bis-GMA-based resin achieved good implant stability under weight-bearing conditions. Matsuda et al. (90) reported that a BABC consisting of bioactive glass powder and Bis-GMA-based resin showed a higher bonding strength than PMMA bone cement for up to 6 months after surgery when used for canine total hip arthroplasty (THA).

To achieve a higher mechanical strength and better handling properties, silica glass powder was added as a second filler to a BABC consisting of bioactive glass ceramic powder and Bis-GMA-based resin (91). We also reported that BABC with the same components showed a greater intrusion volume in 5 mm holes than PMMA bone cement when used for acetabular cup fixation in a simulated acetabular cavity (92). In this study, we performed canine THA using a BABC with the same components and followed up the outcome to 2 years (93). The outcomes were compared with the results of PMMA bone cement. Under load-bearing conditions, we subsequently compared the bonding

strength and histological findings at the bone–cement interface produced by these two types of bone cement.

## 2. Materials and Methods

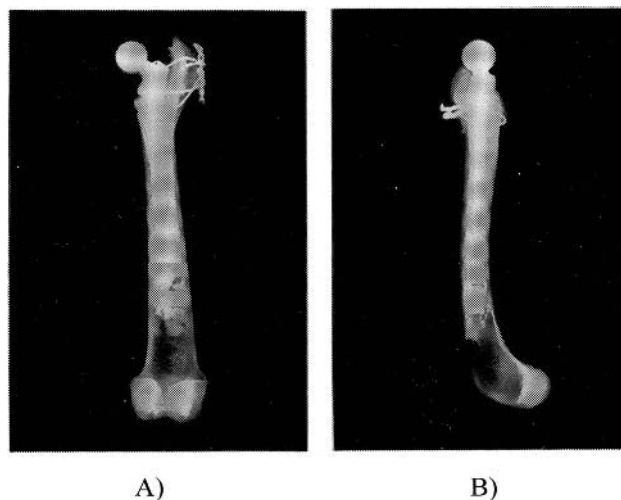

Total hip arthroplasties (THAs) were performed in beagle dogs using a bioactive bone cement (BABC) consisting of a silane-treated apatite and wollastonite-containing glass ceramic (AW glass ceramic) powder and a silica glass powder as the filling particles, and a bisphenol-A-glycidyl dimethacrylate-based resin (bis-GMA-based resin) as the organic matrix. Bis-GMA-based resin was prepared from equal weights of bis-GMA and triethylene-glycol dimethacrylate (TEGDMA) (Fig. 40).

BABC is composed of two pastes, type B paste and type T paste. Type B paste consists of fillers, bis-GMA-based resin, and benzoyl peroxide (BP) in a proportion of 1.2% per unit weight of the resin in type B paste. Type T paste consists of fillers, bis-GMA-based resin, and *N,N*-dimethyl-*p*-toluidine (DMPT) in the proportion of 1.1% per unit weight of the resin in type T paste, and phenothiazine, as an inhibitor of the polymerization reactions, at a proportion of 300 ppm of the resin in type T paste. We prepared two different compositions of BABC; the proportion by weight of the powder mixed into the cement was 85% for the acetabular side (dough type) and 79% for the femoral side (injection type), because the contemporary cemented THA uses the manual cementing technique for the acetabular side and the injection cementing technique for the femoral side. The viscosity of the dough type is high, which enables, manual handling of the cement, whereas that of the injection type is low, which enables injection into the femoral canal with a syringe. The two pastes (each weight is 40 g, 80 g in total) were packed and sterilized separately in ethylene oxide gas. In use, they were kneaded together for about one minute using a high-vacuum mixing system, Mixevac II (Stryker Co. Ltd., USA). Both cements polymerized within 8 minutes.

## 3. Results

The mechanical properties of the BABC were stronger than those of PMMA bone cement. The compressive strength of the two types of BABC was approximately 2.5 times stronger than the compressive strength of PMMA bone cement. The bending strength and the fracture toughness of both types of BABC were stronger than the bending strength of PMMA bone cement. The elastic modulus of the BABC was 3 to 5 times higher than the elastic modulus of PMMA bone cement.

All dogs were able to bear their body weight within 1 week and walked without a limp by 3 weeks. There was no postoperative hip dislocation. Two deep infections, one

**Figure 21.41** Radiographs taken 24 months after implantation using BABC. (A) Anteroposterior view; (B) lateral view of the femur. The radiograph showed neither loosening of the hip prosthesis nor abnormal bone resorption around the cement mantle of the femur.

in one dog in the BABC group and one in one dog in the PMMA bone cement group, were shown on gross examination at the time of sacrifice at 24 months after implantation, so these two dogs were excluded from the present study. In the other 30 dogs, neither infection nor abnormal inflammatory reaction of the hip was shown on gross examination, and all the implants appeared to be fixed securely to the skeletons. Radiographs for both groups showed neither loosening of the hip prosthesis nor abnormal bone resorption around the cement mantle of the femur at 1 to 24 months (Fig. 41).

Histological examination showed direct bonding between the BABC and the femoral bone for up to 24 months after implantation (Fig. 42A). However, with PMMA bone cement, an intervening soft tissue layer was observed consistently at the bone–cement interface (Fig. 42B). Direct bonding at the interface between the BABC and the bone through a calcium phosphorous layer, 30  $\mu\text{m}$  thick, was revealed by scanning electron microscopy (Fig. 43). Cement fractures of the BABC were observed on the acetabular side 24 months after implantation. The bonding strength of the BABC to bone in the dogs' femora increased with time and reached 3.7 MPa at 24 months after implantation, whereas that of PMMA bone cement was 2.0 MPa ( $p < 0.05$ ).

## 4. Discussion

It is well known that oxygen is responsible for the formation of an uncured layer on the surface of a resin that has

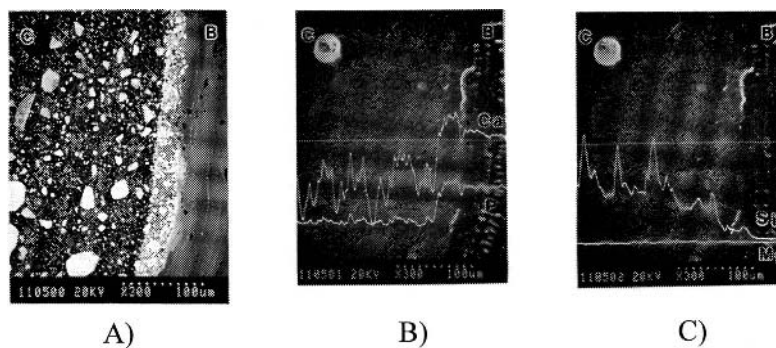

**Figure 21.42** Giemsa surface staining of the femur at the bone cement interface of the (A) BABC and (B) PMMA bone cement at 24 months after implantation. Original magnification,  $\times 100$ ; scale = 100  $\mu\text{m}$ . The star indicates the bone and the asterisk indicates the cement. (A) Direct bonding between the BABC and the bone was observed at the bone–cement interface. (B) An intervening soft tissue layer approximately 10 to 400  $\mu\text{m}$  thick was consistently observed at the bone–cement interface.

been in contact with the atmosphere or with fluids, which include oxygen (94). Oxygen consumes radicals produced by benzoyl peroxide and *N,N*-dimethyl-*p*-toluidine and stops the polymerization chain, which leads to the formation of an incompletely polymerized thin layer (an uncured layer) on the surface of the resin.

Miyaji et al. reported that when a composite resin containing bis-GMA and TEGDMA, with a bioactive filler, was soaked in simulated body fluid (SBF) (95), incompletely polymerized resin, mainly TEGDMA, dissolved from the uncured layer into the solution within 1 hour, and

glass grains exposed to SBF were converted into silica gel (96). The silica gels then induce apatite nucleation between the spaces of the grains, which induces the ability to bond directly to living bone. Okada et al. reported that the uncured layer was completely filled with newly formed bone-like tissue by their transmission electron microscopic (TEM) study when BABC was implanted in rat tibiae (97). They also revealed that this layer consisted of calcium, phosphorus, and some silicon by energy-dispersive x-ray microanalysis (EDX). In the scanning electron microscopy of the present study, direct bonding between the cement

**Figure 21.43** Back-scattered scanning electron micrograph of the femur at the bone–cement interface of the BABC group 24 months after implantation (A); electron probe microanalysis (B and C). Original magnification,  $\times 300$ . The dotted line indicates 100  $\mu\text{m}$ . B indicates the bone and C indicates the cement. (A) BABC showed direct bonding to bone without any intervening soft tissue layer. The surface of the cement was covered with a calcium phosphorus layer 30  $\mu\text{m}$  thick, through which direct bonding between the cement mantle and host bone was accomplished. (B) The calcium level did not change, and the phosphorus level increased slightly across the bone–cement interface. (C) The silicon level decreased, and the magnesium level did not change across the bone–cement interface. A calcium phosphorus layer approximately 30  $\mu\text{m}$  thick was present on the surface of the BABC, and the cement bonded directly to the host bone through this layer. No marked degradation of the fillers was observed in the cured region of the BABC.

and the host bone, both acetabular and femoral, was observed through the calcium phosphorous layer formed on the surface of the BABC.

Using a dog model, Pilliar et al. reported that bone ingrowth can occur in the presence of small movement (up to 28  $\mu\text{m}$ ) (98). In the present study, BABC bonded directly to bone under load-bearing conditions for up to 6 months and maintained this bond for up to 24 months and 12 months on the femoral and acetabular sides, respectively. This implies the high bioactivity of this material and indicates that adequate initial fixation was performed.

The failure on the acetabulum side at 24 months can be explained by several factors. Detachment between the BABC and the acetabular component occurred at 12 months, followed by cement fracture at the edge of the groove on the surface of the acetabular component. Although the loading mechanism in the acetabulum is not precisely known, it is believed to be a combination of compression, shear, and torsion. As the acetabulum of beagle dogs is shallow and the range of motion is wide, an excessive force may have loaded on the acetabular component. Moreover, the thickness of the acetabular component used in this study was 3 mm. This thinness of polyethylene also poses a concern in regard to creep of the cup, which can affect stress in the cement and the bone. An excessive load may have been applied to the bone–cement interface, which could have led to the breakage of the bone–cement interface. This breakage consistently occurred in the calcium phosphorus layer. In addition, the evaluation of the bone–cement interface after the push-out test demonstrated that breakage consistently occurred in the calcium phosphorus layer. Taken together, it has been revealed that the mechanically weakest layer of the bone–cement interface was the calcium phosphorus layer formed on the surface of the BABC.

In general, it is assumed that biomaterials with higher bioactivity tend to be more degradable and can show marked degradation after long-term implantation in the human body. In this study, cement fractures were observed on the acetabular side at 24 months after implantation, although no apparent degradation of the BABC was observed on the femoral side. The thin cement mantle of the acetabular side may have accelerated the degradation of the BABC.

BABCs are composite materials of glass ceramic and polymers, with their elastic moduli (dough type 14.4 GPa, and injection type 9.7 GPa) being lower than those of metals (stainless steel 193 GPa), higher than those of cancellous bone (0.2 to 0.5 GPa) and UHMWPE (0.012 GPa), and almost identical to those of cortical bone (10 to 20 GPa) (99). In the present study, the elastic moduli of the

BABCs were higher than those of PMMA bone cement, which had an elastic modulus of 2.7 GPa due to the large amount of filler, mixed with bis-GMA-based resin in the BABCs.

On the acetabular side, bone cement lies between cancellous bone and UHMWPE. It is generally known that a discrepancy in an elastic modulus leads to stress concentration at the interface. Hori and Lewis reported that an intervening fibrous tissue layer is very compliant and deformable and can withstand large strains from a load applied to the bone–cement interface (100). As BABC bonds directly with bone, no shock absorber exists between BABC and cancellous bone, which leads to breakage inside the calcium and phosphorous layer. On the other hand, in the case of PMMA bone cement, an intervening soft tissue layer lies consistently between PMMA bone cement and the cancellous bone, which may act as a shock absorber.

On the femoral side, bone cement lies between the stainless steel and the cortical bone. As BABC and cortical bone have an almost identical elastic modulus, the bonding between BABC and the bone could be maintained for 24 months. Moreover, the bonding strength between metals and BABC or PMMA bone cement is stronger than the bonding strength between UHMWPE and BABC or PMMA bone cement (our unpublished data).

Wear debris is now considered to be one of the major factors responsible for osteolysis, resulting in aseptic loosening of the implant. Several attempts at resolving this problem are currently in progress, one of which involves improving the characteristics of the bone–cement interface (74,76). The improvement of the characteristics at the bone–cement interface can be achieved by using BABC, which has an ability to bond directly with bone. In the present study, the affinity indices of BABC for the femur was higher than that of PMMA bone cement at 12 and 24 months after implantation. This may result in closer adhesion and less micromotion at the bone–cement interface of the BABC group compared with the PMMA bone–cement group. The BABC used in the present study produced a calcium phosphorous layer at the bone–cement interface, and through this layer, direct bonding between the BABC and the host bone was observed. Although the affinity indices of the BABC for the femur were approximately 40% at 6, 12, and 24 months after implantation, the number of cells that can phagocytise wear debris of polyethylene and/or metal may be reduced at the bone–cement interface.

In the present study, the effectiveness of the BABC for fixation of the hip prosthesis was examined. This cement showed good bioactivity and bone-bonding ability on the femoral side for up to 24 months after implantation. Com-

bination of weak bonding between BABC and UHMWPE, relatively high elastic characteristics of BABC, and weakness of the calcium phosphorous layer formed on the surface of this cement led to failure on the acetabular side at 24 months. We are now conducting a further fundamental study to produce a cement with a thinner uncured layer to strengthen further the bone–cement interface. Currently, we are also conducting studies to modify the elastic characteristics by changing the composition of the polymer. Further investigations will be necessary before a BABC is finally developed that is suitable for human THA.

### E. Cementing Technique

Since its introduction by Charnley (60) in 1960, polymethyl methacrylate (PMMA) bone cement has generally been considered to be one of the most effective means for fixing hip prostheses. However, aseptic loosening remains a most serious long-term drawback. There have been a number of advances in the methods of cement fixation of the femoral component in total hip arthroplasty (THA), including pulsatile lavage (101), intramedullary plugging (102,103), vacuum mixing (104,105), retrograde insertion by cement gun, and final compaction. These techniques have been shown to enhance the fixation of cement to bone, and superior clinical results have been documented using them (106). An essential prerequisite to this procedure is adequate plugging of the distal femoral canal.

### F. Intramedullary Plug

Various methods for plugging the canal have been reported, such as doughy acrylic cement (107), bone plugs (108,109), polyethylene plugs (110), biodegradable copolymer (111,112), and hydroxyapatite (113). There are advantages and disadvantages with each method. In general, plugging converts the femoral canal into a closed space, facilitates preparation of bone surfaces, prevents introduction of cement into the distal canal, and may reduce the potential hazard of embolization of canal contents into the venous circulation (114,115).

Cancellous bone chips obtained from resected femoral heads have generally been used in our institute for primary THAs. However, when it is difficult to obtain bone chips, as in revision surgery, porous apatite-wollastonite-containing glass ceramic (AW-GC) has been used for intramedullary plugging.

Autografts have been used widely for repairing bone defects. This technique has been successful, but the amount of available bone is limited, and harvesting it necessitates two operations. Implantation of allografts and

xenografts does not require a second operation but does cause problems of antigenicity. Therefore artificial bone substitutes, such as alumina, hydroxyapatite, tricalcium phosphate, Bioglass<sup>R</sup>, and AW-GC (78) have been investigated.

Dense AW-GC has been reported to have high mechanical strength as well as the capacity to form strong chemical bonds with bone tissue (80,81). Ijiri et al. (116) investigated porous AW-GC, which induced ectopic bone formation combined with bone morphogenic protein (BMP) and collagen.

The efficacy and biocompatibility of porous AW-GC as an intramedullary plug in canine total hip arthroplasty (THA) was evaluated for up to 2 years. Cylindrical porous AW-GC rods (70% porosity, 200  $\mu\text{m}$  mean pore size) were prepared and provided by Nippon Electric Glass Co. Ltd. (Otsu, Japan) (Fig. 44). The chemical composition of the porous AW-GC was 4.6% MgO, 44.7% CaO, 34.0% SiO<sub>2</sub>, 16.2% P<sub>2</sub>O<sub>5</sub>, and 0.5% CaF<sub>2</sub>, and the crystallized glass-ceramic consisted of 28% residual glass, 38% apatite [Ca<sub>10</sub>(PO<sub>4</sub>)<sub>6</sub>(O, F)<sub>2</sub>], and 34% wollastonite (SiO<sub>2</sub> · CaO), as described previously (79), being the same as that of dense AW-GC. Its compressive strength was 17.54  $\pm$  3.82 MPa (mean  $\pm$  S.D.) (16), which is identical with that of cancellous bone. Porous AW-GC has been used for bone defect filler in Japan. Twenty-two adult beagle dogs underwent unilateral THAs, and 4 dogs were sacrificed at 1, 3, 6, and 12 months each and 6 dogs at 24 months after implantation. Radiological evaluation confirmed the efficacy of po-

**Figure 21.44** Scanning electron micrograph of the porous AW-GC used in the present study. Original magnification,  $\times 50$ . The dotted line indicates 600  $\mu\text{m}$ .

**Figure 21.45** Back-scattered scanning electron micrograph of the femur at the bone–implant interface at (A) 1 month, (B) 6 months, and (C) 24 months after implantation. Original magnification,  $\times 50$ ; the dotted line indicates  $600\ \mu\text{m}$ . (A) Newly formed bone in the pores of the porous AW-GC was observed at one month. (B) The amount of bone increased until 6 months. (C) At 24 months, the walls of AW-GC pores were almost totally resorbed and replaced by newly formed bone.

rous AW-CG as an intramedullary plug. Histological evaluation showed osteoconduction at 1 month and resorption of porous AW-GC, which was replaced by newly formed bone, at 24 months (117) (Fig. 45).

There are various methods for plugging femoral canals, each with advantages and disadvantages. PMMA plugs have the disadvantage of a prolonged operation time plus additional mass cement handling and instruments (107). Also, the insertion of a cancellous bone plug taken from the removed femoral head requires experience and specialized instruments (108,109). Moreover, the femoral head is not always available, as in revision surgery. Polyethylene plugs are easier to use but are deficient in achieving adequate and consistent occlusion of the femoral canal because of its elliptical shape (103,111). Although cylindrical porous AW-GC may be insufficient to occlude the elliptical shape of the femoral canal, insertion of several spherical AW-GCs and compacting them is thought to achieve complete plugging of the femoral canal without any migration or leakage.

Raut et al. reported excellent clinical results from one-stage revision of an infected total hip arthroplasty with discharging sinuses using antibiotic-soaked PMMA bone cement (118). Kawanabe et al. reported on the efficacy of antibiotic-soaked AW-GC blocks as a new drug delivery system (DDS) for osteomyelitis *in vitro* and *in vivo* (119). They also showed in their pilot clinical study that antibiotic-soaked AW-GC blocks appeared to be useful for treating chronic osteomyelitis and infected arthroplasties with bone defects. On the basis of these two reports, we con-

clude that porous AW-GC is suitable as a DDS and that the combination of porous AW-GC plugs and antibiotics will be effective for preventing and treating infections at THA combined with antibiotic-impregnated PMMA bone cement.

Neo et al. reported that particles ( $100$  to  $220\ \mu\text{m}$  in diameter) of AW-GC implanted in rat tibiae have not been resorbed completely, even 96 weeks after implantation (120). They reported that the resorbed or replaced width of the surface of AW-GC was less than  $50\ \mu\text{m}$  per year. In the present study, the thickness of the wall of porous AW-GC was  $10$  to  $30\ \mu\text{m}$ , and it was reasonable that the porous AW-GC was subtotally resorbed within 2 years (117). At revision surgery, we always remove all remaining cement, including the plug, because of possible infection. In many cases it is very difficult to remove the plug through the medullary canal. Giardino et al. reported that intramedullary plugs made of poly (D,L-lactic acid) (PDLLA) completely disappeared in the femoral medullary cavity of rabbits 26 weeks after implantation (112). Although the resorption rate of porous AW-GC was lower than bioresorbable materials including PDLLA, use of porous AW-GC plugs will also overcome this problem because of their resorption within 2 years. We are currently conducting clinical trials using porous AW-GC with a special design and have met with good preliminary results.

We conclude that porous AW-GC is effective as an intramedullary plug. AW-GC plugs appear to be promising for clinical application, having good biocompatibility and DDS capacity and showing resorption within 2 years.

### I. ARTIFICIAL HEART VALVE PROSTHESES

Replacement of diseased human heart valves with prostheses has become a common treatment modality today. The trileaflet aortic valve between the left ventricular outflow tract and the aorta, as well as the bicuspid mitral valve between the left atrium and the left ventricle, are subjected to high pressure generated due to the contraction of the heart. Valvular heart diseases and hence valve replacement predominantly occur for these two valves (1,2). With the advent of blood oxygenators and cold potassium cardioplegia to arrest the heart and perform open-heart surgery about four decades ago, many different artificial valves have been implanted. The valve prostheses commonly available today for replacement can be broadly classified into mechanical valves and biological tissue valves (1).

The biological tissue valves consist of either a porcine aortic valve or a trileaflet valve made of bovine pericardial tissue. The aortic valve of pigs, which has an anatomy closely resembling the human aortic valve, is treated with a preservative and mounted in flexible supporting struts for implantation. Similarly, treated bovine pericardial tissue is used to make a trileaflet valve and mounted in supporting

struts for implantation. Tissue valves, being subjected to relatively large stresses as they open and close, fail due to fatigue stresses and need to be replaced about 10 to 12 years after implantation. Further, in patients below 40 years of age, tissue valves fail in 3 to 5 years due to calcification of the leaflets. On the other hand, mechanical valves made with high-strength biocompatible material are durable and have a long-term functional capability. However, mechanical valves are subjected to thrombus deposition and subsequent complications resulting from emboli, and patients with implanted mechanical valves need to be in long-term anticoagulant therapy.

The designs of the early mechanical valves were of centrally occluding caged ball or caged disc valves. In 1960, Harken et al. reported the successful implantation of a caged ball valve in the subcoronary position for severe aortic insufficiency (3), while later that year Starr performed the first long-term successful mitral valve replacement with a caged ball valve (4). During the following five years, thousands of Starr–Edwards mitral and aortic valves made of a Stellite® cage and a silicone rubber ball were implanted throughout the world with good overall results.

Following the initial successes, reports of problems with the caged ball design started. In some patients there

was outflow tract obstruction, while in others there were late deaths due to ventricular fibrillation induced by septal irritation by the rubbing of the cage apex. Autopsy specimens demonstrated bulky and oversized ball valves projecting into a contracted left ventricular cavity, proving this point. This resulted in the search for a low-profile prosthesis in the mid-1960s. Hufnagel and Conrad described a polypropylene and silicone rubber caged disc valve. Many others designed similar disc valves with polymeric disc occluders. The notable ones are the Cross-Jones, Kay-Shiley, Harken-Cromie, Beall-Surgitool and Starr-Edwards models (4).

The early clinical trials established the vulnerability of the caged disc valves to catastrophic malfunction, high pressure drops, and thrombus formation behind the disc. The polymeric discs had a high propensity for degradation, wear, and getting stuck due to small thrombi on the struts. In this context, the Starr-Edwards group carried out extensive *in vitro* and *in vivo* testing to find a compatible combination of cage and disc material. Testing of 14 different polymers to determine the best abrasion-resistant material revealed ultra-high molecular weight polyethylene (UHMW PE, Hifax<sup>®</sup>) and Delrin<sup>®</sup> (acetal homopolymer, Dupont) to be superior to the others in wear resistance. Because of the possibility of water absorption by Delrin, Hifax<sup>®</sup> was chosen (4). However, due to poor hemodynamics and a higher propensity for the disc to get stuck, this model soon fell into disuse with the introduction of tilting disc valves at the end of the 1960s.

Wada was the first to introduce clinically a tilting disc design using a notched Teflon<sup>®</sup> (polytetra fluoroethylene, Dupont) disc, which engaged in another pair of notches in the cage (5). The stepped occluder with notches was not free to rotate. This design permitted a large orifice diameter to be used when compared to equal-sized caged ball or disc valves, thus reducing the forward pressure drops considerably. The quest for a valve with optimal hemodynamics inspired Björk to analyze the cardiac catheterization data on early caged ball and disc valves (6,7). He switched over to the Wada-Cutter valve, impressed by its low pressure drops. Clinical data during the next couple of years indicated catastrophic thrombus formation around the notches and wear of the Teflon disc leading to severe valvular regurgitation or fatal disc embolization (8). From these studies, it became clear that any type of hinge created an area of low flow and stasis, which led to thrombus formation around it. Hence, the need was to do away with the hinge and make the disc free floating.

The year 1969 saw the introduction of two truly hingeless free floating disc valves, the Björk-Shiley (9) and the Lillehei-Kaster (10). The Björk-Shiley valve made use of a depression in the disc and two welded wire struts in the

cage to retain the disc. This permitted the disc to tilt open and close, while it was free to rotate around its center. The Lillehei-Kaster valve used a pair of projecting arms on the outlet side and a pair of stubs on the inlet side to retain and allow the disc to tilt and rotate freely as well. The free rotation of the disc distributed the wear on the complete surface of the disc and allowed it to be washed well at the same time, thus preventing thrombus buildup on it.

The main features of these tilting disc valves compared to the caged ball and disc valves were

1. A large orifice diameter for a given tissue annulus diameter, resulting in very low pressure drops.
2. With an opening angle of 60° or more, the flow was more central.
3. The disc was free to rotate around its center, thus preventing any buildup of thrombus.

The Björk-Shiley valve used a Stellite-21 welded cage, a Delrin<sup>®</sup> disc, and a Teflon<sup>®</sup> sewing ring. The Lillehei-Kaster valve consisted of a pivoting disc suspended in a titanium housing encircled by a knitted Teflon fabric sewing ring. The disc was flat and consisted of a graphite substrate coated all around with a 250-micron-thick layer of carbon-silicon alloy (Pyrolite<sup>®</sup>) developed by Gulf Energy and Environmental Systems. A couple of years later, the disc material of the Björk-Shiley valve was also changed to Pyrolite<sup>®</sup>, as Delrin<sup>®</sup> had a propensity to swell during autoclaving (11,12).

Since its introduction, pyrolytic carbon has proven to be a very durable and blood-compatible material for use in prosthetic heart valves. Valve designs fabricated with this material and with a single tilting disc or two leaflets are the most popular mechanical valves in use today. The notable ones are the Hall-Kaster tilting disc valve (presently called the Medtronic-Hall valve), the St. Jude Medical bileaflet valve, the Carbomedics, and the Sorin tilting disc and bileaflet models. The bileaflet designs emerged as having superior forward flow dynamics in comparison to the tilting disc ones. However, clinical results indicate only a marginal reduction in the complication rates with the use of these models.

In spite of these many developments in prosthetic valve design and materials, problems of thrombosis, thromboembolism, and tissue overgrowth continue in all these valves. The thromboembolic complications associated with mechanical valves have been correlated with the forward flow dynamics (1,2). The flow characteristics suggested as factors causing thrombus deposition include turbulent stresses on the downstream side with flow across a fully open valve, and regions of relative stasis and flow separation.

Recently, a number of studies have associated thrombus initiation in the mechanical valves with the stresses in-

duced during valve closure. Almost all currently available tilting disc and bileaflet mechanical valves have relatively rigid pyrolytic carbon occluders. At the instant of the impact of the occluder on the seat stop or the seating lip, the occluder tip comes to a sudden stop, resulting in a water hammer effect. Large positive pressure transients are induced near the leaflet tip close to the valve on the downstream side of the valve. Similarly, large negative pressure transients have been recorded on the upstream side of the valve close to the leaflet tip. This water hammer effect can be the source of several fluid dynamically induced stresses that can initiate hemolysis and platelet activation. Further, in many cases the negative pressure transients fall below the vapor pressure of blood near the occluder edge on the upstream side of the leaflet, leading to vapor phase cavitation. Numerous *in vitro* studies have demonstrated the formation of cavitation bubbles during valve closure (13–21). The cavitation bubbles visualized near the leaflets for a period of less than 1 ms in this region correspond to the regions where the negative pressure transients have also been recorded.

In recent *in vivo* studies, negative pressure transients have been recorded in the atrial chamber very close to the mitral valve *in vivo* and they were also remarkably similar to those measured with a single closing event of the same valve *in vitro*. Therefore it is clear that there is a *potential* for cavitation to occur *in vivo* with implanted mechanical valves. Even in the absence of cavitation bubbles, the negative pressure transients can result in the viscoelastic expansion of the formed elements in blood, resulting in thrombus initiation.

Similar valve closure studies were repeated with the Chitra tilting disc valve with a relatively flexible UHMW PE occluder, both *in vitro* and *in vivo*. Under the same closing conditions, the amplitude of the pressure transients with the Chitra valve was significantly smaller compared to that with a rigid leaflet valve. Since the negative pressures with the polyethylene leaflet valve never reached magnitudes close to the vapor pressure for the blood analog used in these studies, no cavitation bubbles were observed with these valves. These studies suggest that during valve closure with the flexible leaflets, the yielding of the flexible leaflets absorbs part of the energy during impact. Thus the fluid dynamically induced stresses in these regions during closing can be anticipated to be significantly smaller than those with the currently available mechanical valves. Whether this will lead to reduced incidence of thrombosis and embolism in the clinical situation needs to be assessed by well-controlled clinical studies.

In the light of these data, the development and evaluation of the Chitra tilting disc valve prosthesis using UHMW PE occluder is described in this chapter. The cur-

rent data available from a multicenter clinical study is presented. The closing mechanics of the valve is compared with that of the other clinical models with rigid occluders, which clearly brings out the advantage of a relatively flexible occluder.

## II. DESIGN OF THE TILTING DISC VALVE WITH A ULTRA-HIGH MOLECULAR WEIGHT POLYETHYLENE DISC OCCLUDER

One major need for heart valve surgery in India and other developing countries continues to be rheumatic valvular disease. Most of these patients are from low socioeconomic levels and suffer lack of access to diagnosis and prophylaxis. In view of this, the need for valve replacement continues to be large and insistent. The high cost of imported valves was and continues to be one factor limiting the number of replacements being performed. Therefore a project was initiated in the late 1970s at the Sree Chitra Tirunal Institute for Medical Sciences and Technology (SCTIMST), India, for the development of an indigenous heart valve prosthesis, at a time when very little expertise and few facilities for biomedical research existed in the country. As in other valve development programs, the road was rough and had to go through a couple of failures. These details have been presented earlier (22), and the valve is now available under the name of TTK-Chitra Tilting Disc Heart valve prosthesis (manufactured by TTK Pharma Ltd., Chennai, India). For convenience however, the valve will continue to be referred here as the Chitra heart valve (CHV).

### A. Choice of Design and Materials

#### 1. Choice of Valve Type

As per the 1981 census, there were 200 million children in the age group of 5 to 15 years, and the Indian Council for Medical Research has estimated that 6 out of 1000 children in this age group were at risk of acquiring rheumatic disease. Hence the average age of valve replacement patients was below 30 years, and this could well be expected to continue for a few more decades. This ruled out the choice of a bioprosthetic valve, despite its advantage of not requiring long-term anticoagulant therapy. Further, the beef and pork industries were so poorly organized and emotionally charged that a manufacturing program based on such tissue collection was impractical. Thus the choice was limited to a mechanical model. In view of the lack of experience in valve development, and to ensure a reasonable chance of success, the choice was limited to the time-

**Figure 22.1** Photograph of a Chitra valve with a UHMW PE occluder.

tested ones, viz., the caged ball, the caged disc, and the tilting disc designs. With the majority being mitral valve replacements, the caged ball design with its high profile and relatively higher pressure drops was discarded. Between the other two, the tilting disc with its superior hemodynamics (lower pressure drops and more central flow) was considered the best available choice.

## B. Design Features

The Chitra valve in current clinical use is shown in Fig. 1. It has an ultra-high molecular weight polyethylene (UHMW PE) disc, a Haynes-25 alloy (Haynes International, USA) cage, and a polyester suture ring. To start with, some of the basic design features of the Chitra tilting disc valve were drawn from the established designs, while others were modified to suit the current situation. It featured:

*Free floating disc* able to rotate on its center to avoid the problems of thrombosis around a hinge and to distribute the wear over its surface.

*Tilt axis* at one-fourth of the disc diameter (i.e., at the quarter chord point).

*Cage entrance and exit curvature*: bell mouthing of the inlet and outlet edges of the cage to permit smooth entrance and exit of blood.

*Disc shape*: A planoconvex disc with inlet side flat, increasing the inflow area into the minor orifice and making the fabrication of the cage and disc easier.

*Opening angle*: 70° opening angle for reduced pressure drops.

*Cage structure*: The struts machined integral with the ring from a solid block. The main feature of this design was that it enabled the cage to be machined with the indigenous capability at that time without the need for expensive CNC techniques.

## C. Choice of Material

Four material combinations have been tried during this developmental program (Table 1). The first one, using a titanium cage and a polyacetal disc, was given up, as this plastic could swell and distort during steam sterilization (23). The second model used a titanium nitride (TiN) coated Haynes-25 alloy cage and a synthetic sapphire disc. This model successfully completed the accelerated durability test. In animal evaluation, the sapphire disc fractured in 5 out of 14 animal implants. In spite of this, sapphire proved to be an excellent blood-compatible material (24).

With ceramic materials being subject to unpredictable failures and LTI carbon being not available in the country, the search for a new disc material from a range of engineering plastics was initiated. Based on the need for low wear, high fatigue resistance, high toughness, and known biocompatibility, the choice of polymer for the disc was headed by UHMW PE and followed by Delrin ST<sup>®</sup> and Delrin AF<sup>®</sup> (Delrin super-tough and Delrin-PTFE mixture of Dupont, USA) and EKONOL<sup>®</sup> (composite of PTFE and a high-temperature polyester, Carborundum, USA). These

**Table 1** Materials Used in the Different Models of the Chitra Valve

Valve model	Cage		Disc		Sewing ring
	Material	Fabrication	Material	Fabrication	
1	Titanium	Integral major strut; electron beam welded minor strut	Polyacetal (Delrin)	Injection molded	Polyester knitted fabric
2	Haynes-25 alloy with TiN coating	Integrally machined struts	Single crystal synthetic sapphire	Machined and polished	Polyester knitted fabric
3	Titanium	Integrally machined struts	UHMW PE	Solid state polishing and cryomachining	Polyester knitted fabric
4	Haynes-25 alloy	Integrally machined struts	UHMW PE	Solid state polishing and cryomachining	Polyester knitted fabric

four polymers were screened for their water absorption and adhesive and abrasive wear resistance (25).

Water absorption was measured by soaking five specimens 25 mm in diameter and 2 mm thick in distilled water for periods of up to 15 days. The samples were carefully dried and weighed at intervals of 24 hours, 96 hours, and 360 hours. Figure 2 shows that the water absorption of UHMW PE was extremely low and was less than one-tenth that of the Delrin-based polymers. The very low water absorption of UHMW PE ensured that the disc was unlikely to swell and change shape like the Delrin disc occluder of the first Bjork–Shiley model during steam sterilization (23).

Adhesive and abrasive wear are the two main types of wear occurring in conditions like those of artificial heart valves. Adhesive wear is predominant when highly polished surfaces in contact articulate against each other (26). Table 2 shows the data from these studies of the four poly-

mers and clearly indicates that UHMW PE had the lowest wear rates.

The processing of UHMW PE for valve discs involves many thermal cycling stages such as compression molding, die polishing, annealing, and autoclaving of the valve for sterilization. UHMW PE specimens were thermally cycled as listed below and then tested for their wear resistance by both the methods.

- Autoclaved once
- Autoclaved thrice
- Heated to 135°C
- Heated to 160°C

These results, given in Table 3, establish that any thermal cycling of a material above 135°C can cause deterioration in its wear properties (the reported glass transition temperature of UHMW PE is 136–138°C). These tests showed that steam sterilization does not considerably increase the wear properties of UHMW PE.

Prototype valves were fabricated and evaluated as per the guidelines of the American National Standard for Cardiac Valve Prosthesis, ANSI/AAMI CVP3-1981, initially and later based on the guidelines of the International Stan-

dard—Cardiovascular implants—Cardiac valve prostheses, ISO: 5840: 1989. The studies covered in vitro evaluation for hydraulic performance and accelerated durability followed by in vivo evaluation in animals and clinical trials.

**III. IN VITRO FLOW DYNAMIC STUDIES**

The hydraulic performance of the Chitra heart valve has been evaluated under different flow conditions in 1:1 model test flow channels and its performance compared with some of the standard models in current clinical use.

**A. In Vitro Steady Flow Studies**

The flow channels proximal and distal to the aortic and mitral valves (Fig. 3) were patterned on published work and provide cross-sectional areas analogous to the flow tracts in the human heart (27,28). The pressure drop mea-

**Figure 22.3** The aortic and mitral valve flow chambers used in the in vitro experiments.

surements were made at tap P<sub>1</sub> located one valve diameter upstream and tap P<sub>2</sub> four diameters downstream of the test valve. This ensured that full pressure recovery had taken place at the point of measurement (29).

The steady flow system (30) consisted of the mitral test flow channel connected on its inlet side to a constant level tank via a venturi flow probe and a 1.5-meter-long straight entrance section. The outlet was connected to a flow control valve, which discharged into the main reservoir. The pressure drops across the test valves (at wall taps P<sub>1</sub> and P<sub>2</sub> as shown in Fig. 3) were measured using a signal conditioned semiconductor differential pressure transducer. The flow rate was accurately measured using a venturi tube, which was designed as recommended by the American Society for Mechanical Engineers (31).

The hydraulic performance of the 27 mm Chitra mitral valve (CHV) was compared with that of four popular valves of the same size, the Björk–Shiley standard (BSS), the Björk–Shiley monostrut (BSM), the Medtronic-Hall valve (MHV), and the St. Jude Medical bileaflet valve (SJM) under steady flow rates of 0 to 35 L/min.

Figure 4 shows the pressure drop of the 27 mm mitral valves under steady flow. The Björk–Shiley standard valve showed the highest pressure drop among the tilting disc valves due to its lower opening angle of 60°. A mild flutter was noticed at high flow rates, showing that for this disc shape, the center of pressure is just at the pivot point at full opening. The Medtronic-Hall valve also showed a similar flutter at its opening angle of 70°, while the Björk–Shiley monostrut with its convexoconcave disc did not show any. Woo and Yoganathan (32) have reported a similar observation, that the occluder of the MHV was oscillating during

**Figure 22.4** Comparison of steady flow pressure drop data for the various mechanical valves. BSS, Björk–Shiley standard; MHV, Medtronic-Hall; BSM, Björk–Shiley Monostrut; CHV, Chitra; SJM, St. Jude Medical.

diastole under pulsatile testing in the mitral position of a pulse duplicator, and they indicate that the flow could become nonstationary. The MHV is able to open to 70° in spite of its more central pivot location and a flat disc shape due to the presence of disc sliding. As shown by many workers, the St. Jude valve exhibited the lowest pressure drop, while the Chitra valve showed marginally higher magnitudes. The higher pressure drop of the BSM valve than the Chitra valve is probably due to the use of thicker struts.

### B. Relative Flow Between Major and Minor Orifice Areas

The relative flow rates through the major and minor orifice areas of tilting disc valves were measured under steady flow rates of 15 to 25 L/min using the steady flow setup. Pressure drops across the fully open test valves were carefully measured at three flow rates of 15, 20, and 25 L/min; the flow rate being set using the venturi flow meter. Then with the disc in the fully open position, the minor orifice was blocked by sewing a piece of Teflon sheet over it and then filling the well thus formed in the valve with RTV silicone adhesive. In this state, the flow rate through the major orifice was measured using the venturi meter at the same pressure drop as measured first with the fully open valve. This procedure was then repeated with the major orifice similarly blocked. The percentage of the total flow rate for each orifice was then calculated and averaged over the three flow rates. The results are shown in Table 4.

The basic assumption in this technique is that the potential field across the valve is not significantly disturbed due to the blocking of the major or the minor orifice and remains nearly the same as when the valve is fully open. This of course is not strictly true and hence results in some error. Over this flow rate range, it can be seen that the technique yields fairly good estimates of the relative flow through the two orifices, and the effect of the differences in design can be appreciated.

**Table 4** Relative Flow in Major and Minor Orifices of Tilting Disc Valves

Valve model	Percent of total flow through the valve	
	Major orifice	Minor orifice
Medtronic-Hall	69	29
Björk-Shiley monostrut	70	28
Björk-Shiley standard	80	19
Chitra heart valve	75	23

The present model of the Chitra valve exhibits a 4% improvement over the BSS due to the use of the planoconvex disc. The good improvement of flow through the minor orifices of the newer generation tilting disc valves, viz., Medtronic-Hall and Björk-Shiley Monostrut over the Björk-Shiley standard design can also be seen. These improvements in the minor orifice flow for the BSM and MHV have been documented by laser Doppler velocimetry by a number of investigators (28,29,32–34). However, there are no reports of such quantification of volumetric flow rates, which could be more meaningful to the cardiac surgeon.

### C. In Vitro Pulsatile Flow Evaluation

*Pulse duplicator setup.* Many workers (35–39) have described the requirements and concepts for the design of a left heart pulse duplicator. The variety of systems that have been used reflects the problems and constraints involved in modeling the left ventricular dynamics and systemic circulation (27,28,36–38,40–42). The test system used (22) was an improvement of an earlier system developed here (25). The mitral and aortic flow channels were the same as those used in the steady flow test. The design of the systemic impedance was based on earlier work and was simulated by means of hydraulic elements consisting of two capacitances and resistances (38,43).

The blood analog fluid was a 35% solution of glycerol in water having a specific gravity of 1.06–1.08 at room temperature (28–30°C). The test parameters were

- Cycling rate: 70 per minute
- Cycle time: 856 ms
- Systolic duration: 300 ms
- Mean aortic pressure: 100 ± 2 mm Hg

The mean atrial pressure varied between 12 and 18 mm Hg depending on the mean flow. Adjusting the variable systemic resistance and controlling the pressure of the driving air set the mean aortic pressure at 100 mm Hg. Tests were conducted at mean flow rates of 2.5, 3.0, 4.0, and 5.25 LPM. Signals were acquired at 1000 samples/s for 32 consecutive cycles. Two such ensembles of data were acquired at each flow rate and averaged separately. The closing volume, the mean diastolic pressure drop across the valve, and the root mean square (RMS) diastolic flow rate were all calculated from the ensemble averaged data.

The effective orifice area (EOA) at each test flow rate for each valve was calculated using the well-known equation (28). The mean EOA for each valve and its standard deviation were obtained from these calculated values.

$$EOA = \frac{Q}{51.6 \sqrt{\Delta p}}$$

where

$$Q_{rms} = \text{RMS systolic/diastolic flow rate or steady flow rate in cm}^3/\text{s and}$$

$$\Delta p = \text{mean pressure drop in mm Hg (systolic/diastolic in pulsatile).}$$

The EOAs under both steady and pulsatile flow are given in Table 5. Among the mitral valves under steady flow, the St. Jude had the maximum EOA. The Chitra valve came a close second. Under pulsatile flow, all the valves showed comparable EOAs.

**D. Closing Volume Measurement**

Willshaw et al. (44) have used an artificial heart and a pneumotachograph to obtain more accurate measurements of the closing volumes and leaks of tilting disc valves. In this system, there is no dynamic pulsatile flow of the fluid at a given mean flow rate. The system essentially works with only the test valve, thus ensuring more controlled conditions of measurement. The pulse duplicator setup was modified. The ventricular pumping chamber and the mitral flow channel were used. The aortic side of the pumping chamber was sealed, and the valve under test was placed in the mitral position in the conventional manner.

The system was filled with the test fluid to a level of 10 cm above the valve, leaving a column of air space above. Inflating and deflating the rubber bag using compressed air generated the pumping action. A pneumotachograph was designed, fabricated, and calibrated (30). The device acts like a resistance and produces a differential pressure proportional to the rate of airflow through it. The principle of measurement in this system is based on the fact that any volume of water that passes through the valve under test must displace an equal volume of air through the pneumotachograph probe. As the differential pressure across the probe is kept small by design, the volume change due to the compressibility of air is negligible in comparison to the total flow.

This setup functions well with valves whose occluders are denser than the test fluid, like LTI carbon discs. In the

case of the Chitra valve with its UHMW PE disc (specific gravity of UHMW PE = 0.94), the disc opens down fully at the start of forward flow. However, since the forward flow is small (equal to the total regurgitant volume), the flow rate falls to zero towards the end of the filling phase. At this point, the disc floats up and is in a semi closed position. At the start of the systole (bag inflation here), the valves close rapidly, exhibiting a small closing volume.

In order to test the UHMW PE disc valves more fully, the system was modified as shown in Fig. 5 with the disc opening upwards. The UHMW PE discs float up to a fully open position, while the denser discs tend to move down to a small opening angle. In this mode, the pneumotachograph probe was connected to a compliance chamber as shown in the figure. This compliance could be pressurized by pumping air into it. The valve mounting direction was reversed to open upwards in a manner similar to the aortic valve of the pulse duplicator. The mitral test chamber was used for all the tests. During inflation, the fluid flows up, displacing air into the compliance chamber. During deflation of the bag, the air pressure in the compliance chamber

**Table 5** Effective Orifice Area

Valve	Steady flow (cm <sup>2</sup> )	Pulsatile flow (cm <sup>2</sup> )
St. Jude Medical	3.07 ± 0.05	2.51 ± 0.10
Medtronic-Hall	2.80 ± 0.02	2.41 ± 0.09
Björk-Shiley Monostrut	2.82 ± 0.02	2.57 ± 0.13
Björk-Shiley Standard	2.68 ± 0.01	2.51 ± 0.10
Chitra UHMW PE	2.98 ± 0.02	2.47 ± 0.14

**Figure 22.5** Schematic of the closing volume and impact force experimental setup: valve opening upwards.

forces the valve to close; the movement of air being equal to the closing volume as before. The cycling rate, timings, and data collection were all carried out as before

Figure 6 (top) shows typical ventricular pressure and air flow rate ensemble averaged waveforms for the valve opening downwards. In this figure, four phases can be seen. Phase 1 consists of a delay between the starting pulse from the computer (time zero) and the moment at which fluid begins to flow through the valve (point a). The delay, approximately 20 ms, was caused by the time required for the solenoid valve actuation and the buildup of air pressure in the ventricular bag. Phase 2 was the closing phase, during which water accelerated rapidly through the valve, reaching a peak flow rate that was abruptly terminated by valve closure. This abrupt termination produces resonance in the air space above the water column, which was phase 3. The start and finish of the closing phase was detected by the change in sign of the values. The valve closure was defined as the first zero crossing of the resonant phase (point b in the figure).

Figure 6 (bottom) shows typical ensemble averaged waveforms in the case of the valves opening upwards. As before, phase 1 was the delay for the inflation of the bag

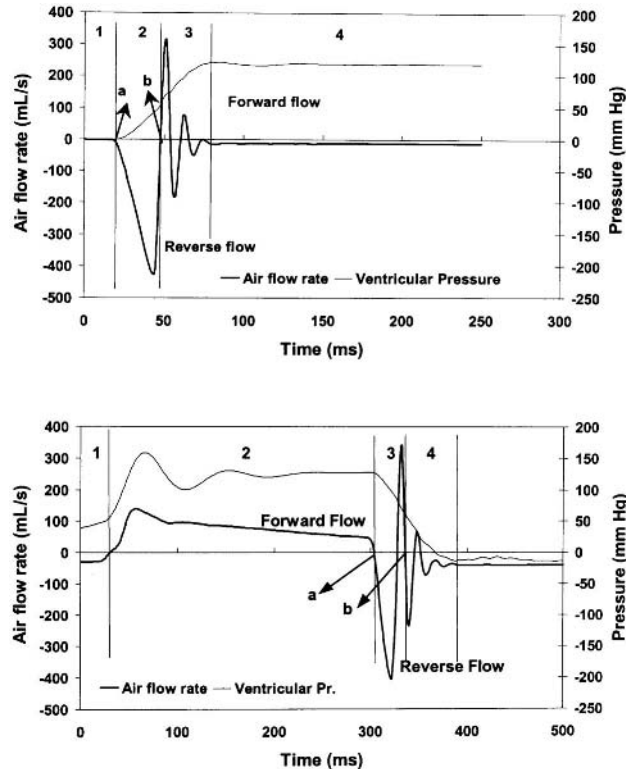

Figure 22.6 Ensemble averaged flow rate waveform: (top) valve opening downwards; (bottom) valve opening upwards.

to start. Here phase 2 was the forward flow through the valve, when the air above the valve was displaced into the compliance chamber with consequent buildup of pressure there. At the start of deflation, the forward flow was terminated by the fall in ventricular pressure, resulting in valve closure due to the higher pressure in the compliance chamber—this was phase 3, the closing phase of the valve. The end of valve closure (point b) was followed by phase 4, when the air column resonates. The closing volume was the area under the curve during the closing phase, i.e., between points a and b. The closing volume, (CV in mL) was determined by integrating the flow signal from the start to the finish points. The results are given in Table 6.

Closing volumes under dynamic pulsatile flow conditions were obtained by integrating the area under the EM flowmeter signal for the duration of the closure period as defined in the international standard. The results are also given in Table 6. The St. Jude valve with its minimal leaflet travel shows the lowest closing volume, while that of the Chitra valve was marginally higher. Other investigators have shown that the closing volumes for the SJM are comparable to others like MHV and BSM (28,45). Knott et al. indicate that closure volumes are mainly dependent on the opening angles (42).

### E. Closing Impact Force Measurements

For the efficient working of any prosthetic heart valves it is necessary that the valve close quickly at the start of reverse flow. To achieve this quick closure, the occluder has to accelerate from its fully open position to the closed position and thereby impact with the cage mechanism before coming to rest. This impact at closure results in an impact force of short duration being transmitted through the cage, sewing ring, and sutures to the heart muscle. Large impact forces can naturally cause problems: suture dehiscence, fatigue fracture, wear of components, and probably tissue overgrowth due to chronic inflammatory response of the host tissue.

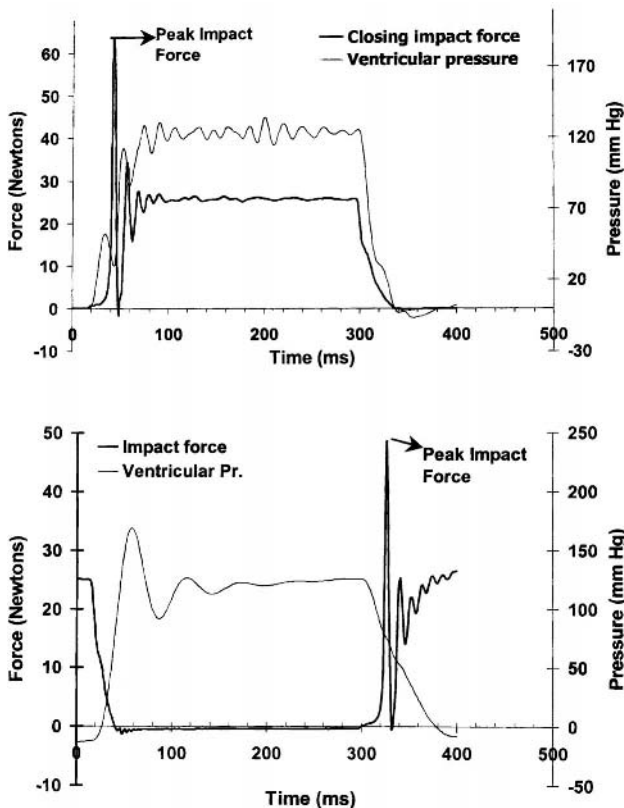

Table 6 Closing Volume and Impact Force Results

Valve model	Closing volume (mL)	Closing impact force (newtons)	Dynamic closing volume (mL)
Björk–Shiley monostrut	6.4	67.5	6.7
Björk–Shiley standard	5.4	51.1	5.7
Medtronic–Hall	6.2	66.0	6.5
St. Jude Medical	3.6	50.6	4.8
Chitra heart valve	4.9	34.3	5.2

The closing impact forces were measured in the same setup as for the closing volume measurements. The air flow probe was removed. Tests were conducted with the valves opening down for the denser discs and opening up for UHMW PE discs for the same reasons as before. The test and data acquisition conditions were also similar. The test valve was sutured to a force transducer plate. The transducer plate was a specially made stainless steel valve holder with strain gauges mounted for measuring the forces. The details of the design and calibration have been described earlier (30).

In the case of valves opening downwards, the initial force is zero with the valve open. At the onset of inflation, the valve closes rapidly with an impact followed by a short ringing. The force signal then settles at a high value due to the ventricular pressure during systole. In the case of valve opening upwards, the closure occurs at the start of deflation.

The closing impact force was taken as the peak value of the force waveform. The peak values were averaged over the 64 cycles. Figure 7 shows typical ventricular pressure and force waveforms for the two cases. The results

**Figure 22.7** Closing impact force plots: (top) valve opening downwards; (bottom) valve opening upwards.

of the closing impact force measurements are given in Table 6. The BSM showed the maximum impact force, followed by the MHV, BSS, and SJM. The Chitra valve showed the lowest impact force. This is due to the use of the soft UHMW PE occluder, which considerably absorbs the shock of impact at closure. This data correlates well with the closing mechanics for this model described in the following section.

#### IV. FLEXIBLE (UHMW PE) LEAFLETS AND VALVE CLOSING DYNAMICS

##### A. Mechanical Valve Closing Dynamics and Induced Stresses

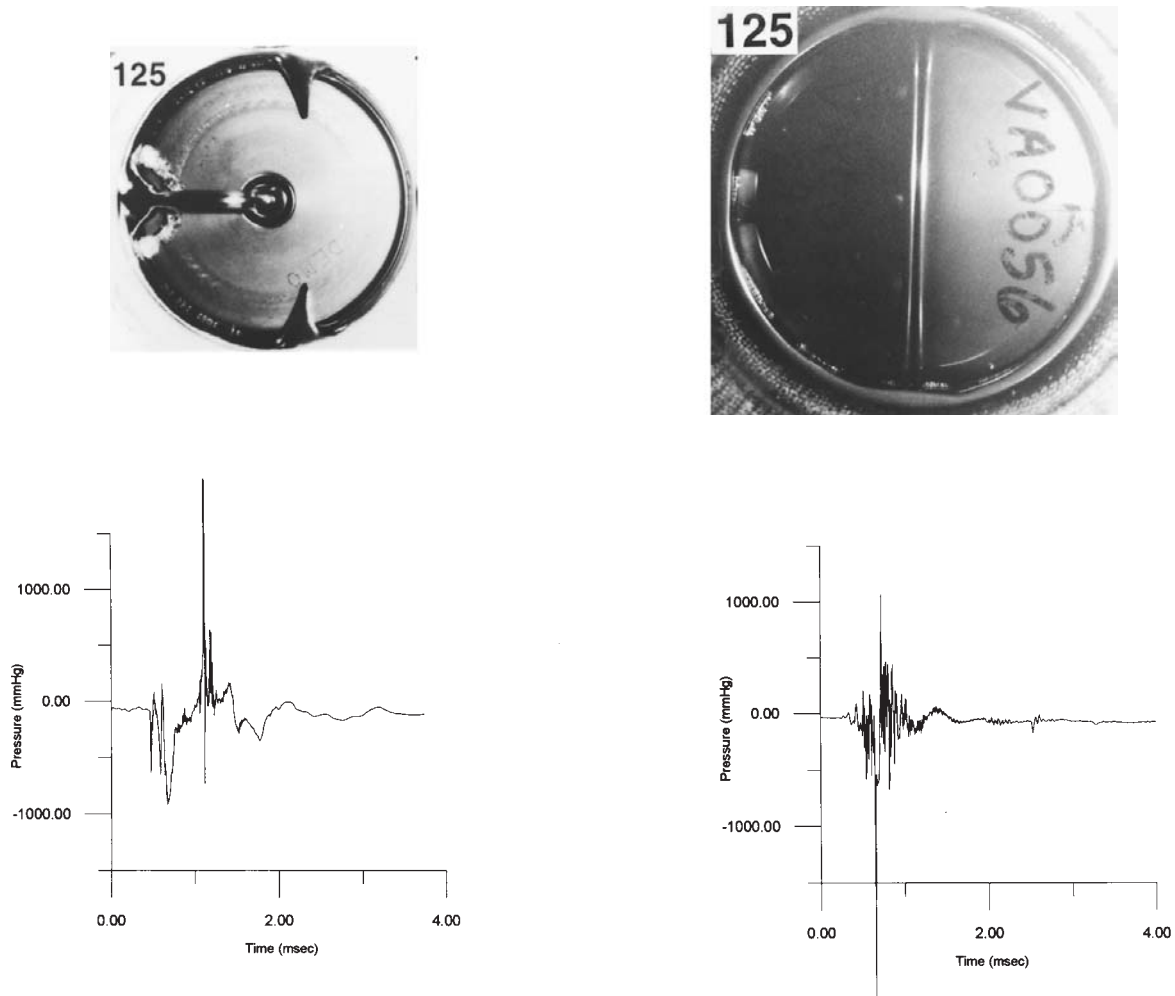

The thromboembolic complications associated with mechanical valve implants have been correlated with the forward flow dynamics since the introduction of mechanical valves (1,2). The flow characteristics suggested as factors causing thrombus deposition include turbulent stresses on the downstream side with flow across a fully open valve, and regions of relative stasis and flow separation. In spite of design improvements to reduce fluid induced stresses in the mechanical valve function, thromboembolic complications continue to be significant with these implants. In the last decade, problems associated with pitting and erosion in mechanical valves implanted in the artificial heart (46) as well as with a bileaflet valve implanted in animals and patients (47) have been reported. Structural failure with mechanical valves have included leaflet fracture (48) and fracture of pivot components and housing (49–52). Recently, a number of studies have associated thrombus initiation in mechanical valves with the stresses induced during valve closure. The occluder of a mechanical valve moves towards the closing position due to the adverse pressure gradient (larger pressure on the downstream side than on the upstream side) during the valve closing phase. All currently available tilting disc and bileaflet mechanical valves have relatively rigid pyrolytic carbon occluders. At the instant of impact of the occluder on the seat stop or the seating lip, the occluder tip comes to a sudden stop, resulting in a water hammer effect. Large positive pressure transients are induced near the leaflet tip close to the valve on the downstream side of the valve. Similarly, large negative pressure transients have been recorded on the upstream side of the valve close to the leaflet tip. This water hammer effect can be the source of several fluid dynamically induced stresses that can initiate hemolysis and platelet activation. The large pressure gradient induced across the valve leaflet, even though for a fraction of a second, can force blood through the clearance region between the leaflet and the valve housing. Model studies have demon-

strated that relatively large wall shear stresses and local negative pressures can develop in this region at the instant of valve closure (53–56). In the simulation performed by Aluri (55,56), a simplified geometry of the leaflet and valve housing was employed to study the stresses induced by the flow through the clearance region during valve closure. In order to delineate the effect of leaflet motion during the valve closure, the first simulation involved the leaflet in the fully closed position with the ventricular pressure rise. The second simulation started with the leaflet in the open position and the leaflet moving towards the closed position with the ventricular pressure rise. A moving boundary for the rigid leaflet motion was included in the computational analysis for the latter simulation. At the instant of valve closure, the second simulation demonstrated the presence of a large negative pressure on the downstream side of the leaflet. The computed wall shear stress with the moving leaflet at the instant of valve closure was about 4000 Pa compared to about 580 Pa when the leaflet was held in the fully closed position. This study clearly demonstrated that the moving leaflet and the sudden closure of the rigid leaflet induced wall shear stresses of an order of magnitude larger than that when the leaflet was held stationary in the closed position. The clearance region between the leaflet and the valve housing in the periphery is also the region in which relative stasis and flow separation are usually observed during the forward flow phase of the cardiac cycle. Hence it is logical to assume that activated platelets subjected to relatively large shear stresses during valve closure can induce thrombus deposition at these sites in the subsequent forward flow phase.

The flow through the clearance region during valve closure has also been shown to induce regurgitant jets, resulting in relatively large turbulent stresses near the edge of the leaflet (57). The turbulent stresses measured in the regurgitant jets were significantly larger than the magnitudes measured downstream to the valve during the forward flow phase. Relative damage to blood during the forward and reverse flow phases of the cardiac cycle were studied in a steady flow system (58). In this study, damage due to steady forward flow through a fully open mitral valve was measured periodically at flow rates of 3 to 7 L/min. The blood damage was assessed by the measurement of plasma free hemoglobin in blood. Reversed flow across a closed mitral valve was also assessed at flow rates of 0.1 to 0.2 L/min in the same steady flow set up (by reversing the orientation of the valve). The levels of hemolysis observed were the same for both the forward and reverse flow phases, even though the flow rates in the reverse flow were an order of magnitude smaller. Significantly higher levels of hemolysis were also observed in pulsatile flow simulation. Even though pulsatile flow studies could not delineate

the amount of blood damage between the forward and reverse flows through the valve, the significant increase in blood damage during pulsatile flow can be attributed to the valve closure induced stresses.

Cavitation is the rapid formation and collapse of vapor-filled bubbles caused by a transient reduction in local pressure to below the liquid vapor pressure. For glycerol solution, the vapor pressure is  $-743$  mm Hg (59), and for whole blood, the magnitude is  $-713$  mm Hg. Should the negative pressure transient (NPT) reach magnitudes below the vapor pressure for blood for a sufficient duration, cavitation bubble formation and collapse can result. The implosion of the bubbles can damage the blood cells and activate the platelets. The pitting and erosion observed on the occluder and housing surfaces with implanted mechanical valves suggest cavitation damage (46,47). It is not surprising that the suggestion of cavitation damage on valve surfaces has resulted in numerous *in vitro* studies on the visualization of cavitation bubbles during valve closure (13–21), the measurement of negative pressure transients at the instant of valve closure and cavitation initiation (13–16,18–21), and the velocity of the occluder tip at the instant of valve closure (14,60–64). These studies have demonstrated the presence of negative pressure transients with pressure below the vapor pressure of blood near the occluder edge on the upstream side of the leaflet. The cavitation bubbles visualized near the leaflets for a period of less than 1 ms in this region correspond to the regions where the negative pressure transients have also been recorded. Typical negative pressure transients recorded with tilting disc and bileaflet mechanical valves at the instant of valve closure, and the corresponding cavitation bubbles visualized, are shown in Fig. 8. Mechanisms that have been suggested to initiate cavitation bubbles during valve closure include the water hammer effect and the presence of negative pressure transients (13–15), vortices generated at the edge of the leaflet during valve closure (18), and the additional pressure drop induced by the velocity of fluid being squeezed between the leaflet and the seat stop at the instant of valve closure (16). In comparing the closure mechanics with valves of the same geometry (e.g., tilting disc valves), it was demonstrated that even with the presence of negative pressure transients, initiation of cavitation bubbles was dependent on the design of the valves. In valves where there was an interaction between the occluder and a seat stop at the instant of valve closure, bubbles were present, whereas no bubbles were observed in valves without such interaction (13,15). These studies suggest that the local flow dynamics in the vicinity of the leaflet edge and the squeeze flow effect are important in cavitation initiation. Numerical simulation of the squeeze flow effect has been reported (65–67), and these studies suggest that the fluid velocity

**Figure 22.8** Negative pressure transients recorded in vitro with mechanical valve closure and the cavitation bubbles visualized in vitro. The inserts on the photographs indicate the time in microseconds after the instant of valve closure when the bubbles were visualized.

induced by the squeeze flow effect are of the order of several m/s and hence can induce additional local pressure drop that may initiate cavitation bubbles. Simulations have also suggested that the relatively rigid pyrolytic carbon leaflets in the mechanical valves rebound after the initial impact with the valve seat and hence induce additional negative pressure transients as well.

Studies performed on cavitation bubble visualization in pulse duplicators with the mechanical valve in the mitral position have used the peak ventricular pressure rise ( $dp/dt_{\max}$ ) as an index for the threshold for cavitation. However, the motion of the leaflet during valve closure will be governed by the ventricular pressure rise during the valve closure (about 30 ms after the beginning of the ventricular pressure rise), whereas the peak ventricular  $dp/dt$  occurs after the valve is fully closed in the mitral position. Hence

the ventricular pressure rise rate during the leaflet closure,  $dp/dt_{cl}$ , has been suggested as the appropriate parameter to compare the closure mechanics of the various valve designs (13–17) and has been adopted by the FDA in mechanical valve closure studies. These studies were performed with controlled pressure rise rates during valve closure, and measurements of pressure transients, valve leaflet velocity, and bubble visualization were performed with a single closing event of the valve rather than simulating the periodic closure that the normal valve undergoes. However, a comparison of the cavitation bubbles visualized, as well as the characteristics of the pressure transients, in the studies with a single closing event with those obtained in the pulse duplicator have been observed to be similar.

The pressure transients in the above-referenced studies were from in vitro studies, generally in rigid flow chambers

with the valve rigidly mounted in the mitral position. The effect of the flexibility of the mount (to simulate the valve sutured in the mitral orifice in vivo) has been suggested as important (64). However, studies with a single closing event with rigid and flexible valve holders have shown that this effect is not important. The water hammer effect and the local flow dynamics inducing cavitation bubbles will be due to the relative velocity between the valve housing and the leaflet and hence should not be affected by the relative rigidity of the valve holder (17).

Questions have also been raised about the presence of such negative pressure transients with mechanical valves implanted in vivo, since the in vitro studies do not simulate the distensibility characteristics of the atrial chamber. The only indirect evidence that cavitation is possible in vivo with implanted valves is the pitting and erosion observed in explanted valves that are characteristic of cavitation damage. At present, there are no techniques to visualize the presence of cavitation bubbles in vivo. However, if negative pressure transients similar to those demonstrated in the in vitro studies can be recorded with implanted mechanical valves in vivo, one can assert that at least a *potential* exists for cavitation to occur in vivo. Studies were performed in an animal model in which mechanical valves were implanted in the mitral position in sheep and a high-fidelity transducer was positioned very close to the leaflet in the closed position in the atrial chamber. The ventricular pressure rise was also recorded for a range of ventricular contractions with the aid of pharmacological interventions. These studies demonstrated that the ventricular pressure rise measured during mitral valve closure in vivo (68,69) were in the same range as those that were used in the in vitro studies earlier (13). Furthermore, negative pressure transients were recorded in the atrial chamber very close to the mitral valve in vivo, and they were also remarkably similar to those measured with a single closing event of the same valve in vitro. These studies further demonstrate that there is a potential for cavitation to occur in vivo with implanted mechanical valves. Typical negative pressure transients measured in vivo with the mechanical valve implanted in the mitral position are compared with those obtained in vitro with valves of the same design in Fig. 9. It should also be pointed out that these studies have demonstrated that the presence of negative pressure transients is not the only necessary condition for cavitation to be initiated; local fluid dynamics based on the valve designs play an important role. Since structural failure with implanted mechanical valves is not significant, one can assume that cavitation damage occurred in a very small fraction of mechanical valves and is due to the local flow dynamics related to the interaction of the leaflets and the valve housing in certain designs. Even in the absence of cavitation bub-

**Figure 22.9** Comparison of negative pressure transients recorded during valve closure in vitro (top) with valve implanted in the mitral position of an animal model to that recorded for the same valve in vivo (bottom).

bles, the negative pressure transients can result in the viscoelastic expansion of the formed elements in blood, resulting in thrombus initiation. All these fluid dynamically induced stresses, including high shear stresses in the clearance region in the vicinity of the leaflet edge and the housing, significant regurgitant jet turbulent stresses, stresses induced by cavitation bubble collapse, and viscoelastic expansion of formed elements in the negative pressure region, can result in the activation of platelets and thrombus initiation. This region near the valve housing is also the region of flow reversal and relative stasis in the subsequent forward flow phase; hence induced thrombus will likely deposit and grow in this region. Thus mechanical valve closure and fluid dynamic stresses resulting during this phase of the cardiac cycle may be the dominant factors in thrombus deposition with implanted valves in the absence of anticoagulation.

## B. Occluder Flexibility and Valve Closing Dynamics

The studies described above have concentrated on the currently available mechanical valve prostheses with relatively rigid pyrolytic carbon leaflets. As such a leaflet impacts against the seat stop at the instant of valve closure, the water hammer effect results, since the leaflet does not yield significantly to the impact nor absorb part of the impact energy. Studies have shown that the leaflets rebound after impact and create additional negative pressures on the upstream side of the leaflets. Polymeric valves have flexible leaflets, which can absorb part of the energy during impact, and hence one can expect that the negative pressure transient amplitudes will be significantly smaller. Studies were done with the Chitra valve (with its relatively flexible UHMW PE leaflet) both in vitro and in vivo. Comparisons were made on the leaflet tip velocity at the instant of valve closure, negative pressure transients, and presence of cavitation bubbles in vitro under similar closing loads between mechanical valves with rigid leaflets and the Chitra valve (13–15). For a valve with the same design (e.g., tilting disc geometry) and the same size, the leaflet tip velocity at the instant of valve closure was the same irrespective of the rigidity of the leaflet. However, under the same closing conditions, the amplitude of the pressure transients with the Chitra valve was significantly smaller than those with a rigid leaflet valve. Since the negative pressures with the polyethylene leaflet valve never reached magnitudes

**Figure 22.10** Comparison of negative pressure transients with a rigid leaflet mechanical valve with the flexible leaflet Chitra valve from in vitro and in vivo experiments.

close to the vapor pressure for the blood analog used in these studies, no cavitation bubbles were observed with these valves. Similar results were obtained from the in vivo studies as well. A comparison of the pressure transients of mechanical valves with rigid leaflets with those of the Chitra valve in vivo is shown in Fig. 10. These studies suggest that during valve closure with flexible leaflets, the yielding of the leaflets absorbs part of the energy during impact. Thus the fluid dynamically induced stresses in these regions during closing can be anticipated to be significantly smaller than those with the currently available mechanical valves. A controlled study on thrombus initiation with rigid and flexible leaflet mechanical valves is necessary to evaluate whether flexible leaflets will help minimize the problem.

## V. ACCELERATED DURABILITY TESTING FOR WEAR AND FATIGUE RESISTANCE

The mechanical durability of the heart valves in terms of their wear resistance and fatigue properties was determined by accelerated life cycling testing. The test protocol is based on the guidelines of the ISO standard Cardiovascular implants—Cardiac valve prostheses: ISO: 5840:1989. Testing at normal heart rates in mechanical systems or animal models for over 10 years is unrealistic. Several methods of accelerated testing of prosthetic heart valves have been tried and used (70). These include pneumatic cycling and several variations and combinations of mechanical and hydraulic cycling.

The test system in use for the past 20 years has been described earlier (25,30). The hardware of the system presently in use is third generation, and many problems with the reliability of the equipment have been minimized so that the test results can be interpreted with reasonable accuracy. Five equally spaced valves are mounted on a stationary housing and covered with an acrylic chamber. The test fluid (distilled water treated with trace amounts of copper sulfate to control fungal growth) is supplied through the center inlet of the test housing. A DC motor with a variable speed control drives the rotor inside the housing. A rotor sequentially actuates each of the five test valves and distributes the fluid at a pressure of 200 mm Hg (26.7 kPa). The test valves are mounted with their sewing rings stitched to silicone rubber supports to isolate and damp their vibrations during cycling.

Two combinations of test valves (Haynes-25/UHMW PE: three each of size 27 mm and 23 mm; Titanium/UHMW PE: two of size 23 and one of size 27 mm) and two 27 mm Björk–Shiley standard valves were tested in

this system for over 350 million cycles each. The valves were cycled at 800–840 times a minute, the rate being periodically checked using a strobe. The valves were removed after 1, 2, 5, 10, 20, and 40 million cycles and thereafter at intervals of 40 million cycles. In these instances, the assemblies were removed from their sewing ring holders, cleaned, degreased, and dried before weighing.

Wear of the valve components was measured by weighing them (or the cage/disc assembly during the test) to an accuracy of  $\pm 0.1$  mg in a single-pan electronic balance. The cage and disc were weighed separately before assembly. Control weights of titanium (coated with titanium nitride to prevent erosion) were used to monitor the reliability and consistency of the weighing balance over the prolonged period of the test.

The end of the cycling of any valve was determined when

1. There was a failure of any its components.
2. Excessive wear was noticed and the valve was expected to fail very soon.
3. The valve reached 400 million cycles without failure.

At the end of the test, the valves were dismantled and the components weighed again. They were also inspected for signs of wear and other degradation. The volume of wear was calculated from the weight loss and the density of the material. During cycling, since the cage and disc cannot be weighed separately, the weight loss was attributed to the component that wears most. The error due to this was found to be small as borne out by the final weighing.

Figure 11 shows the results of these tests. The volume of wear was calculated from the weight loss and the density of material (UHMW PE = 0.94 and LTI carbon disc = 2.0 g/mL). The bulk of the wear was in the UHMW PE disc. These rates are marginally higher than those of the Björk-Shiley standard. No mechanical failure or signs of excessive wear were encountered in any of the test valves.

The extrapolation of the wear data obtained from accelerated wear testing to predict actual implant durability depends on the relation of the wear occurring in vivo to that measured in the test system. To assess this factor, valves implanted in sheep have been carefully monitored for weight loss. The number of cycles that the valve has gone through is estimated by assuming that on an average, the heart of the animal beats at 70 per minute. Table 7 shows the weight loss of valves recovered after implantation and the corresponding weight loss interpolated from accelerated wear data. The clinical valve was recovered at reoperation for a thrombosed valve and cleaned well including enzymatic treatment to remove adherent proteins. It should

Figure 22.11 Volume loss plots from the accelerated wear tests.

be noted that the accuracy of the electronic balance over such long periods of time is at best  $\pm 0.2$  mg, even with the careful calibration that was followed. The data clearly indicate that there are no signs of either excessive wear or absorption of body fluids; the polymer seems to stabilize inside the body as expected.

Accelerated testing inherently imposes unrealistically severe conditions because of

1. The inability to achieve adequate system damping
2. Increased pressures that are required to achieve full valve excursion
3. Inferior lubricating properties of the test fluid
4. High frequencies imposing stresses that are not found at lower rates

Accurate prediction of device durability is of considerable importance in the development of life-saving devices like prosthetic heart valves. The reliability and durability of the test apparatus can be a significant problem, when one considers that it must outlive a relatively simplistic device designed to withstand an equivalent of 38 million cycles per year for over 50 years or more. Hence the design of the test system and the subsequent results obtained with a certain model of valve need to be validated with data from explanted devices, either animal or clinical.

The system used here has proved to be reliable in terms of long-term performance. Table 7 shows that this system gives a reasonably good 1:1 correspondence to the wear rates obtained from explanted valves.

The Björk–Shiley standard valves have been in clinical use since 1971 and have had an excellent record of durability. Their durability based on wear rates was estimated to be 400 years (70). The wear rate of UHMW PE disc valves

**Table 7** Explant Data from Animal Trials

Implant duration (Days)	Estimated cycles (millions)	Wt. loss (mg)	Explant	Accelerated test
			Reasons for explantation	Interpolated wt. loss (mg)
<i>Titanium cage—UHMW PE disc valve—animal explant</i>				
210	21	0.2	Elective terminated—good healing	0.42
220	22	0.5	Elective terminated—good healing	0.44
418	42	0.4	Animal died—tissue overgrowth at the inflow side—valve disc got stuck	0.70
454	46	0.8	Elective sacrifice—excellent healing	0.75
498	50	0.3	Animal weak—terminated—evidence of myocardial infarction	0.81
<i>Haynes-25 cage—UHMW PE disc valve—animal explant</i>				
96	9.7	0.2	Elective sacrifice	0.17
175	18	0.2	Elective sacrifice—good healing	0.28
1457	148	0.9	Animal died—bronchopneumonia	1.30
2765	280	2.1	Animal died—viral infection	2.48
3213	322	2.2	Animal died—valve thrombosis	2.60
<i>Haynes-25 cage—UHMW PE disc valve—clinical explant</i>				
758	76	0.3	Reoperation for thrombosed valve	0.78

is marginally higher than that of the Björk–Shiley valve. The wear of the plastic disc gets distributed over its surface as it rotates during working. Hence, for a given volume of wear loss, the thickness of the component worn out is very much smaller than it would be if the cage struts were to wear. Clinical use of UHMW PE in artificial hip joints over the last 35 years has shown this material to be extremely stable in the body environment. Considering all this, valves with UHMW PE discs can be expected to last for over 50 years of implant life at a minimum.

## VI. IN VIVO EVALUATION

### A. Animal Studies

Adult sheep in the weight range of 30 to 40 kg are the animal model for this study. It was carried out with the authorization and supervision of the Institute's Animal Care Committee. *The International Guiding Principles for Biomedical Research Involving Animals* of the Council for International Organization of Medical Sciences (CIOMS) were strictly followed (71). Sheep were chosen as the model for this trial for the following reasons:

1. Adult sheep in the weight range of 30 to 40 kg had a heart size suitable for implantation of a 23 mm valve in the mitral position.

2. Well-established procedures for the conditioning, anesthesia, surgery, and postoperative care already existed following the development of a bubble oxygenator.
3. Earlier experiments showed pigs, dogs, and calves to be poor candidates for open-heart surgery in comparison.

The details of these studies for the clinical model of the Chitra valve have been published earlier (22). The mitral valve of the sheep was replaced with the test valve (23 mm sewing diameter) using standard open-heart surgical procedures.

Postoperatively, the animals were given antiplatelet agents for the first 14 days to reduce platelet aggregation and deposition. No anticoagulants were given. They were closely watched for signs of ill health such as loss of weight and appetite and general alertness. Valve sounds were regularly auscultated.

All animals that either died or were electively terminated were subjected to a detailed autopsy, covering the following areas:

1. Cause of death
2. Inspection of the valve for thrombus/platelet-fibrin deposit and tissue buildup
3. Evidence of thromboembolism by gross and histo-

pathological examination of the brain, kidneys, spleen, and liver

4. Explant analysis of the valve covering
5. Physical changes: Weight loss of the components as a measure of wear

Five mitral valve replacements of each of the Ti/UHMW PE and Haynes-25/UHMW PE models (all of 23 mm size) were carried out successfully. Three animals from the Ti group at 7 months and two from the Haynes-25 group at 3 and 6 months were electively terminated (Table 7). In the titanium group one animal died at 1 year and 2 months due to tissue overgrowth on the inflow side of the valve, leading to immobilization of the disc. The last animal became very weak and was electively terminated at 1 year and 4 months. An autopsy revealed evidence of myocardial infarction—the valve was clean, the sewing ring was well healed, and the disc was moving freely. Whether the infarction was due to a thromboembolism from the valve could not be determined at autopsy.

In the Haynes-25 group, three animals died at various periods as given in the Table 7. One died at 4 years due to bronchopneumonia and the second at 7 years and 7 months due to a viral infection. In both the cases the sewing ring was well healed all round and the disc was moving freely. In the third animal, which survived for the longest duration, 8 years and 9 months, a large thrombus was noticed on the valve at autopsy, which effectively immobilized the disc. It should be noted that except for the first 14 days following the valve implantation, the animals were not given any antiplatelet or anticoagulant medication.

The pressure drop across the valve was measured by transthoracic cannulation of the left atrium and the left ventricle in three anaesthetized animals (two from the titanium group and one from the Haynes group). The cannulae were connected to a semiconductor differential transducer using extension tubing and three-way stopcocks. ECG and the differential pressure signals were digitized and acquired using a data acquisition system. The end diastolic pressure drop was read for 10 consecutive cycles and averaged. The mean end diastolic pressure drop for the three animals was 3 mm Hg.

The hemolytic effect of the valve was determined by measuring free hemoglobin in plasma, the reticulocyte count, and the lactose dehydrogenase (LDH) before and after surgery and then after the third month. Hemolysis due to the valve could not be detected (22).

The explanted valves in general (except for the two noted earlier) showed excellent healing of the suture ring. No physical changes, including dimensional changes or degradation of the polymer, were observed. Weight loss of the cages was not measurable. The weight loss of the

discs is given in Table 7. The good correlation between the weight loss in animals and the equivalent estimates interpolated from the accelerated wear data even at 7 and 8 years clearly indicate the stability of the polymer and its durability.

## B. Clinical Studies

Based on engineering and animal data, it was clear that both combinations, titanium/UHMW PE and Haynes-25/UHMW PE, were equally good. Polishing of Haynes-25 with its high chromium content was found to be easier than with titanium. Obtaining a consistently high quality of surface finish with titanium alloys is more difficult than with chromium-containing alloys like stainless steels and the cobalt-chromium alloys. In view of this, it was decided to use a Haynes-25 cage and a UHMW PE disc for further clinical trials and commercial production.

On the basis of the engineering and *in vivo* animal data, the Ethics Committee of the Sree Chitra Tirunal Institute approved the evaluation of the Chitra valve in patients on October 27, 1990. The study was based on a common protocol developed at a joint meeting of the investigators with a senior statistician and approved by the institutional ethics committees. In the first phase, from December 1990 to November 1991, forty valves were implanted at the Institute. In the second phase, from January 1992 to January 1995, five additional centers across the country were included in the study. After a total of 306 valve replacements (101 aortic and 205 mitral), an analysis was carried out in February 1995 for the Monitoring Committee of the multicenter study, and the results have been reported previously (22).

A detailed follow-up was carried out from September 1997 to September 1998 for this same group of patients. This clinical data analyzed separately for aortic and mitral valves as per the American Association for Thoracic Surgery (AATS) guidelines of 1996 are being reported in detail (72). The overall analysis of all the patients, which brings out the clinical performance of this valve model, is highlighted in this section.

### 1. Patients

As mentioned, between December 1990 and January 1995, 306 patients underwent isolated mitral (=205) and aortic (=101) valve replacement. On discharge, written and verbal instructions on anticoagulation were given to the patients and families. Anticoagulation was achieved by Dicoumarol or Nicoumalone to maintain prothrombin time at 1½ to 2 times the control value.

The mean age was 28.9 years, the youngest being 6 and the oldest 58 with a male-to-female ratio of 1.2:1. Over

**Table 8** Preoperative Clinical Profile

Population	306 patients
Age (years)	
Mean	28.87
Range	6–58
Male/female ratio	1.20 (167/139)
NYHA class	
II	99 (32.4%)
III	172 (56.2%)
IV	35 (11.4%)
Heart rhythm	
Atrial fibrillation	88 (28.7%)
Sinus rhythm	211 (68.9%)
Unknown	7 (2.4%)
Valve lesions	
Stenosis	71 (23.2%)
Insufficiency	140 (45.8%)
Mixed	95 (31.0%)
History of CCF	85 (27.8%)
History of embolism	8 (2.6%)

two-thirds belonged to NYHA classes III and IV and shared a poor socioeconomic background (Table 8). Sixty-five percent of AVR patients had aortic insufficiency as the main lesion, while insufficiency and mixed lesions dominated (72%) the MVR group.

Early mortality (defined as death within 30 days of surgery or before discharge from the hospital, whichever is later) was  $6.9 \pm 1.5\%$  (21 patients). While one patient died from anticoagulation related hemorrhage and another succumbed to infective endocarditis, four patients (two each of AVR and MVR) died suddenly at home within a month of the operation. Non-valve-related causes claimed 15 patients ( $4.9 \pm 1.3\%$ ).

## 2. Postoperative Valve Function

In the first phase unicentric trial, postoperative valve function was assessed by Doppler echocardiography before discharge from the hospital. Eighteen aortic (all size 23 mm) and 20 mitral (all size 25 mm) valves were studied. Systolic or diastolic pressure drop and valve orifice areas were measured by the pressure half-time method. Regurgitation was assessed qualitatively.

This assessment showed that the systolic pressure drops were 8–26 mm Hg (mean 20) with the 23 mm aortic valves. With the 25 mm mitral valves, the diastolic pressure drops were 2–5 mm Hg (mean of 3) and the valve areas ranged from 2 to 3.4 cm<sup>2</sup> (mean 2.5). Doppler showed mild intravalvular regurgitation in most aortic and some mitral valves. This was acceptable and consistent with the leak allowed by the nonseating disc.

## 3. Follow-Up

Two hundred eighty five patients were reviewed at their respective institutions, initially at 1, 3, 6, and 12 months and thereafter at approximately yearly intervals. Between December 1997 and March 1998, 75 patients with no follow-up prior to September 1997 were vigorously traced. About 50% responded to direct letters and two-thirds of the remaining recalcitrant patients could be traced by direct house visits. At the end of the study period in September 1998, 13 patients remained lost to follow-up (defined as not having a checkup or any other form of contact (if not confirmed to have died) during the 12 months of the study period. Thus the net follow-up was 272/285 or 95.4% in terms of patients. The duration of follow-up ranged from 1 month to 7.5 years with a mean of 4.25 years; the minimum follow-up for survivors was 3 years. Total follow-up years actually observed was 1212 patient years.

## 4. Data Analysis

The linearized incidences and the actuarial probabilities of survival were calculated according to the method of Grunkemeier and Starr (73) and Lefrak and Starr (74). Percentages are expressed as percent  $\pm$  1 standard error.

## 5. Late Mortality

Late deaths occurred in 52 patients ( $4.3 \pm 0.6\%$  per patient year), 12 due to known valve-related causes (Table 9) and 17 due to non-valve-related causes. Twenty-three patients died at home between 2 months and 8 years after the operation, and the cause of death could not be determined. These unknown deaths have been treated as valve-related in all analyses.

## 6. Postoperative NYHA Status (Figure 12)

The majority of the operative survivors (258 of 285) moved up to NYHA Class I following valve implantation

**Table 9** Valve Related Late Events and Deaths

Event	No. of patients	%/patient year	No. of deaths
Valve thrombosis	11 (13) <sup>a</sup>	$1.1 \pm 0.3$	5
Systemic embolism	22 (22)	$1.8 \pm 0.4$	1
AC bleeding	3 (6)	$0.5 \pm 0.2$	3
Infective endocarditis	6 (6)	$0.5 \pm 0.2$	3
Unknown deaths		$2.4 \pm 0.44$	23
Total			35

<sup>a</sup> The figure in brackets gives the number of events in that category. AC = anticoagulant related.

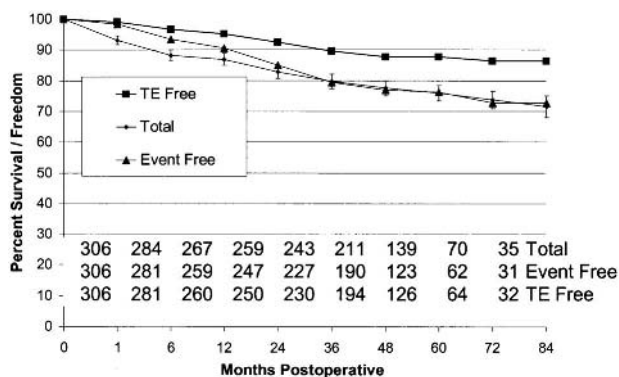

**Figure 22.12** Postoperative status of the patients implanted with the Chitra valve.

and full recovery, while none remained in the preoperative levels of cardiac dysfunction (NYHA III and IV).

### 7. Valve-Related Mortality and Late Events

Twelve patients died due to confirmed valve-related complications (Table 9). To this figure was added the 23 unknown deaths, which resulted in a linearized incidence of  $2.9 \pm 0.5\%$  per patient-year. Among late events during follow-up (Table 9), 13 episodes of valve thrombosis occurred in 11 patients ( $1.1 \pm 0.3\%$  per patient-year). Ten of these patients had discontinued anticoagulants for periods ranging from a few days to 3 months. Five patients in this group died before hospitalization became available to them. Four responded well to thrombolytic therapy, and the other two underwent successful valve re-replacement, one with a Starr–Edwards valve and the other with a CHV. Embolic episodes occurred in 22 patients ( $1.8 \pm 0.4\%$  per patient-year) of whom four had discontinued anticoagulants. Twenty-one patients in this group made a full recovery without residual neurological deficit, while one died. Six patients had anticoagulant-related bleeding ( $0.5 \pm 0.2\%$  per patient-year) of whom three succumbed to intracerebral bleeding. Of six patients who developed infective endocarditis ( $0.5 \pm 0.2\%$  per patient-year), three died.

The long term actuarial survival rates for the 285 survivors are shown in Fig. 13. At 5 years, the survival rate was  $75.8 \pm 2.6\%$ , and at 7 years it was  $71.5 \pm 3.5\%$ . Figure 13 also shows the actuarial data for thromboembolism free survival, which includes both valve thrombosis and systemic embolism. At 5 years, the freedom from thromboembolism was  $87.7 \pm 2.0\%$ , and at 7 years it was  $86.4 \pm 2.4\%$ . The freedom from all valve related mortality and morbidity was  $76.3 \pm 2.6\%$  at 5 years and  $72.6 \pm 3.2\%$  at 7 years.

**Figure 22.13** Long-term actuarial survival rates for the 285 survivors with Chitra valves.

There has so far been no report of mechanical failure, either in this study or elsewhere. Interestingly, there has been no incidence of paravalvular leak in this study. Also, there have been no complaints of discomfort due to the valve sounds. The closing sounds are soft and dull due to use of the UHMW PE disc. Even in the generally young and lean patients, the valve sounds are not easily heard nearby.

The important features of this patient profile are advanced disability (68% in NYHA classes III and IV) and poor socioeconomic background. The advanced preoperative functional disability would adversely influence operative mortality and long-term survival. The poor socioeconomic background is a major cause for late attendance at the hospital and, above all, lack of compliance in taking anticoagulants and other medications. It was not rare for poor patients to skip medications for financial reasons or because of nonavailability in a remote village. Nor was it rare for patients with valve thrombosis to delay reporting to the hospital in spite of progressive dyspnea, until they were in the terminal stage of pulmonary edema. These problems are encountered in varying degrees in third-world populations (75).

The low incidence of anticoagulant related bleeding in the present series probably reflects the less aggressive policy of physicians in the use of anticoagulants. The absence of any report of paravalvular leak is noteworthy and could be due to the low closing impact forces of this valve design. This needs further confirmation via larger and longer follow-up of patients.

Table 10 shows a comparison of the valve related complications, mortality rates, and actuarial estimates of the present series with those reported by Antunes *et al.* (75) with the use of the Medtronic-Hall valve in a third-world population. The striking similarities in the complications

**Table 10** Comparison of Mortality, Complication, and Actuarial Values

Mortality/complication/ actuarial value	Incidence in %/patient-year	
	CHV	Antunes et al.
1 Late mortality	4.3 ± 0.6	6.3 ± 0.5
2 Valve related mortality	2.9 ± 0.5	2.9 ± 0.3 <sup>a</sup>
3 Thrombosis	1.1 ± 0.3	1.2 ± 0.2
4 Embolism	1.8 ± 0.4	3.3 ± 0.3
5 Paravalvular leak	0.0	2.2 ± 0.2
6 Infective endocarditis	0.5 ± 0.2	0.7 ± 0.2
7 Anticoagulant related hemorrhage	0.5 ± 0.2	0.7 ± 0.2
8 Freedom from thrombo- embolism at 5 years	87.7 ± 2.0	85 ± 2.0
9 Freedom from all valve related mortality and mor- bidity at 5 years	76.3 ± 2.6	75 ± 3.0
10 Total survival at 5 years	75.8 ± 2.6	75 ± 2.0

<sup>a</sup> This excludes 41 of 64 cases of sudden or unknown death.

and survival rates highlight the comparable performance of the CHV and the Medtronic-Hall valve.

Bain and Nashef (76), in their review of the performance of different models of tilting disc valves, have quoted the incidence of bleeding at 0.3 to 1.1% per patient-year, paravalvular leak at 0.7 to 2.0% per patient-year, and infective endocarditis of 0.8% per patient-year. They have also quoted the following figures for valve thrombosis and embolism for Björk–Shiley valves (all models): Embolism for aortic valves at 0.4 to 1.6% per patient-year and for mitral valves at 1.5 to 3.0% per patient-year; thrombosis varies between 0.9 to 1.1% per patient-year. The data in this study are comparable to these. This study confirms the earlier observation (22) that the CHV is mechanically sound, structurally reliable, and hemodynamically and clinically comparable to other tilting disc valves of similar design.

## SUMMARY AND CONCLUSIONS

In this chapter, the concept, design, development, and evaluation of a mechanical valve with a flexible polymeric occluder has been described. The development of a UHMW PE occluder enabled the technology to be indigenous to countries like India and proved to be cost-effective in treating a significant percentage of patients who cannot afford implantation of imported valve prostheses. The in vitro and accelerated wear evaluation assured that the prototype valve will have performance characteristics comparable to the currently available mechanical valve prostheses in the

United States. Careful analysis of the valve closing dynamics and the stresses induced in this phase of the cardiac cycle suggests that valves with flexible occluders have significantly less fluid dynamic stresses, which may prove to be advantageous. The in vivo evaluation both in the animal model and in implants in patients proves to be promising. A carefully controlled study comparing the implant experience with the Chitra valve and the presently available mechanical valves with the pyrolytic carbon occluders is necessary for further investigation.

## Blood-Contacting Polymers

T. Avramoglou, J. Jozefonvicz, and M. Jozefowicz  
*Université de Paris, Villetaneuse, France*

### I. INTRODUCTION

When a foreign body is brought into contact with blood, it is confronted with two complex biological systems, coagulation and immunity. Although these protective mechanisms are essential in man, they create problems when a foreign body is intentionally brought into contact with blood for medical purposes. However, since the early 1950s, polymers have been widely used for a large range of medical applications, from long-term implants to short-term dressings, in all fields of medicine and surgery. Examples of practical devices that implicate blood contact polymers are (1):

- Extracorporeal blood-circulating devices
- Catheters
- Blood bags and tubing used for blood transfusion
- Membranes, hollow fibers, and tubing used for dialysis devices, plasmapheresis and plasma detoxification, and oxygenators
- Cardiac valves and blood vessel replacement such as aortic bypasses
- Drug delivery systems
- Plasma expanders and blood substitutes
- Contrast agents
- Embolization agents

The medical use of such devices has increased during the second half of the 20th century due to improvements in the quality of the devices and that of the polymers used

to produce them. These polymers are increasingly prescribed for use in cardiac surgery and in the treatment of renal and cardiovascular disease. Without the use of polymers, some of the major improvements made in the past decades, in medical and surgical practice, would have been impossible.

The global market for medical devices was approximately \$120 billion in 1995. The market of blood-contacting polymers is relatively large and has an annual increase of approximately 5% (2). Synthetic materials are used in contact with blood in millions of medical devices and diagnostic systems. The number of devices used worldwide each year is impressive: 100,000 heart valves, 500,000 vascular grafts, >250,000 stents, 200,000 pacemakers, 200,000 blood oxygenators, 50,000,000 blood bags, and millions of catheters (3).

The polymers commonly used to produce blood-contacting devices are essentially either classical synthetic polymers or natural polymers (1) (Table 1) (Fig. 1). Poly(vinyl chloride) (PVC) is the most extensively used polymer for all short-term devices, such as extracorporeal blood-circulating devices, catheters, and blood bags. Silicone rubber and polyethylene present alternative materials for these devices. Cellulose and cellulose derivatives, polyamides, polypropylene, polyacrylonitrile, polysulfone, and polyesters are the basic materials for membranes and hollow fibers for dialysis. Commercially available vascular grafts and cardiac valves are essentially made from polyesters, mainly poly(ethylene terephthalate) (Dacron<sup>®</sup>) and

**Table 23.1** Main Blood-Contacting Polymers

Polymer	Device
Cellulose and derivatives	Membranes for dialysis
Cross-linked collagen	Heart valves
Dextran	Plasma expanders
Human albumin	Plasma expanders
Polyacetal	Heart valves
Polyacrylonitrile	Membranes for dialysis
Polyamides	Catheters, heart valves, membranes for dialysis
Polycarbonates	Syringes, catheters, heart valves
Poly(ethylene terephthalate)	Vascular prostheses
Polypropylene	Syringes, catheters
Polysulfones	Membranes for dialysis
Poly(tetrafluoroethylene)	Vascular prostheses, artificial hearts, catheters
Polyurethanes	Vascular prostheses, artificial hearts, catheters
Poly(vinyl chloride)	Blood bags, catheters
Silicones	Catheters, artificial hearts

poly(tetrafluoro ethylene) (Teflon®). Finally, polyurethanes and related polymers such as poly(ether-urethane) have also been developed as biomaterials (4,5). Biopolymers have been developed simultaneously, mainly for cardiovascular prosthetic devices. These materials are essentially collagen derivatives from animals, highly cross-linked by glutaraldehyde or other agents. Cross-linking improves the mechanical properties of the material and depresses its immunogenicity, which is important as collagen degradation products are known to be inflammatory (6–8).

The major improvement of the past decade, in this field, is the use of so-called medical grade polymers, i.e., polymeric compounds that release neither toxic nor carcinogenic products into the bloodstream. Moreover, the degra-

ation products of such materials are nontoxic and noncarcinogenic and do not accumulate in the body (9–12).

A further improvement has been achieved through the modification of the processing technique employed to produce the polymers. The following desirable properties have been attained (13):

Increased permeability and mechanical strength of the membranes and hollow fibers used in dialysis.

Increased mechanical strength and relative porosity in vascular grafts. The porosity of the wall allows the healing process to occur within the walls of the vascular graft.

Despite their extensive use, the polymers available are essentially unsatisfactory, because of the undesirable events produced when blood comes into contact with the polymer. The first problem is the rapid adsorption of protein (14), which is the trigger for blood coagulation and leads to platelet adhesion. The second problem arises from the large difference between the mechanical compliance of the polymers and that of the natural blood vessel wall (15). Turbulence in the bloodstream results from the described variation, which in turn induces hemolysis, platelet activation, and aggregation (16–18). Moreover, the rugosity of the surface in contact with the blood may also produce similar undesirable effects (19). It should be noted that for long-term uses the loss of the mechanical strength of mobile devices (e.g., artificial heart membranes) might be a cause of failure of the device itself. It appears that these events are related to calcification processes occurring within the polymer matrix, after several months of exposure to blood (20). The third problem is created when the compounded polymer releases some of the adjuvant, stabilizers, and plasticizers into the bloodstream. This may induce blood damage (21). A literature survey carried out the early 1970s examined commercially available PVCs. These polymers, even when of medical grade, exhibit different blood compatibilities with respect to their ability to induce the blood coagulation process. This can be attributed to the release of plasticizers or stabilizers. The fourth undesirable event is produced by the degradation of the material. This may result from the long-term exposure of the polymers to blood. In this case nontoxic and noncarcinogenic products are released, which induce blood coagulation. This degradation effect is not necessarily related to the mechanical failures previously described. Finally, the exposure of polymers to blood may promote both a cellular and a humoral immune response, and may also carry a risk of bacterial infection. All these events can be catastrophic, and they sometimes require surgical intervention to replace the implanted device. This is the case for biovalves made

**Figure 23.1** Weight distribution for blood contacting polymers. (From Ref. 357.)

of cross-linked collagen, which have a replacement rate of 25% after 10 years in the body (22).

In order to overcome the thrombotic problems encountered when using blood-contacting polymers, the medical professional can utilize an anticoagulant long-term adjuvant therapy, based on heparin and a vitamin K antagonist (coumarin, etc.). However, this type of therapy may induce some undesirable side effects.

The grafting of prostheses, made of synthetic materials, is adequate for the treatment of large arteries. However, the low hemocompatibility of these prostheses in small-diameter blood vessels does not allow their use in coronary or below-the-knee arterial replacement. The absence of an endothelium, in conjunction with the thrombogenic properties of the synthetic material, results in a high percentage of thrombosis when synthetic prostheses are grafted at these anatomic sites. To overcome this problem, it is possible to seed endothelial cells on expanded PTFE and then implant the endothelialized prosthesis. Although this technique is time-consuming, requiring approximately one month between the sampling of the autologous cell and the grafting, it leads to excellent results (23). Superior results are achieved with total vessel rebuilding (24). The latter technique is highly complex.

A considerable amount of research, during the past decades, has been devoted to the synthesis and tailoring of new biomaterials suitable for use as blood-contacting polymers. These new materials should not induce either the coagulation of blood or the immune response. Furthermore, they should not allow bacterial adhesion. With the availability of new materials, considerable progress in the field of blood-contacting artificial devices is expected in the near future.

In this chapter the following subjects will be reviewed:

- The physiological aspects of hemostasis.

- The events that occur when blood contacts a polymer, with particular attention to the coagulation of blood and the immune response. As a result, the blood compatibility of polymers will be defined.

- The factors that may affect the blood compatibility of polymers and their relevance to experimental data. In addition, the suitability of both commercial and noncommercial blood-compatible polymers for the manufacture of blood-contacting devices will be considered.

- The new concept of "bioactive biomaterials."

The response of blood to the artificial surfaces of polymers is inevitable, and it is possible to list the different interactions as follows: protein adsorption, platelet reaction, intrinsic coagulation, fibrinolytic activity, complement activation, and interaction with circulating cells.

## II. BLOOD COAGULATION

Normal coagulation, or hemostasis, prevents vital internal fluids leaking, but pathological and inappropriate coagulation results in thrombosis. The hemostatic mechanism appeared at a very early stage of evolution (25,26), even before the formation of the vascular system (27,28).

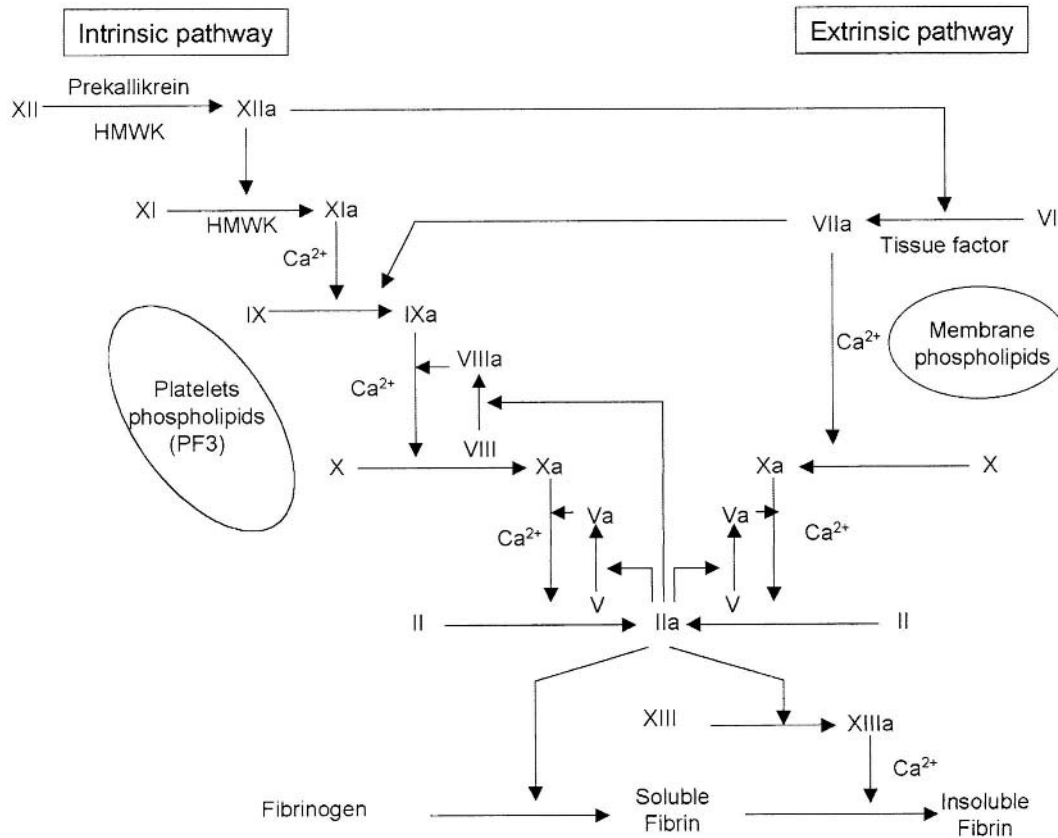

Coagulation enables man to survive hemorrhaging following a trauma. It has to occur in a restricted area around the cut to avoid disturbing the general circulation of the blood. When the vascular breach is repaired, the blood clot will dissolve so that the circulation of the blood in the previously damaged vessel can resume: this is fibrinolysis (29). This mechanism prevents the permanent obstruction of damaged vessels. Thrombosis, which is the obstruction of undamaged vessels, is also avoided by fibrinolysis.

Coagulation represents the transformation of soluble fibrinogen into an insoluble fibrin network under the influence of thrombin, the key enzyme. It is a complex phenomenon and involves several enzymes, cofactors, and phospholipidic surfaces. All these elements are termed coagulation factors. The latter circulate as inactive precursors, of which some are zymogens and others are cofactors. Each zymogen is converted to an active form (a serine protease), which in turn activates the next coagulation factor in the sequence. However, this coagulation "cascade" is not a linear process; it implies intricate positive and negative feedback, in which thrombin affects its own formation and its own breakdown. Numerous steps in the hemostasis process are heterogeneous catalysis implying calcium ions and negatively charged phospholipids. Comprehension of the physiological nature of the coagulation is essential in order to elaborate a blood-compatible polymer.

Initiation of blood coagulation has been divided into two pathways (Fig. 2), the intrinsic and the extrinsic. Both pathways culminate in the generation of thrombin. The intrinsic cascade is initiated when blood comes into contact with an anionic surface and as only dependant on factors intrinsic to the flowing blood. The extrinsic pathway is initiated by tissue factor (TF or thromboplastin or factor III). This protein only becomes exposed to the bloodstream when a vascular wall is damaged (30).

### A. Extrinsic Pathway and Primary Hemostasis

Primary hemostasis is a physiological process necessary to preserve homeostasis, as well as being the first step of the process of tissue repair. Primary hemostasis involves all of the complex interactions between the vascular walls, platelets, and coagulation factors described above, as well as hemorheological factors such as blood viscosity and flow.

**Figure 23.2** Overview of blood coagulation. The coagulation factors are designated with roman numerals, and the suffix a indicates a proteolytically activated factor.

Primary hemostasis in small blood vessels is determined by the standardized measurement of bleeding time. In man, the bleeding of sectioned small blood vessels stops after approximately four minutes. This process takes place in several stages. Cutting the vascular wall causes it to contract, which then modifies the local hemodynamic conditions and exposes the subendothelial conjunctive tissue. The surface of the endothelial cells is thromboresistant, whereas the collagen-rich subendothelium is thrombogenic. The platelets adhere to the subendothelium when submitted to hemodynamic forces and in the presence of the von Willebrand factor (factor VIII). This is the first stage of hemostasis. Both the coagulation pathways are activated, in conjunction with the activation of platelets. Upon vascular injury, the thromboplastin is exposed to blood and readily forms a one-to-one stoichiometric complex with the circulating factor VII (convertin). Complex formation with thromboplastin has two functions. It augments the activation of the factor VII to VIIa, and it enhances the proteolytic activity of factor VIIa with respect

to its substrates. The factor VIIa/TF complex, then, initiates blood coagulation by proteolytically activating its substrates, factors IX and X, leading to the rapid formation of factor IIa (thrombin) (31). The subendothelium collagen activates the factor XII (Hageman factor) and leads to the slower, intrinsic formation of thrombin.

### B. Intrinsic Pathway and the Contact System

The initiation of the intrinsic pathway involves four proteins forming a system termed a “contact system” (32). This pathway is triggered when factor XII (Hageman factor) comes into contact with collagen present in the exposed subendothelium. The activated factor XII (factor XIIa) then activates factor XI, which, in the presence of calcium ions, cleaves a peptide from factor IX. The latter reaction produces the activated form, factor Xa, in the presence of the phospholipids of the platelet membrane, factor VIII, and calcium ions. The activated factor X together with factor V bind to the platelet phospholipids in the pres-

ence of calcium. This complex, referred to as prothrombinase, catalyses the conversion of prothrombin (factor II) to thrombin (factor IIa). The effect of cofactors V and VIII is greatly enhanced by positive feedback created by the action of the thrombin.

### C. Platelet Activation

In case of endothelium damage, the procoagulant subendothelium is exposed to the circulating platelets. Platelets, which are small nonnucleated cells, are very important for blood coagulation, because they provide procoagulant phospholipids and factor V.

The platelets are activated by the subendothelium, to which they adhere, and by the localized formation of trace thrombin. Platelets adhere to the subendothelium through their surface receptor (glycoprotein GP Ib-V-IX) via the von Willebrand factor (a polymer of factor VIII) and are activated to change shape and spread, undergo the release reaction, and stimulate the arachidonate pathway. Released adenosyl diphosphate (ADP) and thromboxane A<sub>2</sub> (TxA<sub>2</sub>) cause the circulating platelets to change shape, express the fibrinogen receptor (glycoprotein GP IIb-IIIa), and stick to other platelets. Simultaneously, the platelets rearrange their phospholipidic membrane in such a way that the procoagulant lipids such as phosphatidyl serine, that normally remain inside the membrane, appear on its outer surface. Thus the growth of the thrombus is initiated. In addition, thrombin generated at the site of vascular injury causes further release and aggregation of platelets and transforms fibrinogen into fibrin, thereby contributing to the growth of the thrombus and its stabilization with a fibrin mesh (33). The surface of this thrombus exhibits a phospholipoprotein (designated platelet factor 3 or PF3). The latter promotes and accelerates the generation of the factor X (Stuart factor) and thrombin at the surface. It also enables these elements to be protected from the inhibiting action of antithrombin (AT). Furthermore, the platelet factor 4 (PF4), which has a great affinity for heparin, is released by activated platelets (see below). Therefore PF4 inactivates heparin, rendering it unavailable to catalyze the inhibition of thrombin by antithrombin (34).

### D. Thrombin and Clot Formation

When materials are in contact with blood, the cascade of enzymatic reactions described above leads to the formation of thrombin, which plays numerous important roles in the coagulation of blood (35). Thrombin is able to induce both platelet aggregation and release. This enzyme has the possibility of catalyzing its own formation. Thus when small

amounts of thrombin become available, increasing quantities of the enzyme will be readily formed. Thrombin is able to activate fibrinogen in a hydrolysis reaction that produces fibrinopeptides A and B and the soluble fibrin polymer (36). The cross-linking of the soluble fibrin is catalyzed by factor XIII (37), and this results in the formation of the insoluble fibrin clot. It should be noted that aggregated platelets, other blood cells, and plasma proteins are entrapped in the cross-linked fibrin network.

### E. The Fibrinolytic System

Fibrinolysis is a physiological phenomenon that results in the enzymatic destruction of the thrombus (29,36). This process involves plasmin, which is a serine protease produced from an inactive precursor: the plasminogen. All the physiological activators of fibrinolysis are all serine proteases. The latter are formed from zymogens by limited proteolysis after clotting or by the formation of a thrombus, which can occur in two different ways (Fig. 3). The activation of fibrinogen is dependent on the contact system, coagulation, circulating activators, and the endothelium of the vessel. The intrinsic pathway is initiated when the factor XII is activated to XIIa by interaction with a negatively charged foreign surface in the presence of high molecular weight kininogen and prekallikrein. The extrinsic pathway, however, seems to be more relevant to the physiological changes in fibrinolysis. There are two kinds of physiological activators, one of which is the tissue plasminogen activator (t-PA) synthesized within and released from the endothelial cell. The tissue plasminogen activator is predominately responsible for the lysis of clots in the vessels. The other type of activator is the urinary plasminogen activator (u-PA), which was initially identified in human urine and was later found in plasma (29). It should be noted that some foreign proteins, for example streptokinase and staphylokinase, and proteins from bacteria, have an enzymatic ability to form a complex with plasminogen and to promote plasmin formation (38).

The powerful inhibitor alpha-2-antiplasmin immediately inhibits any plasmin that may appear in the blood. It can be concluded that fibrinolysis is a localized phenomenon occurring at the surface of the thrombus or blood clot when it is confined in a closed cavity. In reality, plasmin is only observed in circulating blood during thrombolytic treatment using streptokinase.

Plasmin degrades the fibrous network of cross-linked fibrin as well as the fibrinogen. The products of this enzymatic digestion are called the fibrin degradation products (FDP). The quantity of the latter is an indirect measure of the action of the plasmin.

Figure 23.3 Schematic diagram showing the activation pathways of the fibrinolytic system.

**F. Coagulation Control**

From the discussion of the whole coagulation process, it would appear that the formation of the clot should occur when blood contacts any surface, including the normal vessel endothelium. However, this would result in the general thrombosis of the blood circulation system. As this is not the case in reality, it is obvious that other control systems are involved. Moreover, the normal healthy vessel endothelium is able to control the coagulation cascade. Thus blood coagulation is carefully controlled in vivo by several anticoagulant mechanisms, which ensure that clot propagation does not lead to occlusion of the vascular system (39,40).

1. Circulating Coagulation Inhibitors

Thrombin plays a central role in hemostasis, so there must be enough to ensure hemostasis but not so much as to cause thrombosis. As in all the important biological systems, thrombin generation is ensured by a delicate system of positive and negative feedback, in which thrombin influences both its own formation and its own breakdown. There are three types of coagulation inhibitors: the “enzyme kidnapers” (such as alpha-2-macroglobulin), the inhibitors that block active sites (such as antithrombin), and the serine proteases (such as alpha-1-antitrypsin) Table 2. These inhibitors are generally able to form complexes with several proteases, at variable rates. For instance, alpha-2-macroglobulin reacts readily with kallikrein but slowly with

thrombin. In plasma, about 70% of the thrombin generated is inhibited by antithrombin, 20% by alpha-2-macroglobulin, and the rest by other inhibitors such as alpha-1-antitrypsin.

The most potent plasma inhibitor is antithrombin, which is able to form inactive stable complexes with serine proteases including factors IIa, IXa, Xa, XIa, and kallikrein. The reactions are irreversible and slow. They suggest the formation of a chemical bond between the serin active site of the protease and an arginyl residue of the inhibitor (41). These reactions are more or less subject to be catalyzed by heparin and heparin analogs that might be present in some subendothelial or endothelial tissue (42).

Another thrombin inhibitor, the second heparin cofactor (HC II), is also able irreversibly to form a stable complex with thrombin (43–45). However, unlike antithrombin,

**Table 23.2** Coagulation Inhibitors in Human Plasma

Inhibitor	Concentration in plasma (g/L)
Alpha-1-antitrypsin	2–4
Alpha-2-antiplasmin	0.085
C1 inactivator	0.25
Alpha-1-antichymotrypsin	0.48
Alpha-2-macroglobulin	3
Antithrombin	0.15–0.25
Heparin cofactor II	0.079

this inhibitor is not able to react with other proteases involved in the coagulation cascade. In this case, the most effective catalysts appear to be dermatan sulfate and pentosan polysulfate rather than heparin (46–48).

## 2. Endothelial Cell Control

The endothelial cells associated with thrombin employ several different pathways to achieve the control of hemostasis.

Welsler et al. (49) showed that thrombin stimulates the endothelial cells to secrete prostacycline (PGI<sub>2</sub>), a prostaglandin that is a very potent inhibitor of platelet aggregation and hence restricts the growth of the thrombus.

Intact endothelial cell membranes contain a receptor called thrombomodulin. In the presence of the latter, thrombin loses its procoagulant properties and catalyzes the hydrolysis of protein C (50–52). The resulting activated protein C (aPC) is able to bond to platelet membranes. It has been suggested that activated protein C is able to catalyze the hydrolysis of factors Va (53) and VIIIa (54) when fixed onto the platelet membrane. As a result, the rate of activation of the factors X and II is decreased in the vicinity of the endothelial cells. During this process, the protein S also plays a role. Activated protein C, together with protein S, inactivates both tenase (a complex of factor IXa, factor VIIIa, and calcium ions on phospholipid, activating the factor X) and prothrombinase, hence stopping the formation of thrombin. Activated protein C is also a profibrinolytic (55).

Thrombin also stimulates the production of the plasminogen activator by the endothelial cells, which initiates the fibrinolytic degradation of thrombi (56). Other mechanisms are also involved in the control of thrombosis by endothelial cells. For example, endothelial cells can synthesize and release nitric oxide (NO), which is a potent vasodilator and also an inhibitor of platelet aggregation (57).

All of these preceding pathways, and probably others, are involved in the control of clot formation (58,59). Their

failure may contribute to atherothrombosis and therefore appears to be one possible manner by which general thromboses occur as a consequence of this disease. Other plasmatoc control systems are involved in the prevention of general thrombosis.

## 3. Glycosaminoglycans

The ability of certain sulfated polysaccharides (such as glycosaminoglycans, the best known of which is heparin) to interfere with blood coagulation is well known (60,61). More than 80 years after its discovery, heparin remains an important antithrombotic agent in clinical use. The main effect of heparin (and heparan sulfate) is to accelerate the inactivation of coagulation enzymes by antithrombin, the most potent serine protease inhibitor (serpin) (42,62). Another serpin, the heparin cofactor II, which is activated by heparin and also by another glycosaminoglycan, dermatan sulfate, selectively inactivates thrombin (47,63). Control of blood coagulation is *via* the protein C pathway and involves a glycosaminoglycan-containing molecular species as the protein C activator thrombomodulin, which is a proteoglycan. The exact chemical nature of the catalytic site on heparin was a matter of controversy until Choay *et al.* (64,65) proved that a synthesized pentasaccharide was a replica of the catalytic site (Fig. 4). The conformational change of antithrombin bonded to the heparin is now well described (66).

The endothelial cells of blood vessels synthesize a minor subpopulation of proteoglycans, which exhibit heparan sulfate with the appropriate pentasaccharide to bind antithrombin (67–71). This interaction serves as the basis of the natural anticoagulant mechanism of the vascular system (72).

## G. Procoagulant Regulation

It is important to ensure a fast initial thrombus formation and stabilization to prevent bleeding. Thus, in plasma, a specific inhibitor inhibits the anticoagulant properties of

Figure 23.4 Pentasaccharide corresponding to the minimal sequence in heparin for binding to antithrombin.

the activated protein C: the protein C inhibitor (PCI). PCI is a member of the serine protease inhibitor family (serpin) (73). The reaction rate between aPC and its inhibitor is increased in the presence of heparin or dextran sulfate (74). The fibrinolytic system is controlled by two proteins: plasminogen activator inhibitors 1 and 2 (PAI-1 and PAI-2), which are also serine protease inhibitors (75,76).

The complement inhibitor S protein, which is identical to the adhesive protein vitronectin, functions as a heparin neutralizing factor by protecting thrombin and activated factor X against rapid inactivation by antithrombin. The vitronectin counteracts the anticoagulant activity of heparin and pentosan polysulfate but not that of dermatan sulfate (77). Vitronectin also plays another role in hemostasis, as it can strongly bond with a high affinity to PAI-1. The formation of the complex with vitronectin not only increases the half-life of PAI-1 in circulation but also enables the active inhibitor to be stabilized at sites of vascular injury and initial platelet plug formation (78).

## H. Conclusion

Clot formation appears to be the normal consequence of the contact between blood and polymers, unless the latter have been specifically designed and tailored to prevent this catastrophic event. Clots initiated by contact may develop in different ways depending on the nature of the surface. The final result is always thrombin formation. The latter may well be the pivotal event in coagulation. Pro- and anticoagulant mechanisms generally favor anticoagulation under physiological conditions. However, the anticoagulant system is restrained, and procoagulant forces predominate at sites of vascular injury.

Blood and the natural endothelium of the vessel wall are able to control the coagulation process. One of the most potent control systems available is the heparin-catalyzed formation of the antithrombin–serine protease complex.

It must be emphasized that the coagulation of blood is a complicated process. Its kinetics cannot be completely described by the schematic models given above, as the formation of a clot is a complex combination of each of the reactions involved. Moreover, these kinetics are dependent on the flow rate of the circulating blood. This adds one further parameter to the multiparameter system controlling the coagulation of blood.

## III. BLOOD COAGULATION ON FOREIGN SURFACES

It has been known for a long time that prothrombin time (a coagulation test) is shorter in glass than in plastic. This is a consequence of a relationship between the contact sys-

tem and extrinsic coagulation: factor VII can be activated by factor XIIa. This is an indication of the importance of the surface composition in the coagulation process. The blood reaction to a foreign surface is driven by interfacial phenomena that are determined by the surface properties of the material (79) and blood flow characteristics (80).

### A. Role of the Adsorption of Protein

As a result of different interactive forces (Tables 3 and 4), a competitive adsorption of proteins and glycoproteins occurs at the polymer surface, and they form a complex protein coating (81). Some of these adsorption processes are partially or completely reversible (82,83). Depending on the nature of the surface, some of the deposited proteins may initiate coagulation. Therefore in order to improve the blood compatibility of insoluble polymers, it is necessary to understand the phenomena that govern the adsorption of the proteins. The latter is the first essential step to triggering coagulation or to promoting complement activation by a foreign surface.

When a foreign surface (solid, liquid, or gas) is brought into contact with a protein solution like blood, a certain

**Table 23.3** Fundamental Interaction Forces Between Materials and Blood Components

Interaction forces	Description
van-der-Waals forces including	Attractive dipole–dipole interaction considerably weaker than ionic or covalent bonds. These forces decrease rapidly with the distance (by the factor $1/d^7$ for London forces and by the factor $1/d^4$ for others).
Keesom forces (between two permanent dipoles)	
Debye forces (between permanent dipole and induced dipole)	
London forces (between instantaneous dipole and induced (dipole))	The typical energy is about $2 \text{ kJ} \cdot \text{mol}^{-1}$
Hydrogen bonds	Attractive, a special case of very strong dipole–dipole interaction. Typical energy is about $20 \text{ kJ} \cdot \text{mol}^{-1}$
Ionic interactions	Attractive or repulsive, these forces decrease by the factor $1/d^2$ . Typical energy is about $250 \text{ kJ} \cdot \text{mol}^{-1}$

**Table 23.4** Resultant Interaction Forces Between Materials and Blood Components

Interaction forces	Description
Electrostatic double layer forces	Attractive or repulsive long-range forces, depending on the electrolyte content of the medium
Hydration forces	Repulsive
Hydrophobic interactions	Attractive long-range forces
Polymer-induced forces	Sterical repulsion or bridging attraction
Specific forces	Attractive short-range (e.g., acid-base, Ca <sup>2+</sup> bridges)

Source: Adapted from Ref. 357.

amount of the dissolved protein will be adsorbed on the surface. The amount of protein adsorbed and the composition of this protein layer depend mainly on the nature of the foreign surface. To a great extent, the biological properties of the surface depend on the adsorbed protein. Unfortunately, the hemocompatibility is difficult to predict from the characteristics of the surface.

During the last 30 years, it has been established that the first event to occur when blood contacts a foreign body is the adsorption of plasma proteins to the surface. Vroman (84,85) has shown that a protein layer is formed on the surface within a few seconds of being in contact with blood. In the same period, Dutton *et al.* (86) showed that there is a protein layer between the substrate and the adhered platelets or thrombi. Hence the comprehension of the protein adsorption mechanism is essential in order to understand polymer/blood compatibility. The composition of the adsorbed layer is dependent on the chemical nature of the surface of the material (87,88). Furthermore, the conformation adopted by the adsorbed proteins plays an important role in the biological behavior of the surface (89,90).

Protein molecules in aqueous solutions are compact structures with hydrophilic amino acids at the surface, whereas hydrophobic ones are inside. In contact with a polymeric surface, hydrogen bonds, hydrophobic interactions, and ionic and polar forces can induce a conformational change of the adsorbed protein, sometimes leading to the unfolding of the macromolecular chain (91,92).

Prevention of protein adsorption is crucial for blood-contacting devices, including catheters, dialyzers, vascular grafts, blood containers, and oxygenators. When a material surface is brought into contact with blood, the initial stage of the adsorption of serum proteins successively triggers the thrombogenesis and then enhances the complement activation via the classical pathway (Sec. IV.A).

Experimental evidence shows that surface grafting can minimize both protein adsorption and thrombogenesis. The grafting effect lasts for approximately a month, which is sufficiently long for the specific purpose of the devices, such as dialysis and oxygenation, to be accomplished. However, the long-term durability of the grafting effect is still under examination (93). Permanent implants, such as vascular grafts and catheters for blood access, require a nonfouling effect over a long period of time.

Various water-soluble polymers have been used for surface grafting to create nonfouling surfaces. They include nonionic hydrophilic polymers such as polyacrylamide (PAAm), poly(*N,N*-dimethylacrylamide) (PDMAAm), poly(ethylene glycol) (PEG), ethylene-vinyl alcohol copolymer (EVA), and poly(2-hydroxyethyl methacrylate) (PHEMA). A polymer containing phosphorylcholine, a cell membrane containing zwitterions, has also been employed. Grafting of these polymers can be achieved by surface graft polymerization following a low-temperature plasma treatment (94,95), or with a coupling reaction (96–99).

Fujimoto *et al.* demonstrated, with an *ex vivo* adsorption experiment using radio-labeled immunoglobulin G (IgG), that IgG adsorption onto a PU film was considerably reduced by grafting of PAAm to the surface, employing a glow discharge treatment (100) and ozone oxidation (101). Interaction between the PU surface and the platelets was greatly reduced by this modification. The latter was assessed with an *ex vivo* arteriovenous shunt experiment in rabbits (100,101). Ruckert and Geuskens (102) reported that surface graft polymerization of PVP effectively reduced the adsorption of fibronectin onto a styrene-(ethylene-co-butene)-styrene triblock copolymer film. They also reported that the surface of PU catheters with tethered PDMAAm chains remained unfouled even 3 weeks after implantation in the inferior vena cava of a rabbit (103). Recently, Kishida *et al.* (104) used a reverse transcription-polymerase chain reaction (RT-PCR) to examine the expression of interleukine-1 beta mRNA secreted by macrophage-like cells (HL-60). The latter were cultured on a grafted PE surface as an index of inflammatory stimulation. They observed that the cells cultured on the PAAm-grafted surface had a low level of IL-1beta mRNA, indicating the nonfouling capacity of the grafted surface.

The prevention of protein adsorption to the outermost grafted surface is attributed to a steric hinderance effect created by the tethered chains. A grafted surface in contact with an aqueous medium, which is a good solvent of chains, exhibits a diffuse structure (105). The reversible deformation of the tethered chains, due to the invasion of mobile protein molecules into this layer, produces a repulsive force. This force is governed by the equilibrium be-

tween the entropic elasticity of the chains and the osmotic pressure resulting from a rise in the concentration of segment. The repulsive force prevents direct contact between the protein molecules and the substrate surface. It is interesting to note that the extent of protein repulsion is related to the polymer graft density (100).

### 1. Role of Platelets and Rheology

As previously described, a clot is generally produced when blood comes into contact with polymers. The clot is a consequence of the induction of the coagulation cascade. The mechanism is initiated by

1. The polymer/blood contact.
2. The products released in the bloodstream.
3. The platelet activation and hemolysis produced by turbulence in the bloodstream. This is the result of the poor mechanical compliance of the prosthesis.

The interaction of platelets with various stimuli both soluble and surface bound leads to activation with shape change from disc to sphere with pseudopodia. Activated platelets spread on the surface and aggregate with other platelets (33). Initially, the von Willebrand factor (a polymer of factor VIII) controls the bonding of platelets to the surface. Some of the internal constituents are then released from the aggregated platelets, into the plasma. These transformations, which are controlled by prostaglandins, calcium ions, cyclic adenylyl monophosphate, and the concentration of adenylyl diphosphate, are essential as they make both specific proteins and platelet membrane phospholipids available. The latter elements are of prime importance for the acceleration and control of the coagulation process. Thrombin adenylyl diphosphate and other reactants also initiate platelet activation. It can also be produced by turbulence in the blood flow and is a function of the flow rate (106–110).

### 2. Conclusion

Coagulation on artificial surfaces is a complex phenomenon involving several systems: the intrinsic pathway of the coagulation cascade, triggered by the contact phase and controlled by antithrombin; the adhesion and activation of the platelets; and finally the fibrinolytic system. Therefore there are different methods for obtaining a hemocompatible polymer:

To stimulate the catalytic inhibition of the thrombin by the antithrombin. This is the case of heparin-bearing or heparinlike polymers (108,111–114).

To avoid the adhesion of proteins and platelets. This is the case for nonfouling materials, which can be, for

instance, produced by grafting a hydrophilic polymer with a large hydrodynamic volume onto a polymeric substrate (20,98,99,115).

To stimulate fibrinolysis. This is the case for plasminogen-bearing materials (116).

All of these possibilities are currently being explored.

### B. Contact System and the Intrinsic Pathway

When artificial surfaces are placed in contact with blood, the activation of the coagulation process is induced by the activation of the contact phase. This process involves four proteins: high molecular weight kininogen (HMWK), prekallikrein/kallikrein (Fletcher factor), factor XII (Hageman factor), and factor XI [plasma thromboplastin antecedent (PTA)], and their complexes. The proteins are bound to the surface in a cascade of enzymatic reactions, which result in increasing amounts of factor XIa attached to the surface.

In the intrinsic pathway, thrombin (factor IIa) formation results from the enzyme activation cascade triggered by the contact between factor XII (Hageman factor) and an electronegative surface. This intrinsic pathway is self-accelerated as the formation of the enzymes subsequently activates the zymogens. In a purified medium, the rate of the latter reactions is slow and calcium dependent. In contrast, these reactions are accelerated when platelet factor 3 (PF3), from the platelet membranes, and cofactors VIIIa and Va are present.

Nowadays, coagulation is divided into two stages rather than two pathways: an “initiation” stage, which is controlled by the tissue factor–dependent pathway, and an “augmentation” stage, which is controlled by components of the intrinsic pathway (30). Both pathways are able to generate fibrin, but the tissue factor stage is impeded by the tissue factor pathway inhibitor-1 (TFPI-1) soon after its initiation.

## IV. THE INFLAMMATORY RESPONSE

Polymers promote an inflammatory response when placed in contact with living systems. This response can be acute and/or chronic. These responses may be both beneficial and deleterious to the host (9,10,12). For example, inflammation is a major protection mechanism for the host, which uses it to rid itself of foreign materials. However, when a host is seriously impaired, the inflammatory response becomes a risk of infection. The acute inflammatory response appears to increase the rate of reaction, whereas the chronic inflammatory response may increase the infection rate (12).

The inflammatory response is a series of complex reactions involving various types of cells whose functions are controlled by various endogenous and exogenous mediators. The first phase of the acute inflammatory response is initiated when the formation of a blood clot occurs in the space around the biomaterial, after the latter has been exposed to the living system. This process is initiated by changes in the permeability in the adjacent vessel, which, in turn, are controlled by the intrinsic and extrinsic coagulation systems, the complement system, the fibrinolytic system, the kinin-generating system, and the platelets. It has been established that leukocytes have receptors for P-selectin, an alpha-granule membrane protein, expressed on the surface of the activated platelets (117,118).

Following these events there is preferential migration of the neutrophils towards the site of bonding. The differentiation of these cells into macrophages is therefore the first step of normal wound healing. This is then followed by the proliferation of the fibroblast, the deposition of collagen, and the capillary endothelial cell proliferation.

Various agents control monocyte and macrophage movement towards the site of injury within the tissue. This movement is defined as either chemotaxis or chemokinesis.

### 1. The Complement System

The complement system is one of the most important agents controlling chemotaxis. Like the coagulation system, the complement system consists of a series of plasma glycoproteins and inhibitors. Its activation can be initiated by antigen-antibody complexes, bacterial polysaccharides, viruses, endotoxins, and synthetic polymers. Once initiated, activation proceeds along one of two pathways, classical or alternative (Fig. 5). The cascades of enzymatic events generate components that produce an inflammatory or immune response.

To summarize, the contact between living systems and polymers induces a blood-controlled inflammatory response that may result in

1. Increased ability to resist infections
2. The isolation of the implant by fibrous tissue, resulting in the rejection of the implants
3. Acute inflammatory response with a hypersensitivity reaction

The activation of the complement system is one of the major agents controlling the inflammatory response. It consists of more than twenty components and plasma proteins, which are involved in the recognition of foreign substances and in both specific (immune) and natural (nonimmune) host defense (119). It appears necessary to control

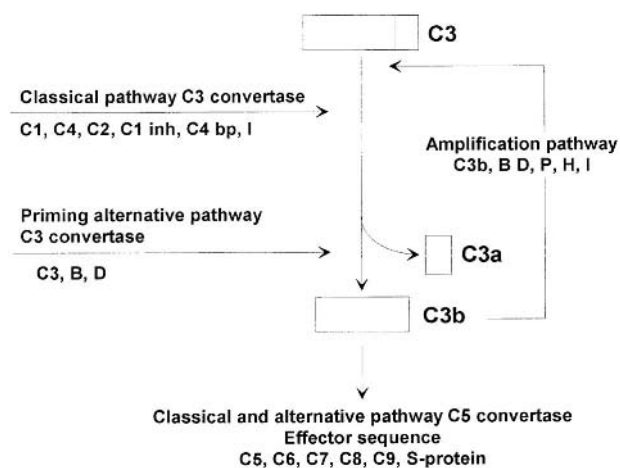

Figure 23.5 Pathways of complement activation.

this inflammatory response, and this can be achieved through the control of the complement system (120–122).

Both classical and alternative pathways of the activation of the complement system involve the formation of potent C3-convertases. These convertases catalyze the activation of zymogen C, a plasma protein, into a potent enzyme. This enzyme then mediates the formation of the C5–C9 complex, which is the final step of the activation of the complement system. Both alternative and classical C3-convertases can be inhibited by natural plasma inhibitors like H and I proteins (123).

This inhibition effect is promoted by heparin (124) either in solution or when bound to activating polymeric surfaces such as Zymosan or Cuprophan (125), a potent complement-activating polysaccharide. This control mechanism of the complement system, which includes the action of a potent plasma inhibitor called C1 inhibitor (C1inh), has already been employed to control both the inflammatory response and particularly the hypersensitivity reactions induced by dextrans, as described in this chapter.

The small fragments generated by the cleavage of the proteins C3 and C5 are the anaphylatoxins C3a and C5a. These anaphylatoxins induce smooth muscle cell contraction, the enhancement of the vascular permeability, and the release of histamine. The C5a is also a potent chemotactic factor for neutrophils. The activities of C3a and C5a characterize the common postcoagulative reactions associated with tissue injury. The larger portions of the activated complement factors C3 and C5 (C3b and C5b) participate in the amplification phase of the humoral immune system, serving as enzyme modulators, opsonins, and effectors of cellular recognition.

The first phase described above is followed by the production of small molecules such as cytokines. The latter

modulate the inflammatory response by playing the role of a mediator between the cells of the immune system and those of the vascular system.

## V. INFECTION

In spite of good hemocompatibility, a polymeric prosthesis may fail because of bacterial contamination. Most prosthesis-related infections are initiated during the surgical procedure, when bacteria-carrying particles from the air contaminate the host. Bacterial colonization is promoted by high hydrophobicity and the irregularity of the surface of the biomaterial surfaces (126). Glycocalyx, a slime layer produced by the bacteria, represents a factor of adhesion and plays an important role in the pathogenesis of the infection (127). Increased exopolysaccharide production produces a biofilm that protects the bacteria from leukocytes, antibodies, and the action of antibiotics (128,129).

As a result of the immune response, infection in the vicinity of the implanted material may occur, which results in the failure of the device. It has been demonstrated that  $10^6$  organisms cause infection in normal human skin, whereas only  $10^2$  organisms are necessary to produce the same effect when a suture is present (12).

One of the features of deep-tissue implants, in neurosurgical, cardiovascular, orthopaedic, and ophthalmic patients, is delayed infection. It develops 6 months or a year after surgery in patients who show successful rehabilitation. This delayed infection at the implant site is often caused by organisms of low virulence and is observed in total joint infections, sternal osteomyelitis, and heart valve infections as well as at the site of urinary catheters (12).

The mechanism by which the implanted materials alter the ability of the host to resist infection is not well understood. It has been suggested that the inflammatory response developed by the host as a protective mechanism increases the risk of infection. The acute inflammatory response appears to reduce the infection rate, whereas the chronic inflammatory response may increase the rate of infection (12).

Intravascular catheters are frequently used in hospitals. Several studies have demonstrated that catheter-associated infections are a significant source of nosocomial morbidity and mortality (130). The data reported in the literature indicates the complexity of biomaterial-associated infections. It appears increasingly probable that there is not one simple explanation for the latter. A series of events occur at the time of implantation. Bacterial adherence to the biomaterial occurs initially, followed by the colonization and the formation of an adherent biofilm. The biofilm then im-

plants the bacteria onto the surface of the material, rendering any antibiotic treatment and host defense mechanism ineffective (131,132). Therefore this zone can be assumed to be a site of continuous infection.

There is no correlation between the physical properties (e.g., hydrophilicity, zeta potential, surface charge, rugosity) of the surface of the biomaterial and the bacterial attachment. Hence more specific interactions between the chemical groups, on both the surface of the bacteria and the biomaterials, need to be considered (133).

## VI. FATE OF SYNTHETIC POLYMERS IN THE BODY

### A. Insoluble Polymers

Living tissues present a very aggressive environment. Polymers, which appear to be very stable *in vitro*, can be dramatically degraded *in vivo*. The *in vivo* failure of polymeric cardiovascular devices has been attributed to calcification, hydrolysis, oxidation, and environmental stress cracking (ESC) (134).

#### 1. Calcification

Deposition of calcium containing apatite mineral has been associated with the implantation of cardiovascular medical devices, such as bioprosthetic heart valves, aortic homografts, and trileaflet polymeric valve prostheses (8,135). Calcification causes the failure of bioprosthetic (136) and polymeric materials (137). Several methods to reduce calcification have been explored, namely, heparin coupling on glutaraldehyde-treated porcine pericardium (138,139) and the chemical modification (phosphonation) of polyurethane (140).

#### 2. Biodegradation

Biodegradation, including hydrolysis and oxidation, has been extensively studied for polyurethanes and their derivatives (141–144). The oxidation of polyurethane is catalyzed by the presence of metallic ions, especially cobalt, which is utilized in numerous biomedical devices (145). *In vivo* polymer degradation results mainly from the synergistic action of enzymatic components in the body fluids, oxidative agents, and stress (146). Alpha-2-macroglobulin (147), cholesterol esterase (148), phospholipase A2 (149), proteinase K (150), and cathepsin B (151) are all enzymes that promote the biodegradation of polyurethane.

To prevent oxidation, it is possible to employ a synthetic antioxidant such as Santowhite® or Irganox®. However, particularly for biomedical applications, it is more

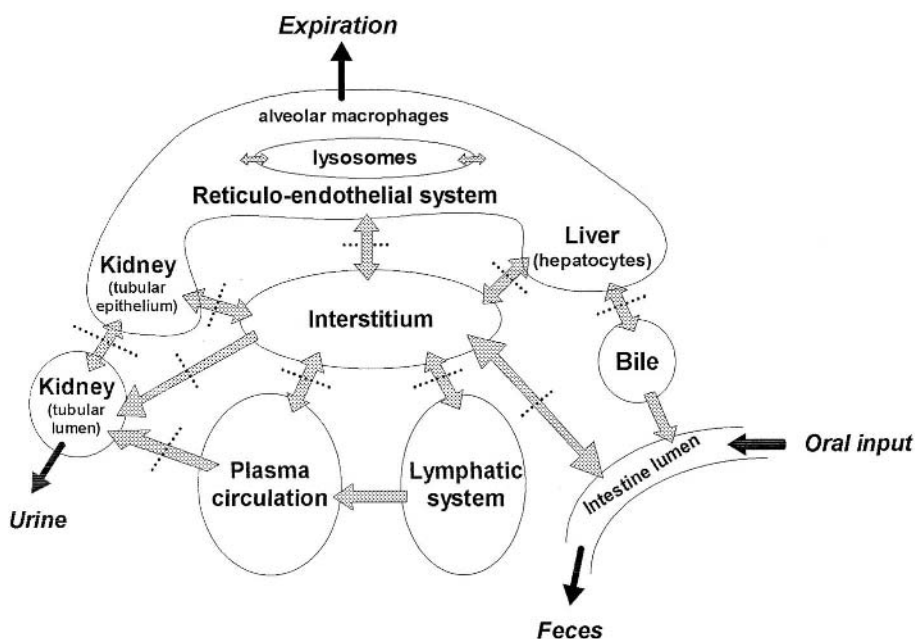

appropriate to use a natural antioxidant such as vitamin E (152,153). The oxidation of a polymeric biomaterial can also be prevented by avoiding the presence of unsaturated bonds and ether groups. Coury was one of the first researchers to develop an aliphatic polyurethane with a polymer backbone free of ether (154). This polymer, although biodegradable, proved too stiff for medical application. Szycher used these fundamental studies to develop a novel aliphatic ether-free polyurethane using a polycarbonate-based macroglycol (155). This polyurethane was shown to be resistant to environmental stress cracking both *in vitro* (156) and *in vivo* (157).

### B. Soluble Polymers

Any substance introduced into the body must be considered a foreign body. The interaction of the latter with the components of the biological environment determines its rate of elimination or storage. Sufficient understanding of its behavior and its fate in the organism is therefore necessary for a reliable evaluation of the benefits and the risks of employing the material.

In pharmacokinetics, it is useful to represent the body as a system of compartments (Fig. 6) (158). Polymers entering into the organism cannot move randomly, as anatomical and physiological barriers control their movement.

Radioactive labeling is a very sensitive method for following the progression of the polymer and its possible metabolites in the bulk of the biological material. Most of the data on the fate of soluble polymers in the living body was obtained after their direct intravascular administration. An injected polymer is rapidly (within a few minutes) distributed to all vascularized parts of the body, and its transport to other compartments of the body starts immediately (158). A polymer introduced into the bloodstream circulates in a closed system of blood vessels. It can be cleared from this compartment either by the endocytic activity of specialized cells (cells of the reticuloendothelial system) or by passage through the endothelial wall, particularly at capillary level. The cells of the reticuloendothelial system (RES) are the cells of the kidney tubular epithelium and the liver hepatocytes. Generally, nonbiodegradable polymers of high molecular weight present a risk of accumulation in the RES (159). Mehvar et al. demonstrated that the disposition of dextran in serum and tissues is molecular weight dependent (160). The low molecular weight dextrans (4 kD) are rapidly excreted into urine with negligible accumulation in the liver, but the larger (150 kD) are mainly accumulated in the liver (161–163). The collection of nonbiodegradable polymers in the body suggests the uptake of the polymer by pinocytosis and its storage in lysosomes. The excessive storage of polymers may provoke an

**Figure 23.6** Multicompartment model of organism. Areas depict the body compartments. The dashed lines symbolize the restricted transfers between compartments. (Adapted from Ref. 158.)

adverse reaction. Therefore biodegradability becomes an imperative criterion for the polymer intended for use as plasma expanders or for other purposes, when large and repeated doses must be employed.

## VII. USE OF BLOOD-CONTACTING POLYMERS

Polymers are not only used in insoluble forms such as tubes or containers, they also have a large array of applications in soluble forms, mainly for therapeutic aims. Polymers can also be employed in coating, for example to improve the hemocompatibility of intravascular grafts (164,165). The following section briefly presents a few applications in this field.

### A. Drug Targeting and Drug Delivery

An important approach to increasing the therapeutic efficiency of bioactive agents while decreasing their toxicity has involved chemically bonding these agents to either synthetic or naturally occurring macromolecules. The rationale behind this approach was to design systems that would undergo hydrolysis or enzyme-catalyzed cleavage when placed in the body, in order to release the agent at a predetermined rate.

Synthetic polymers are widely used as drug delivery vehicles because of the diversity of their composition and their good biocompatibility. Water-soluble polymers are of particular interest as drug carriers, as the polymer dissolves when the drug is released. For example, Kopecek have synthesized and extensively investigated poly(hydroxypropyl methacrylamide) (PHPMA) as a drug carrier (166). Kim and his colleagues examined soluble pH- and temperature-sensitive linear polymers for protein and peptide delivery (167). Xu and Lee also investigated soluble polymers as drug delivery vehicles (168).

Mononuclear phagocytes play a central role in the defense of the human body against important pathologies, particularly infections. However, some of the agents of infection may survive phagocytosis, thus producing intracellular infection. The low permeability of cell membranes to several classes of antibiotics results in drug resistance. Temporary binding of a drug to a macromolecular carrier of natural or synthetic origin was suggested many years ago as a method to overcome the membrane barrier. However, a macromolecule–drug conjugate cannot reach its target unless there is target recognition. This is achieved through specific interactions with a membrane receptor. The conjugate must then be internalized by

endocytosis. The use of mannosyl ligands covalently bound to a hydrosoluble bioresorbable drug carrier ‘poly(L-lysine citramide imide) has been proposed (169). This conjugate targets drugs towards macrophages via the lectin-type specific receptor present on the macrophage membrane.

### B. Polymers with Antitumor Activity

Most of the drugs currently used in conventional cancer chemotherapy do not intrinsically select towards tumor cells and are therefore toxic for normal tissues. Many natural products (e.g., anthracyclins, vinca alkaloids, taxanes, adriamycin) are utilized clinically as anticancer agents. However, their use is frequently restricted by dose-limiting toxicity, poor water solubility, or fast elimination due to metabolism or excretion. The conjugation of an active drug with a polymeric carrier through a biodegradable spacer yields a ‘‘polymer therapeutic.’’ This represents a new class of antitumor compounds (170,171). Two factors underlie the improved therapeutic index of such macromolecular prodrugs. First, many solid tumors possess vasculature that is hyperpermeable to macromolecules, and they usually lack effective lymphatic drainage, so they selectively accumulate circulating macromolecules (172). The second improvement is attained with the use of a polymer–drug linker that is stable in circulation but is degradable intracellularly by tumor-enhanced enzymes (173) or by acidic hydrolysis in a lysosomal compartment (67).

5-Fluorouracil (5-FU) is a phase-specific antimetabolite; it is commonly used in cancer chemotherapy to treat solid tumors, particularly those of a gastrointestinal origin. However, this treatment is often accompanied by adverse reactions that limit the dosage and hence the efficiency of the drug. Various macromolecular prodrugs of 5-FU have been proposed to reduce these side effects (174–176). In vitro and in vivo studies performed with these derivatives have shown that 5-FU is slowly released by nonspecific chemical hydrolysis. Schacht et al. have synthesized a macromolecular prodrug of 5-FU by covalent bonding to a polymeric carrier such as PEG or dextran. The in vitro hydrolysis study has shown that these derivatives are stable in the presence of serum peptidases but can be selectively activated by tumor-associated enzymes such as collagenase type IV or cathepsin B, to free 5-FU at the tumor site (175). The free radical polymerization of various types of 5-fluorouracil (5-FU) vinyl derivatives has also been studied by Akashi et al. (174).

Other polymers that are not prodrugs can be endowed with anticancer activity in vitro (177–179) and in vivo (180). This is the case for a dextran derivative that prevents

tumor growth and tumor angiogenesis (181,182). The mode of action of these polysaccharides having carboxylic and benzylamide chemical functions is still under investigation. But it appears that these bioactive polymers exert an inhibitory effect on the growth of tumoral cell lines by interfering with specific autocrine and paracrine growth factors (181–183).

### C. Immunoadjuvant

The interest in polyphosphazenes for biomedical uses, especially for exploitation in drug delivery and controlled release technology, has increased dramatically in recent years (184). Poly[di(carboxylatophenoxy)phosphazene] (PCPP) appears to be of particular interest as a biomaterial primarily because of its powerful immunoadjuvant properties but also due to its ability to form hydrogel microcapsules under physiological conditions. Polyphosphazene with its carboxylic and ester alkyl functions stimulates the immune response of mice infected by influenza virus (185).

### D. Polymer Conjugates as Contrast Agents

Contrast agents may be categorized as nonspecific or specific. Nonspecific agents diffuse freely in the extracellular and extravascular compartments with the exception of the brain, where the contrast agent can only pass through brain barrier lesions. In the specific agent group, a new class of products has been developed. These are blood pool contrast agents, which are distributed throughout the whole intravascular volume and are slowly cleared from the blood. Diffusion through the healthy capillary wall is limited and depends on both the pathological state of the endothelial permeability tissue of the organ examined and on the characteristics of the contrast agent (size, charge, and molecular shape, etc.). The diagnostic efficacy of perfusion imaging, including cerebral perfusion, is modulated by the pharmacokinetic profile of the blood pool contrast agent. One way to improve the vascular residence time consists in bonding a vector, such as a synthetic polymer or a biological macromolecule, and a metal ion like  $Mn^{2+}$ ,  $Gd^{3+}$ , or  $Dy^{3+}$  (186–189).

Organometallic compounds of gadolinium are used in medical imaging, but the macromolecular compounds (molecular weight 30,000 daltons) are more advantageous than those with a low molecular weight (550 daltons). Dynamic magnetic resonance imaging of breast neoplasms using a polymeric agent may help to differentiate better between benign and malignant lesions as it highlights the

enlarged interstitial space and the increased capillary permeability in carcinomas (190).

### E. Thrombogenic Blood-Contacting Polymers

Hemocompatibility of the polymers used in contact with blood is not always required. In one case, the coagulation of blood is desirable. Thus polymer beads are utilized to embolize the blood vessels above a solid tumor in order to asphyxiate the latter (191–193). Various polymeric embolic materials are currently in clinical use, such as ethylene–vinyl alcohol copolymer mixtures, poly(vinyl acetate), cellulose acetate polymer, and poly(vinyl alcohol) (194).

## VIII. MODIFICATION OF THE POLYMER SURFACE

### A. Chemical Modification of Polymers

The dextran molecule is a polymer formed by glycosidic bonds linking the number 1 and 6 carbon atoms of consecutive  $\alpha$ -D-glucopyranose rings. This polysaccharide is relatively rigid. This property increases with the number of substituents with bonds axial to the glycosidic oxygen and in the presence of bulky equatorial groups adjacent to the linkage (195). The pyranose ring structure of the dextran chain is elastic. It has been suggested that this elasticity plays an important role in accommodating mechanical stresses and modulating ligand bonding in biological systems (196).

Biospecific molecular recognition in living systems is known to be based on the lock and key principle as proposed by Emil Fischer. Based on this concept, Jozefonvicz and Jozefowicz (197) postulated that biospecificity can be achieved by random substitution of a preformed polymer with suitable chemical groups or random copolymerization of suitable functional monomers. Such polymers contain arrangements of the chemical functions, which mimic natural biospecific sites, and the probability of occurrence of such arrangements will depend on the average composition of the polymer. According to this principle, they have developed several functional random copolymer systems that possess a variety of biological properties depending on the type of chemical function. Examples are polymers possessing anticoagulant properties similar to those of heparin (198–202) and polymers that interact specifically with components of the immune system (203–207). These randomly functionalized polymers belong to the new concept of “bioactive polymers” possessing bioactivity through biological recognition (208,209).

## B. Modification of the Surface of Polymers by Grafting

The modification of the surface of polymers can be achieved by grafting (210). Most of the untreated surfaces of polymers used in industry are hydrophobic. Polymer surfaces generally adsorb proteins when brought into direct contact with blood. The attachment of protein to the surface triggers a subsequent series of mostly adverse biological reactions with respect to the polymeric materials. Therefore the technologies for surface modification of polymers or regulation of the polymer surface interaction with other substances have been of prime importance in biomedical polymer applications (93,211). Theoretically, there is a large difference in the properties of the surface and the bulk of the material. Generally, only the outermost surface needs to be taken into consideration. However, this is not the case for polymer surfaces, as the physical structure of the outermost polymer surface changes continuously with time due to the microscopic Brownian motion of polymer segments. The polymer surface generally has high segmental mobility even at room temperature, in contrast to the rigid surfaces of metals and ceramics. There are two methods for producing grafted surfaces: direct coupling of existing polymer molecules to the surface and graft polymerization of monomers to the surface.

### 1. Polymer Coupling

There are two theories behind the grafting of a polymer to a surface: the first conjecture is to separate the blood proteins from the surface by grafting a hydrophilic polymer with a high hydrodynamic volume (for example poly(ethylene glycol)); the second hypothesis is to confer the biological properties of the grafted macromolecule (for example heparin) to the surface.

Kishida et al. directly immobilized poly(ethylene glycol) (PEG) chains onto a cellulose surface through esterification (96). Prior to the coupling reaction, they derivatized the terminal hydroxyl group of PEG molecules to carboxylic acid using succinic anhydride. This PEG molecule with terminal carboxylic acid was then chemically immobilized to the hydroxyl group on the surface using carbodiimide in nonaqueous media like toluene. The molecular weight of the grafted polymer has a significant influence on the blood compatibility. Desay and Hubbell (212) have covalently grafted poly(ethylene oxide) (PEO) of molecular weights between 5,000 and 100,000 g/mol on polyethylene terephthalate (PET) films. It was concluded that PEO of molecular weights of 18,500 g/mol and above was effective in reducing protein adsorption and cellular interactions on the surface. Saito et al. have grafted

photoreactive  $\alpha$ -propylsulfate-poly(ethylene oxide) (PEO-SO<sub>3</sub>), one end of which was capped with an azidophenyl group, onto polyurethane surfaces employing a photochemical technique (115).

Han et al. (213) have studied the adsorption of fibrinogen, albumin, and gamma globulin from plasma onto surface-modified polyurethanes [polyurethane grafted with poly(ethylene oxide) (PU-PEO)], sulfonated polyurethane (PU-SO<sub>3</sub>), and polyurethane grafted with sulfonated poly(ethylene oxide) (PU-PEO-SO<sub>3</sub>). Adsorbed fibrinogen at steady state decreased in the order PU-SO<sub>3</sub> > PU > PU-PEO-SO<sub>3</sub> > PU-PEO, suggesting that sulfonate groups have a specific high affinity to fibrinogen. The intermediate fibrinogen adsorption on PU-PEO-SO<sub>3</sub> can be explained by the compensatory effect between the low protein binding affinity of the PEO chain and the high fibrinogen binding affinity of the sulfonate group. In addition, PU-PEO-SO<sub>3</sub> showed a very fast fibrinogen adsorption due to the high accessibility of the sulfonate group to fibrinogen by the poly(ethylene oxide) spacer. The kinetic profiles of their surfaces showed that as the adsorption time increases, fibrinogen initially adsorbed was decreased and a plateau reached, demonstrating that all the surfaces exhibited the Vroman effect. PU-PEO showed the least fibrinogen and albumin adsorption among polyurethanes, confirming the known nonadhesive property of PEO chains. It is very interesting that PU-PEO-SO<sub>3</sub> exhibited the highest adsorption of albumin and the lowest adsorption of IgG. The authors conclude that such adsorption behaviors of proteins to PU-PEO-SO<sub>3</sub> contribute to improved blood compatibility (213).

### 2. Graft Polymerization

This type of modification involves the radical polymerization of acrylic or vinylic monomers onto the polymeric surface, the latter having previously been oxidized to produce peroxides. A variety of methods for graft polymerization onto different substrate surfaces are available. They include direct chemical modification (214), ozone (215,216), gamma rays (217), electron beams (218), glow discharge (=low temperature plasma) (92,219,220), corona discharge (105,221), and UV irradiation (94).

Both glow and corona discharges are currently used for the modification of the surface of polymeric materials. The corona discharge treatment is far simpler than the glow discharge treatment, as the former technique does not require the evacuation of the discharge system. However, the corona treatment can result in greater damage of the substrate polymers, and the discharge conditions are more difficult to control than those of the plasma treatment. The latter treatment is generally carried out under reduced gas

pressure. UV irradiation appears to be an excellent method for the surface grafting of polymers because it is both simple and clean.

## IX. HEMOCOMPATIBILITY OF POLYMERS

When a polymer comes into contact with blood, it appears that

1. The polymeric compound may release components into the bloodstream that may be toxic, carcinogenic, blood coagulation-activating, and/or inflammatory response-promoting (222–226).
2. The polymeric compound may degrade into components that may induce blood coagulation, the inflammatory response, carcinogenesis, and the toxic response (149,150,227,228).
3. The polymers may not have the desired mechanical compliance, which may promote turbulence in the blood flow. As a consequence, hemolysis, platelet activation, and the inflammatory response may occur, all of which are undesirable effects (101,229–231). Long-term implantation provokes calcification, which leads to the mechanical failures of the devices (20,232,233).
4. The polymeric compound itself may induce the activation of the blood coagulation system. As a consequence, thrombosis on the site of implantation or thromboembolism may occur.
5. The presence of the polymeric compound may promote an inflammatory response (21,234–236), the effects of which can be either beneficial or prejudicial to the host as previously discussed.
6. The polymer may promote an infection in the host either alone or when mediated by the inflammatory response (237,238). Similarly, it may also induce tumorigenesis (10), although this phenomenon has never been accurately described.

The ideal blood-compatible polymer must not exhibit these undesirable properties, though in the case of heart valves and vascular grafts, the occurrence of failure is still high. Morbidity and mortality due to valve-related causes are around 25% of cases within 10 years. The thrombotic occlusion, especially in small diameter synthetic grafts, remains a serious problem, where 36–54% are occluded at 1 year and 50–62% are occluded by 5 years (22). Recently, significant improvement has been achieved with a Dacron® prosthesis coated with nonthrombogenic polymeric materials (239). There is a large array of laboratory tests used by hematologists to explore virtually each step of the coagulation system (240). Most of the tests are only applicable

for the study of the hemocompatibility of soluble polymers, but some techniques are available to test the blood compatibility of insoluble materials (241).

It appears that blood compatibility is a multiparametric function of the characteristics of the polymeric compound. At the present time, only polymers that partially fill blood compatibility requirements are available. However, by employing medical grade polymers, nontoxicity of the released components and the degradation products has been achieved.

The noncarcinogenicity of the materials, their released adjuvants, and the degradation products remains controversial. Large-scale epidemiological studies are needed in order to determine whether the long-term systemic effects of the polymeric implants provoke carcinogenesis (9,10).

The mechanical compliance of the polymer is generally believed to be critical, and considerable efforts have been made to improve this characteristic. As a result, it appears that vascular grafts with improved mechanical properties are now commercially available. These grafts are made from polyesters (polyethyleneterephthalate, commercialized under the name Dacron®), expanded polytetrafluoroethylene (commercialized by Gore Tex), and polyurethanes (242–244). These materials, for various structural reasons, match the mechanical compliance of the vessel wall.

The physical characteristics of the surface also appear to be critical. Various hypotheses have been proposed. One theory claims that the ideal surface is perfectly smooth and is best achieved by polyurethane grafting. Another widely used method employs either knitted or woven grafts of Dacron® or porous grafts of Teflon®. In the latter case, it has been proved that the ingrowth of tissue and the subsequent encapsulation of the implant by fibrous healing tissue provides a suitable smooth blood-compatible surface (245, 246).

The design of the device also affects the overall blood compatibility of the polymeric compound, as it is one of the parameters that controls the hemodynamic characteristics (1). The importance of this parameter is highlighted by the considerable research currently devoted to the improvement of the design of cardiac valves (247,248). Numerous types of cardiac valves are available that differ not only in their design and also in the chemical nature of the polymers used in their manufacture. The remarkable results obtained with biovalves may also result from their superior design. This is also illustrated by the fact that aortic vascular grafts of large diameter are currently successful, whereas small-diameter vascular grafts (of less than 4 mm diameter) fail. Aortic grafts are successful because the blood flow is high. Therefore the blood-polymer surface contact time is restricted, resulting in minimal activation

of the coagulation of blood. Hence, only microthrombi of low adherence are formed and embolyzed. Therefore fibrinolysis is rapid, as the rate of fibrinolysis at a surface is inversely proportional to the diameter of the thrombus. This reasoning can also be applied to explain the failure of small-diameter vascular grafts, which have a lower blood flow rate. The other parameters that control the coagulation process at the blood/polymer interface must also be considered. These parameters include the relationship between the chemical nature of the polymer and that of the blood, and its influence on the formation of a clot at the interface. The inflammatory process can also be considered as a function of the chemical nature of the polymers.

#### A. Blood Compatibility and Chemical Physics of Polymeric Surfaces

The coagulation process, which is initiated at the blood/polymer interface, has been considered in relationship to the chemical structure of the polymer. Originally it was assumed that the formation of a clot was controlled by the physical properties of the surface, such as hydrophilicity or electrical potential. These properties are dependent on the chemical structure of the polymers.

Initially, it was postulated that hydrophilic polymers would be suitable blood-compatible materials, i.e., they should not induce the coagulation process. This assumption originated from the hypothesis that the blood compatibility of the natural vascular wall was a result of its ability either to bind water or to be hydrophobic.

Numerous studies have been devoted to the assessment of this assumption, which remains a matter of controversy. However, no clear correlation has been established experimentally between the affinity of water to the polymers and their blood compatibility. The various testing methods employed to determine blood compatibility are briefly discussed in this chapter.

Another hypothesis suggested that the electrical properties of the surface of polymers, as measured by polarizability, net surface electrical charge, or overall surface potential, control their blood compatibility (249,250). Again the numerous attempts made to check the validity of this hypothesis failed to establish any general correlation. Moreover, in 1977, Boffa et al. (251) studied the blood compatibility of polytetrafluoroethylene-polyvinylpyrrolidone copolymers of various chemical compositions and hydrophilicity. They showed that the ability to induce the formation of a clot of blood plasma is independent of the composition of the copolymers. In order to confirm this observation, the same authors checked the blood compatibility of various purified polymers including polystyrene, polytetrafluoroethylene, silicone, polyvinylchloride, polymethyl methacrylate, etc., either in powder or in film form.

The authors concluded that the blood compatibility of the polymer, as assessed by the *in vitro* tests, did not vary greatly although their hydrophilicity and the polarizability of the monomeric units were markedly different.

In the early 1980s (252–255) it was postulated that the regular stretching of the hydrophilic and hydrophobic zones on the polymer surface would confer blood compatibility to the material if the distribution of the zones was appropriate. It was claimed that a distribution of hydrophilic zones of 5  $\mu\text{m}$  diameter in a hydrophobic matrix would prevent the activation and aggregation of the platelets. Despite the considerable research, the theory that the blood compatibility of polymers is related to the physical properties of the surfaces has not been proved.

#### B. Blood Compatibility and Protein Adsorption

When a material is exposed to blood or blood plasma, adsorption of proteins occurs. This results in the formation of a complex protein layer at the interface which is strongly bonded to the surface.

Extensive studies of this process have been used to determine the blood compatibility of polymeric materials. It has been postulated, from the first results obtained, that the materials with an affinity for human serum albumin (HSA) should be blood-compatible, whereas the polymers with a high affinity for fibrinogen (Fg) should be thrombogenic (250,256,257).

However, studies of the adsorption of these proteins from purified protein plasma solution and whole blood, under either static or dynamic conditions (250,256,258–263), demonstrated that the process is not as simple as was initially suggested. The results of these studies can be summarized as follows:

1. Adsorption of proteins is a rapid process that may initially be reversible. This phase is followed by an irreversible adsorption process (258).
2. Competitive adsorption of the proteins occurs, which result from the reaction of numerous parameters such as the composition of the protein and the flow rate (256,264).
3. Blood cells, such as red blood cells, platelets, and white blood cells, influence the adsorption of HSA and Fg and their relative quantities in the blood layer (265).
4. Transient adsorption processes are observed with HSA, Fg, and immunoglobulins (266).

Therefore it can be concluded that it is not possible to assign a given value for the affinity of a polymeric material for HSA and Fg; hence these affinities cannot be employed as a control parameter of blood compatibility. Moreover, by considering these results, Vroman et al. (258) were able

to show that the adsorption of traces of high molecular weight kininogen (HMWK), and other proteins that play a major role in the coagulation process, may be the determinant phenomenon in the blood compatibility of polymeric surfaces. Furthermore, Brash (256) observed that when a polymer is exposed to blood, the protein layer adsorbed onto its surface is complex. It includes the proteins HSA and Fg, which are always present, but also other proteins including low molecular weight peptides, which may control the coagulation process induced at the blood-material interface.

### C. Antithrombogenic Materials

From the above data it would appear that there are two concepts on which the tailoring of blood-compatible polymers should be based. First, the designed biomaterial should not activate the coagulation process. Unfortunately, as previously described, the theories proposed to guide the tailoring of blood-compatible polymers have not resulted in completely successful biomaterials. Moreover, the vascular endothelium itself may activate the coagulation cascade. Second, the surface of the biomaterial is a blood coagulation activator, as is the case with all known surfaces. In order to prevent thrombus formation at the blood-material interface, the polymer should be able to inhibit the coagulation process.

Moreover, biomaterials should not act as inhibitors. If this were the case, the biomaterial would act as a reagent in an irreversible inhibition reaction, which would then induce the irreversible transformation of the surface of the biomaterial. This reaction would provoke the loss of the inhibiting properties of the biomaterials. Therefore a suitable anticoagulant biomaterial should act as a catalyst of the inhibition reactions of the coagulation process. The surface of such a material should catalyze some of the control mechanisms of the coagulation of the blood.

Several possibilities exist for the design of such biomaterials, and each one has been the basis of active research and development during the past two decades. Historically, the first attempt to produce antithrombogenic materials involved the ionic bonding of heparin onto a polymeric surface by Gott (267). The resulting material enabled the anticoagulant drug to be released slowly into the bloodstream. Since then, the same strategy has been applied in numerous studies but with different potent anticoagulant drugs.

### D. Anticoagulant Drug-Releasing Materials

The Gott strategy has been applied to biomaterials that release prostacyclin (PGI<sub>2</sub>) entrapped in a macromolecular network (268–270). When placed in contact with blood, these biomaterials prevent the aggregation and release of

platelets, thus controlling the coagulation process. Such materials are potent while they are able to release PGI<sub>2</sub>. Unfortunately, PGI<sub>2</sub> is an expensive product and moreover is unstable (its lifetime, after hydrolysis under biological conditions, is less than 1 minute). Therefore this type of biomaterial has no practical uses at present. Other platelet antiaggregating surfaces, based on the incorporation of antiaggregating drugs, such as dipyridamole, in polymers, such as cellulose, cellulose triacetate, nylon, *N*-vinylpyrrolidone, and polyethyleneterephthalate, have been prepared (271–275). The resulting materials are claimed to be potent antithrombogenic materials even when implanted in dogs.

The strong anionic character of heparin enables it to bond ionically to cationic surfaces. This phenomenon has been widely researched. In each case, polycationic polymers have been prepared from polystyrene and its derivatives, cellulose, silicone rubber, epoxy resins, polyurethanes, and from copolymers, such as styrene or acrylonitrile and acrylate derivatives; these polycationic polymers were treated with heparin in various ways. Heparin has been also incorporated into cross-linked collagen. An alternative route was to incorporate heparin and prostaglandins simultaneously, in order to combine the respective thrombin and platelet aggregation-inhibiting effects of the released drugs.

Whatever the technique used, the resulting biomaterials have been proved potent if they release the ionically bonded heparin into the bloodstream. During this release process, the concentration of heparin near the surface is sufficiently high to prevent the formation of a thrombus for several days. Unfortunately, after this period of time, the release rate decreases. Therefore these biomaterials are only suitable for use in short-term devices, examples of which are extracorporeal circulation and catheters (276–278). They were developed for temporary use by Japanese, American, Swedish, and French manufacturers for the production of catheters and peritoneovenous shunts.

An alternative approach to the ionic coating of heparin onto materials, to produce antithrombogenic surfaces, involves the synthesis of polymeric gels, which contain heparin. This can be achieved either by ionically bonding the heparin to the polymer, followed by the chemical or radiation-induced cross-linking of the resulting network, or by trapping heparin in a preformed hydrogel (251,279–282). The latter procedure has been employed for polymeric gels prepared using radiation processing treatments involving vinyl alcohol or vinyl acetate and *N*-vinyl-2-pyrrolidone monomers. Cobalt-60  $\gamma$  rays were employed to graft chloromethylstyrene onto polysilicone samples followed by quaternization with pyridine. As in the preceding case, the uptake of heparin from the solutions occurs by exposure of the polymeric gel.

All these gel procedures have been proved to be effective, i.e., they have allowed the preparation of antithrombogenic biomaterials. When compared to previous procedures, the heparin release level was reduced but was adequate to prevent blood clotting in *ex vivo* assays. However, the potency of the devices is still insufficient to allow their use as permanent implants (283).

### E. Covalent Binding of Anticoagulant Drugs to Polymers

Various physiologically active substances have been immobilized onto polymeric surfaces in order to confer blood compatibility (284–286). The use of fibrinolysis to control the thrombogenicity of biomaterials has been studied. Sugitachi et al. (287) attached urokinase or streptokinase onto polyvinylchloride and silicone rubber tubes. Kishida et al. have immobilized recombinant human thrombomodulin onto a polyurethane surface; the resulting polymer exhibits a very good anticoagulant activity (288,289). These surface treatments significantly improve the blood compatibility properties. Unfortunately, cleavage of the fixed enzyme may occur when the surface is exposed to blood, preventing the long-term use of the biomaterials. However, short-term use is possible.

Since platelet activation is a crucial step in the hemostasis, some authors have immobilized an inhibitor of platelet activation, the dipyridamole, onto a medical grade polyurethane. These experiments revealed that the clotting time was substantially prolonged (290). Other authors have covalently bonded a peptidic thrombin inhibitor extracted from leeches, the hirudin (291), on degradable polymer (292).

Although a heparinized surface, because of its dense negative charge, can initiate the intrinsic pathway of blood coagulation (293), an extensively explored way to obtain antithrombogenic biomaterials is the covalent binding of heparin onto polymeric materials. In principle, these biomaterials will not release their heparin content when exposed to the bloodstream. If the covalently bonded heparin remains active, the biomaterials will remain potent longer than those with ionically bonded heparin. The covalent bonding of heparin onto surfaces has been extensively studied during the past decade.

Covalent bonding of heparin onto polymers can be achieved in different ways. Heparin has been coupled to preformed hydrogels by employing various classical activation techniques. Hydrogels, derived from polyvinyl alcohol onto which heparin was fixed employing acetal links, were prepared (294). Alternatively, heparin has been bonded to agarose and Sepharose using cyanogen bromide or carbodiimide activation (295). The same coupling re-

agents has been utilized to bond heparin covalently either onto radiation-grafted hydrogels derived from hydroxyethyl methacrylate and methacrylic acid or onto the same hydrogels radiation-grafted onto the surface of a silicone rubber (296,297).

In a second general procedure, a polymer is chemically or radiochemically activated and then allowed to react chemically with heparin. This procedure was developed to fix isocyanate groups onto polystyrene and then produce a reaction between the resulting polymer and heparin. Mucopolysaccharide was also bonded to silicone in a two-step procedure. Analogous techniques have been developed to bond heparin onto modified polyvinyl alcohol hydrogels, elastomers, polyhydroxyethyl methacrylate-glycidyl methacrylate copolymers, or cellulosic membranes. Alternatively, heparin may be bonded to suitably prepared substrates to produce thromboresistant materials. This approach has been utilized by Goosen and Sefton (298) to develop a high-strength styrene-butadiene-styrene block copolymers. The same approach has been used by Larsson *et al.* (299), who adsorbed colloidal particles composed of heparin and acetylamine hydrochloride onto sulfated polyethylene and then reacted the mixture with glutaraldehyde. The authors claimed that in the resulting biomaterial heparin was covalently bonded, and the biomaterial was thromboresistant.

In a third general procedure, chemical or radiochemical treatment of heparin induces the formation of a macroradical. The latter then induces the polymerization of a monomer producing a copolymer with a heparin moiety covalently bonded to a synthetic polymeric sequence. This procedure was first carried out by Labarre *et al.* (300) using the cerium (IV) peroxidation of heparin, followed by a reaction with acrylic and methacrylic monomers (300,301). Baquey *et al.* (302,303) described a similar method, using the radicals resulting from the  $\gamma$ -ray irradiation of heparin instead of cerium (IV) oxidation. An end point immobilization of heparin can be achieved by partial depolymerization of heparin, followed by bonding on a cold plasma treated surface.

The heparin immobilization can also be achieved through hydrophilic spacer (304), and in a defined orientation by coupling through its reducing end. This is expected to mimic the attachment of heparin to the protein core in the naturally occurring proteoglycan and impart better ligand binding efficiency by exposing all the binding sites available in the naturally occurring heparin. The coupling chemistry was accomplished by modifying heparin at its reducing end to introduce reactive functionality that can react with appropriately functionalized supports (305). Partially nitrite-degraded heparin allows an end point attachment on the substrate (108,306). When the polymeric

substrate is devoid of chemically reactive groups, it is useful to activate the former by radio-frequency plasma (307). Heparin has also been immobilized on polylactide for application to degradable biomaterials in contact with blood (308). Kim *et al.* (276,309) have compared heparin immobilized on polyurethane surfaces with heparin adsorbed on polyurethane. Immobilized heparin retained its ability to bind and inactivate thrombin and Factor Xa. Immobilized heparin–polyurethane catheters implanted in canine femoral and jugular veins for 1-hour periods exhibited significant reduction in thrombus formation compared with untreated polyurethane contralateral controls. The heparin releasing polyurethane provided even greater improvement in antithrombogenicity.

The properties and antithrombogenic activity of the covalently bonded heparin surfaces have been proved (300,310) to be similar to those of soluble heparin. An alternate method of achieving this consists of modifying the heparin so that it can polymerize or copolymerize. These biomaterials have been shown to be anticoagulant.

The above methods (311) have allowed the preparation of biomaterials with heparin covalently bonded to the surface. However, the anticoagulant heparinlike capacity of these materials depends on the method employed to fix the heparin to the polymer matrix. The activation of the platelets occurs when the surfaces to which the heparin is covalently bonded are exposed to blood or a platelet suspension. However, the preincubation of these surfaces with either aqueous solution of antithrombin or plasma passivates the surface with respect to platelet activation.

In conclusion it has been suggested that the thromboresistance of biomaterials to which heparin is covalently bonded might be due to their heparinlike anticoagulant activity and/or their ability to be passive to platelet activation by the bonding of antithrombin. Nevertheless, the use of such biomaterials is restricted for two reasons. The first of these is economic; the second results from the degradation of heparin by heparinases when exposed to blood. If this is the case, the use of such biomaterials as long-term implants may never be possible. This probably explains the current interest in the synthesis of anticoagulant and heparinlike materials.

## F. Heparinlike Materials

As early as 1951, Lovelock and Porterfield (312) described the anticoagulant properties of polystyrenesulfonates, produced from a reaction of polystyrene tubing with sulfuric acid. The anticoagulant properties of sulfonated soluble polymers, and particularly polystyrene and polyethylene sulfonates, have since been described by Gregor (313). Furthermore, Machovich and Horvath (314) have shown

that polymethacrylic acid exhibits an anticoagulant activity in aqueous solutions.

It has been shown that sulfonate and sulfamate chemical groups are essentials for the anticoagulant activity of the heparin (315–317). Thus it is not surprising to notice that many heparinlike polymers are bearing sulfate groups. Anticoagulant materials have been obtained by reacting *N*-chlorosulfonylisocyanate with an unsaturated polymer, followed by a suitable basic hydrolysis resulting in the formation of a water-soluble polyelectrolyte with *N*-sulfate and carboxylate groups. For example, a soluble polyelectrolyte derived from 1,4-cis-polyisoprene was shown to possess 10% of the anticoagulant activity of heparin (318,319). The anticoagulant activity of the latter polymer, just as with heparin, is related to molecular weight and *N*-sulfate content (320). Akashi *et al.* have synthesized a poly(glucosyloxyethyl methacrylate) sulfate [poly(GEMA) sulfate] that contains sulfated glucoside residues (321). The total human blood clotting time in the presence of poly(GEMA) sulfate is prolonged by increasing the dose or the sulfate content of the polymer (322). Other heparinlike polymers were obtained with bonding sulfate derived groups on various substrates such as polyurethane (323–326), polyethylene (327), hyaluronic acid (328,329), and vinylic polymers (330). Jozefowicz *et al.* (331–339) have obtained resins with significant antithrombogenic activity by bonding sulfonate, carboxylic, amino acid sulfamide, or amide groups onto cross-linked polystyrene, polysaccharides, or polystyrene–polyethylene graft copolymers. The dextran derivatives bearing carboxymethyl, benzylamide, and sulfonate chemical groups (CMDBS family) (Fig. 7) have been extensively studied (200,201,340). They have proved that this activity was antithrombic and anti-Xa, and that it involved plasmatic components (antithrombin and heparin cofactor II), by utilizing tests performed on platelet-poor plasma suspensions of the polymers.

This activity has been established to be on the surface of the polymers. Direct kinetic studies, performed on suspensions of the polymers in aqueous solutions of antithrombin and proteases, were able to show that the anticoagulant activity is heparinlike, i.e., the polymers act as a heterogeneous catalyst with respect to the antithrombin/protease-inhibiting reaction. Thermodynamic studies of the adsorption of proteins on the surface of the resins allowed the authors to propose a mechanism for these catalytic reactions (333–335).

The anticoagulant activities of the materials are strongly dependent on the content and the nature of the substituting groups, which can have either a cooperative or an additive effect. From these observations, a correlation between the anticoagulant activities and the compositions of the heparinlike resins has been established, as shown in Table 5.

**Figure 23.7** Schematic structure of the derivatized dextrans. Hydroxyl units of  $\alpha$ -D-glucose are either unsubstituted or randomly substituted with carboxymethyl, carboxymethyl benzylamide, carboxymethyl benzylamide sulfonate, and sulfate groups.

**Table 23.5** Activity Coefficient of Substituents Linked to Polystyrene Resins

Substituent	Activity coefficient (meq <sup>-1</sup> ) for 1 NIH thrombin unit
SO <sub>3</sub> <sup>-</sup>	50–70
SO <sub>2</sub> NH butyl	0
SO <sub>2</sub> 11-aminoundecanoic acid	40–80
SO <sub>2</sub> alanine	60–80
SO <sub>2</sub> glycine	100–120
SO <sub>2</sub> hydroxyproline	120–150
SO <sub>2</sub> proline	120–150
SO <sub>2</sub> methionine	120–150
SO <sub>2</sub> threonine	120–150
SO <sub>2</sub> N-benzyloxycarbonyllysine	120–150
SO <sub>2</sub> $\alpha$ -alanine	140–200
SO <sub>2</sub> $\beta$ -aminocaproic acid	300–350
SO <sub>2</sub> glutamic acid	350–400
SO <sub>2</sub> $\delta$ -aminovaleric acid	400–450
SO <sub>2</sub> $\gamma$ -aminobutyric acid	500–600
SO <sub>2</sub> aspartic acid	500–600

Based on these results, it has been suggested that it is the isolated functional groups of the polysaccharide chain of heparin that are responsible for its interaction with the antithrombin or the protease rather than the secondary or tertiary structure of this mucopolysaccharide. The comparison and discussion of the estimated activity parameters substantiate the hypothesis that carboxylic functions are essential for heparinlike activity.

*Ex vivo* animal experiments have been performed on surface-treated small-diameter tubing made of polystyrene–polyethylene copolymers. No significant platelet adhesion or aggregation was observed on the wall of the tubing, after it had been pretreated with plasma or antithrombin.

### G. Polymers and the Immune Response

The formation of thrombin that is initiated when polymers contact blood is the most extensively studied phenomenon in the blood–polymer contact field. The inflammatory response induced by the contact of materials with blood has only recently been studied, and consequently the comprehension of this response is limited.

As with the blood coagulation process, the inflammatory response depends on the mechanical features and the shape of the implanted devices. Many polymers will wear when implanted, and there is evidence of giant cell reaction to the wear products. The inflammatory response also depends on the chemical nature of the polymers (12). Little is known about the relation between this characteristic and the immune response.

The complement system is an effective mechanism of the immune system and accomplishes many tasks. The tasks include recognition of infectious agents and foreign surfaces in the tissues, targeting of an object to enhance leukocyte migration and activation processes (e.g., phagocytosis and degranulation), and finally induction of cytotoxicity. The complement activation process includes an enzymatic cascade, which involves approximately 20 different proteins. The activation of the complement cascade is usually considered a characteristic of the hemocompatibility of the material in direct contact with blood.

Several enzyme immunoassay kits are available to investigate the various levels of complement activation. Thus it is possible to evaluate the production of C4d, B<sub>d</sub>, iC3b, and SC5b-9 (341). C4b is a marker for the activation of the classical pathway, B<sub>b</sub> for the alternative pathway, and iC3b and SC5b-9 for the final lytic pathway. A radioimmuno assay for C3a explores the early steps of complement activation in both classical and alternative pathways. It allows us to monitor the newly formed C3a when C3 is cleaved (342). It should be noticed that measuring only

C3a remaining in the fluid phase leads to a wrong value of complement activation, since a part of the C3a may be absorbed on the polymer surface (343).

Zymosan, a polysaccharide, has been reported to be a complement activator. Cellulose and cellulose derivatives have been demonstrated to be responsible for the activation of both pathways of the complement system, in human patients treated by dialysis for renal diseases. In the latter case, cellulose and cellulose derivative membranes and hollow fibres were employed (344–346).

Moreover, soluble polysaccharides and polysaccharide derivatives are activators of the complement system. Dextran induced hypersensitivity reactions in over 40,000 cases when used as a plasma expander in humans. Glycosaminoglycans, such as heparin, may inhibit the complement activation either in solution or when bonded to zymosan. This activity is independent of the anticoagulant one (346).

Kazatchkine, Jozefowicz *et al.* (347) showed that Sephadex is able to activate both the classical and the alternative pathways of the complement system, upon exposure to human blood serum. On the other hand, the same research teams (348,349) showed that the substituted soluble dextrans have the ability to inhibit the formation of the alternative pathway C3 convertase. They demonstrated that a family of dextran derivatives, the carboxymethyl benzylamide sulfonate dextrans (CMDBS) (340), has a high anticomplement activity, which is dependent on the carboxylic and sulfonate group content of the polymer (343, 350,351). Thus these authors were able to synthesize dextran derivatives with high anticomplement and low anticoagulant activities, as shown in Fig. 8. Therefore, these soluble biomaterials are promising candidates for plasma

expanders, as they are expected to prevent hypersensitivity reactions. The insoluble analogs of CMDBS are substituted Sephadex bearing carboxymethyl (CM), CM-benzylamide (CMB), and CMB-sulphonate (CMBS) groups. CM substitution decreases and can suppress the complement activation of Sephadex. Low CMB substitution also decreases the complement activation, whereas high CMB substitutions increase it again after a minimum (352).

In the case of blood substitutes, the infusion of large amounts of modified hemoglobin can potentially result in hypersensitivity and anaphylactic reactions (353,354). The same phenomenon is observed for the perfluorocarbon (PFC) emulsions usually called “artificial blood” (355).

## X. CONCLUSION

Blood-contacting polymers have often been chosen by empirical observation. Nonetheless, cardiovascular devices are now in common use and represent an ever-increasing market. Still, there are limitations to the use of polymers. At the beginning of the 1970s, these limits appeared to be the blood coagulation process. More recently, the immune response of the host to the implants, and its consequence on long-term uses, i.e., delayed infection and calcification of the prosthetic devices, have been examined. Immediate hypersensitivity reactions to blood-contacting polymers were also observed in some patients. At present, nearly all the commercially available blood-contacting polymers are employed in conjunction with a permanent adjuvant anticoagulant therapy, which in turn leads to long-term medical complications.

Therefore considerable research has been devoted to understanding the scientific basis of these limitations. The data available for blood–polymer interactions show that the limitations lie in the fact that any surface, natural (including the healthy blood vessel endothelium) or artificial, probably activates the blood coagulation cascade by contact.

Improved knowledge of the parameters controlling this phenomenon has led to improvements in the design of the artificial devices. It has permitted also the design and tailoring of antithrombogenic polymers, for example heparinlike polymers, which may be suitable for the production of cardiovascular devices in the near future.

Discussion of the available data suggests that fundamental studies of blood–material interfacial reactions are necessary in order to ascertain the structure of the materials, the coagulation factors, and the adsorption relationships responsible for the observed overall thrombogenicity. As a result, the tailoring of new polymers that are

**Figure 23.8** Relationship between anticomplementary activity and anticoagulant activity of the modified dextran.

able to control the coagulation process initiated at the interface may be possible (356).

It can be concluded from observations made that the immune response may be a controlling parameter in the overall biocompatibility of blood-contacting polymers. At present it is not possible to describe completely the consequences of the host immune response on an implant, but from the available data it appears that two complications are of concern:

In the long term, it appears that the presence of an implant increases the risk of infection.

Blood-contacting polymers may induce sensitivity and short-term reactions.

Recent advances show that significant improvements in the tailoring of polymers enable the immune response to be controlled, and undoubtedly similar results will be obtained if sufficient research is devoted to the field of blood-contacting polymers. An example of significant advance in this field is the synthesis of substituted dextrans that control the activation of the complement system, which renders them promising candidates as plasma expanders. New methodologies for the modification and characterization of the biomaterial surfaces have been developed. In order to improve the biocompatibility of biomaterials, new bioactive biomaterials have been produced based on the principles of biological recognition in order to regulate biological pathways. Such biomaterials can be designed using approaches based on the lock and key concept proposed by Emil Fischer a hundred years ago. Oligopeptides such as the Arg-Gly-Asp (RGD) sequence, which are capable of being a binding domain with high specific affinity for cells, have been grafted to polymers. Other bioactive polymers have been developed based on the incorporation of growth factors. The delivery of the growth factors depends on the chemical and physical characteristics of the polymeric carrier. Some polymers also play the role of protecting agents when they are in contact with a living system. Based on Emil Fischer's concept, bioactive polymers have been synthesized by attaching biospecific "keys" along the polymer chain. It has been shown that the random attachment of functional groups, which are analogous to the active groups in the natural messenger molecule (such as heparin), results in materials endowed with biological specificity. Extensive work has been performed to prepare functionalized polymers capable of mimicking some of the actions of heparin. The latter are able to stimulate the healing of a wound in various in vivo models. These polymers may also constitute a family of tissue repair agents because of their protecting and potentiating effects with heparin binding growth factors. These polymers generally affect both cell proliferation and metabolism.

A large amount of work has been also devoted to the development of new methodologies for the characterization and modification of the biomaterial surface. For example, a chemical characterization of the surface is often performed with electron spectroscopy for chemical analysis (ESCA). Modification of the biomaterial surface can be achieved by the use of a gas plasma discharge. This method creates reactive chemical groups onto the surface capable of binding bioactive molecules.

Blood-contacting polymers play an important role in the current market for biomaterial engineering. However, the period of time between the concept and the clinical application is long. It is evident that the penetration of new products onto the market depends on the high cost of development, the extended length of time needed for the approval of the new product, and the collaboration between manufacturers and physicians and surgeons. The latter are often hesitant to try new products with which they are unfamiliar. However, there is no doubt that the market will expand rapidly in the next 10 years if the safety and functionality of new blood contacting polymers compensates for the high cost of their development. Blood-contacting polymers have been widely employed, and their use will continue to extend for the benefit of man.

## ACKNOWLEDGMENTS

The experimental work performed by the authors was partially funded by grants from the Centre National de la Recherche Scientifique (CNRS) and the Ministère de l'Éducation Nationale, de la Recherche et de la Technologie. We are grateful to Stéphanie Cahuzac for assistance in writing the manuscript.

### I. INTRODUCTION

Medium (6–8 mm) and small (<5 mm) internal diameter (I.D.) prosthetic arterial grafts continue to have unacceptably high failure rates when used in the clinical setting. The two major complications associated with these grafts are acute thromboses and incomplete, unregulated cellular healing. Currently available biomaterials for vascular grafts do not emulate the multitude of biological and reparative processes that occur in a normal pulsatile arterial wall. There have been exhaustive studies aimed at creating a novel biomaterial surface by nonspecific binding of a biologically active agent, covalent linkage of an agent with a broad spectrum of activity, or altering the biomaterial surface. Thus far, none of these technologies has resulted in a clinically used prosthetic vascular graft. Based on our clinical and research observations, our hypothesis is that the ultimate prosthetic graft will have to possess multiple structural and biological properties that mimic those processes inherent to the native vessel. The structure of the prosthetic graft will have to possess long-term biodurability (strength over the lifetime of the implant), porosity (permits cellular ingrowth in order to promote complete healing), and excellent handling characteristics (ease of suturing). Biologically, the surface will have to possess both localized antithrombin activity at the blood/graft interface

and specific endothelial cell growth promoting factors (to increase transwall and translumen cellular growth). This chapter will examine the use of polyester (Dacron) as a prosthetic vascular graft, complications associated with graft implantation, our clinical and research observations, previous efforts to develop a novel biocompatible material surface, and our preliminary studies developing technology for covalent linkage of antithrombin and mitogenic proteins onto a Dacron surface.

### II. POLYESTER (DACRON): CHARACTERISTICS AND APPLICATIONS

Polyester (chemical nomenclature—polyethylene terephthalate) fibers were first characterized in 1941 and have become the most widely produced synthetic fibers in the world. They are most familiarly known by the DuPont commercial name Dacron®. The polymer is synthesized by a condensation reaction of derivatives of ethylene glycol and terephthalic acid, resulting in molecules that contain 80 to 100 repeat units (1). These molecules are then extruded through a plurality of holes (a spinneret) to produce multifilament yarns. Dacron yarns are further processed into various structures such as warp-knit, weft-knit, and

woven fabrics (2) and have excellent resiliency as well as resistance to a wide range of chemical and biological challenges.

Dacron is utilized in items ranging from clothing to medical implants. Dacron yarn was first sewn into a tubular form and utilized as a large-diameter vascular graft in the mid-1950s (3). Since that point, Dacron has been incorporated into both large- and medium-bore vascular grafts in knitted and woven form. These grafts have shown excellent long-term biocompatibility, handling characteristics, and capsular tissue incorporation (4).

### III. COMPLICATIONS ASSOCIATED WITH PROSTHETIC ARTERIAL GRAFTING

Failure of all prosthetic arterial grafts including Dacron can be grouped into three periods: acute, delayed, and late. Acute thrombosis (hours to days) is the result of low blood flow through the graft permitting activation of the coagulation cascade at the blood/graft interface with subsequent occlusive thrombus formation. Delayed failure (weeks to months) is the result of an incomplete cellular lining of the luminal graft surface (failure of complete neointimal formation) and associated unregulated smooth muscle cell proliferation at the anastomotic sites causing focal stenosis, decreased blood flow through the graft, and secondary occlusive thrombus formation. Late graft failure (years) is infrequent and most often due to progression of atherosclerosis in the inflow or outflow vessels.

In order to examine these phenomena, an understanding of how humans incorporate and/or heal prosthetic vascular grafts is essential. The capsular surface (non-blood flow) is immediately identified by the host immune system as foreign, thereby eliciting a mixed inflammatory response with ultimate foreign body giant cell reaction. This is subsequently reinforced by collagen-rich tissue, forming what is essentially a scar. Whether the result of inflammatory cytokines, growth inhibitors from the forming luminal pseudointima, or physical factors, cellular growth through the graft interstices from the host tissues does not occur in humans.

The luminal surface (blood flow surface) of all bare prosthetic conduits is inherently thrombogenic, resulting in the formation of a controlled mural thrombus when exposed to flowing blood. The thickness and composition of this mural thrombus is initially a function of biomaterial composition and design, with the final thickness/composition ultimately determined by blood flow velocity through the graft and the thrombogenic potential of the blood. This thrombotic acellular layer has been termed the pseudointima. The body under normal circumstances recognizes

thrombus and organizes the coagulum by proliferation of the underlying blood vessel endothelium and smooth muscle cells. In the case of prosthetic grafts, this recanalization is not possible, since the underlying structure is synthetic and not biological. Recent studies have also determined that the pseudointimal lining itself contains growth-inhibiting compounds, further impeding the development of a cellular neointima (5). While several strategies to diminish or circumvent this incomplete healing response have been investigated (6,7), none has resulted in clinical success.

Thus all prosthetic conduits are lined by highly reactive pseudointima. This surface has the ability to activate platelets and provides for continuous low-level thrombotic events, generating biologically active molecules such as thrombin within the pseudointimal matrix, thereby promoting additional fibrin and platelet recruitment. This healing pattern is unique to humans and canines.

The final site to consider in graft healing is the anastomotic region. Both endothelial and smooth muscle cells from the host artery proliferate into the graft. The stimulus for this cellular migration has yet to be completely defined, but it is related both to the acute injury to the arterial wall at the time of surgery and subsequently to the deposition of pseudointima on the graft surface. Thrombin embedded within the pseudointima is a powerful smooth muscle and endothelial cell mitogen, providing one of the many stimuli for organizing *in vivo* arterial thrombi (8). The organization of perianastomotic pseudointima with subsequent cellular proliferation occurs approximately 1 cm into the graft and abruptly stops. Cellular ingrowth at an anastomosis, or pannus ingrowth, is no more than approximately 1 cm into the graft body regardless of how long a graft is implanted.

Following this initial proliferative cycle, a period of matrix production ensues creating a localized lesion (stenosis) at the anastomotic site. This lesion impacts blood flow through the graft, further enhancing the blood/pseudointima interaction. The observed healing responses of these three domains (capsule, luminal surface, anastomotic region) on graft incorporation is unique to human beings. The only animal model that mimics this healing response is the canine model (9).

### IV. CLINICAL AND RESEARCH OBSERVATIONS: BASIS FOR RESEARCH

In previous studies from our clinical and laboratory experience, mechanisms of prosthetic arterial graft failure have been evaluated. Observations from these studies, which direct our research, are as follows:

Prosthetic arterial grafts, regardless of the material composition, fail to develop a functional cellular neointima within the mid-portion of the graft (incomplete healing). A relatively thrombogenic pseudointima composed of thrombin, platelets, fibrin, and serum proteins forms the majority of the flow surface to which the circulating blood is exposed for the duration of graft patency (Fig. 1) (10).

Pseudointima formation results in low-level chronic activation of platelets and proteins of the coagulation cascade and to some extent cellular and humoral aspects of the complement system (11). The only available cellular source that can respond to this activation is the distal anastomotic site and the adjacent arterial segment (12).

Unregulated smooth muscle cell proliferation and gene expression at the anastomosis results in focal stenosis. Anastomotic stenosis with subsequent lowering of blood flow through the graft amplifies the blood/graft/pseudointima contact time and potentiates the activation of platelets and the coagulation cascade (13). This results in increased pseudointima formation, which is essentially a controlled mural thrombosis or, in severe cases, occlusive graft thrombosis.

Providing a cellular source via increasing graft interstices (porosity) and direct luminal seeding with endothelial cells have been ineffective in forming a stable functional cellular neointima, which is necessary to modulate the blood/materials interaction.

**Figure 24.1** A longitudinal cross-section of a Dacron vascular graft after 30-day explantation from a canine carotid. A neointima composed of endothelial and smooth muscle cells proliferates into the graft and abruptly ends 1 cm from each anastomosis. A pseudointima composed of platelets, thrombin, fibrinogen, red blood cells, and serum proteins occupies the mid portion of the graft.

Systemic antiplatelet, anti-inflammatory, and anti-thrombin agents alone do not affect the onset of intimal hyperplasia or the long-term patency of the graft.

All biomaterials are excluded from direct blood interaction within minutes of establishing blood flow by an amorphous pseudointima composed of platelets, fibrin, fibrinogen, and serum proteins. Thus a biomaterial surface must be developed that will alter pseudointima composition and formation.

Studies evaluating the effects of circumferential compliance alone on graft healing/patency have not yielded conclusive findings.

## V. HISTORICAL APPROACH TO SURFACE MODIFICATION

### A. Prevention of Surface Thrombus Formation

A complication of all implantable biomaterials is incompatibility between blood and the biomaterial surface. The initial interaction of blood and the foreign surface results in a myriad of responses: platelet activation and adhesion (13,14), activation of the intrinsic pathway of the coagulation cascade, resulting in formation of active thrombin (15), leukocyte activation (14), and the release of complement and kallikrein (15,16). If unregulated, these responses lead to surface thrombus formation with subsequent failure of the implanted biomaterial.

Numerous attempts have been made to create a more biocompatible surface by establishing a new biologic lining on the luminal surface that would “passivate” this acute initial reaction. These efforts have ranged from nonspecifically binding albumin to the surface followed by heat denaturation (17) to nonspecifically cross-linking gelatin (18–20) and collagen (21–23). Covalent or ionic binding of the anticoagulant heparin albumin (14,24,25), alone (26–34), in conjunction with other biologic compounds (35–40), or with spacer moieties (41–43), as well as covalent linkage of thrombomodulin (44) have also been performed. Other studies have focused on modifying the composition of the biomaterial either by increasing hydrophilicity via incorporation of polyethylene oxide groups (45) or by creating an ionically charged surface (46).

Each of these methodologies has had limited success in creating a durable, biologically active surface. There are several limitations associated with these surface modifications: (1) thrombin is not directly inhibited, therefore fibrinogen amounts remain constant on the material surface, permitting platelet adhesion, (2) heparin-coated biomaterials may be subject to heparitinases, limiting the long-term use of these materials, (3) nonspecifically bound com-

pounds are desorbed from the surface, which is under shear stresses, thereby re-exposing the thrombogenic biomaterial surface, (4) rapid release of nonspecifically bound compounds may create an undesired systemic effect, and (5) charge-based polymers may be covered by other blood proteins such that anticoagulant effects are masked.

One study that has shown promise involved left ventricular assist devices (LVAD) implanted in a sheep model that were either uncoated or contained covalently bound heparin (47). The heparin-coated LVAD had minimal thrombus formation (i.e., microthrombi, platelet accumulation) with a thin protein layer after implantation for 3 months as compared to uncoated control LVAD that had gross thrombus formation at 1 month. Heparin activity, which was monitored via chromogenic assay, was not detectable after 15 days, thus suggesting that altering the acute bioactivity of thrombin creates a long-term "passivated" flow surface. Despite these promising results, each of these studies has failed to change appreciably the pathobiology of biomaterial failure.

### B. Promotion of an Endothelial Cell Lining

Another proposed mechanism to prevent thrombus formation on a graft surface was to develop a uniform layer of endothelial cells across the lumen. Endothelial cells play a pivotal role in mediating blood interaction with the arterial wall. These cells maintain hemostasis and also synthesizing growth mediators that block abnormal smooth muscle cell proliferation. Ideally, prosthetic grafts should promote endothelial cell adherence and growth on the luminal surface while permitting direct host tissue incorporation at the capsular surface. This type of cellular incorporation does not occur in actuality, thereby predisposing these grafts to infection (48,49), thrombosis (50,51), perigraft seromas (52), and delayed graft failure (53). Thus the failure of appropriate cell type growth and development to these biomaterials significantly limits their expanded use (48).

Endothelial cell adhesion to prosthetic grafts using endothelial cell seeding techniques has been extensively employed (54–56). Adhesive proteins such as fibronectin, fibrinogen, vitronectin, and collagen have served well in graft seeding protocols (57,58). The cell attachment properties of these matrices can also be duplicated by short peptide sequences such as RGD (Arg-Gly-Asp) (59). These adhesive proteins, however, have several drawbacks: (1) bacterial pathogens recognize and bind to these sequences (60,61), (2) nonendothelial cell lines also bind to these sequences (56,62), (3) patients requiring a seeded vascular graft have few donor endothelial cells, so that cells must be grown in culture (63), and (4) endothelial cell loss to shear forces remains a significant obstacle (64).

Modification of the surface has also been employed to modify host response to the foreign body, serving as an approach for improving endothelial cell adherence to Dacron. Endothelial cells after seeding have been shown to attach and grow on a variety of protein substrates coated onto vascular graft materials (58,65). Bioactive oligopeptides (66,67) and cell growth factors (68) have been immobilized onto various polymers and demonstrated to affect cell adherence and growth. Additional studies have described the incorporation of growth factors into a degradable protein mesh, resulting in the formation of capillaries into the graft wall (69). Utilizing these techniques to incorporate growth factors, however, does have limitations: (1) growth factor is rapidly released from the matrix, (2) matrix degradation reexposes the thrombogenic surface, such that endothelialization is not uniform, and (3) release of nonendothelial specific growth factor is not confined to the biomaterial matrix, thereby exposing the "normal" distal artery to the growth factor.

### VI. MODIFICATION OF DACRON: CREATION OF "ANCHOR" SITES

The first step in developing a biocompatible surface was to create a surface to which biologically active agents could be covalently attached. Dacron was selected over other biomaterials due to its clinical acceptance, long-term bi durability, and potential for chemical manipulation. Our objective was to modify Dacron so that reactive sites could be created without significantly altering the physical characteristics of the biomaterial (70). Creation of carboxyl and hydroxyl groups on the Dacron surface was achieved via alkaline hydrolysis. Hydrolysis is typically utilized to break ester bonds on the outer periphery of the fiber surface (71). Applying this technique in the textile industry results in a finer, softer fabric with improved soil release due to the increased hydrophilicity of the material. If, however, concentrations of sodium hydroxide as well as temperature and time parameters are increased, extensive cleavage and loss of low molecular weight products occurs, thereby decreasing the strength and weight of the material. Reduction of tensile strength and fiber weight of a Dacron arterial graft could lead to aneurysmal formation due to the constant pressure exerted on a luminal surface that is under intense flow conditions once implanted. Thus it was imperative that creation of carboxyl groups on the Dacron surface via hydrolysis did not significantly modify the physical properties of the fiber.

Dacron segments were cut from a large fabric sheet and washed in a scouring solution containing  $\text{Na}_2\text{CO}_3$  and Tween 20 detergent for 30 minutes at 60°C. Samples were

then rinsed for 30 minutes at 60°C. Dacron segments were then oven dried for 15 minutes at 60°C to remove moisture, weighed (pretest weight) and combined into groups by closeness in weight. These groups were then exposed to the following solutions at 100°C for 30 minutes: (1) distilled H<sub>2</sub>O (Control Dacron or CD), (2) 0.5% NaOH, (3) 1.0% NaOH, (4) 2.5% NaOH, and (5) 5.0% NaOH (referred to HD). These pieces were then rinsed with distilled H<sub>2</sub>O (room temperature), oven dried for 15 minutes at 60°C, and weighed (posttest weight). Differences between pre and post weights were calculated and averaged (Fig. 2). Examination of the CD and HD for fiber weight loss resulted in the 1.0% (3.1%), 2.5% (11%), and 5.0% (27%) hydrolyzed materials demonstrating significant weight loss as compared to control. The 0.5% HD did not exhibit any significant weight loss.

CD and HD segments, used in determining weight loss, were then tested for tensile strength. An Instron T-1000 Apparatus (Instron Corporation) was calibrated according to manufacturer's specifications in a temperature-controlled environment (room temperature 31°C). Each segment was then placed into two air compressor clamps spaced 1" apart, and the instrument was returned to baseline. Material stretching was then initiated and terminated upon observation of visible tearing. The pounds of force required to tear untreated and NaOH hydrolyzed materials were determined (Fig. 3). Evaluation of tensile strength of CD and HD materials revealed no significant difference between control, 0.5%, and 1.0% hydrolyzed materials. The 2.5% (20%) and 5.0% (40%) HD, however, had significant strength loss as compared to CD.

**Figure 24.2** Fiber weight loss (%) of variously hydrolyzed Dacron segments versus untreated Dacron. The 1.0% (3.1,  $p < 0.001$ ), 2.5% (11%,  $p < 0.0001$ ), and 5.0% (27%,  $p < 0.0001$ ) hydrolyzed materials had significant weight loss in comparison to untreated Dacron. The fiber weight loss of the 0.5% hydrolyzed Dacron was not significant compared to untreated Dacron.

**Figure 24.3** Strength retention (%) of variously hydrolyzed Dacron segments versus untreated Dacron. The 2.5% (20%,  $p < 0.0003$ ) and 5.0% (40%,  $p < 0.0001$ ) hydrolyzed Dacron showed significant strength loss as compared to untreated Dacron, whereas the 0.5% and 1.0% hydrolyzed Dacron were not significantly different in strength.

Thus the 0.5% hydrolyzed Dacron was the only hydrolyzed material in which tensile strength and fiber weight loss were not significantly less than untreated Dacron. No extensive chain scission within the fiber occurred, as was displayed by the close correlation of fiber strength and weight loss (summation of strength retention and weight loss data for each assayed material is approximately equal to 100%). Any evidence of strength loss resulting from the various hydrolysis conditions was solely due to reduction in the surface fiber mass.

## VII. SELECTION OF PROTEIN FOR "BASECOAT" LAYER ON DACRON SURFACE

Covalent linkage of a protein to a biomaterial surface in order to create a "basecoat" layer has numerous beneficial advantages. Nonspecific or covalent attachment of a protein coating has been shown to "passivate" a surface that is relatively thrombogenic, thereby decreasing adhesion of blood products such as platelets, red blood cells, and fibrinogen (17,26). Also, protein incorporated as a basecoat layer has been used as a "scaffolding" in order to promote a specific response, such as linkage of RGD peptides to promote cell adhesion (72). From our foundation studies, utilization of a basecoat layer permitted significant amplification of potential binding sites for secondary protein attachment via heterobifunctional cross-linkers (73-75). Thus utilization of a basecoat creates a biomaterial surface with distinct properties for a specific application.

### A. Albumin Basecoat for Thromboresistant Surface

The effects of albumin coating on Dacron have been extensively examined both *in vitro* and *in vivo*. *In vitro*, albumin nonspecifically cross-linked around the fibers of Dacron via glutaraldehyde was shown to reduce platelet adhesion and coagulation cascade activation, release of platelet factor 4 and  $\beta$ -thromboglobulin, fibrinopeptide A formation, and leukocyte adhesion (14). *In vivo* analysis of aortocaval fistulae was performed between preclotted Dacron and Dacron that was immersed into a 25% albumin solution and autoclaved (17). Decreases of 5.2-, 6.0-, and 1.8-fold in red blood cell adhesion, platelet accumulation, and fibrinogen accumulation, respectively, were observed for the albumin-treated Dacron as compared to preclotted Dacron. Thus albumin was selected as the protein to bind covalently to HD due to the numerous beneficial results demonstrated in these early studies.

### B. Type IV Collagen as Basecoat for Cellular Adhesion

In selecting a basecoat protein that would promote cellular adhesion, the composition of native blood vessels was examined. All mammalian epithelia are separated at their interface by specialized extracellular matrix proteins (basement membrane) composed predominantly of Type IV collagen networks with minor components of elastin, fibrillins, thrombospondins, laminin, fibronectin, and glycoaminoglycans. Endothelial cell growth and differentiation (morphogenesis) has an absolute requirement of this highly structured extracellular matrix environment for normal cell growth and differentiation (76). Additionally, matrix proteins have been shown to be crucial in binding signaling proteins such as fibroblast growth factor (FGF) and transforming growth factor- $\beta$  (TGF- $\beta$ ) (77).

Type IV collagen has several advantages over albumin when considering basecoat proteins for a vascular graft surface. Type IV collagen is a basement membrane protein that is directly involved in cell adhesion as well as regulation of cell function (78). Conversely, albumin is a serum protein that has been shown to have beneficial results on protein adhesion when bound to a graft surface. However, albumin has no cell adhesion properties, an area that may be necessary for neointimal formation. Similar to albumin, Type IV collagen has been shown to provide numerous cross-linking sites suitable for covalent attachment of biologically active agents. Therefore Type IV collagen is a better candidate than albumin to serve as the basecoat protein for cellular adhesion studies.

## VIII. RATIONALE FOR SELECTION OF ANTITHROMBIN AND MITOGENIC AGENTS

### A. Recombinant Hirudin (rHir)

Thrombin, a pivotal enzyme in the blood coagulation cascade, is the primary agent responsible for thrombus formation. The principal function of thrombin is the cleavage of fibrinogen to fibrin (8). Additionally, thrombin also functions as a smooth muscle cell mitogen (79), is chemotactic for monocytes and neutrophils (80,81), and is an aggregator of lymphocytes (81). This enzyme has also been shown to bind to endothelial cells, inducing the release of platelet-derived growth factor (PDGF)-like growth factors (82) and has been shown to be a potent platelet aggregant, stimulating the release of platelet factors (83). Thus thrombin, beyond its role in clot formation, has tremendous secondary effects that induce inflammation at the site of synthesis and enhance cellular proliferation or hyperplasia by various proposed activation mechanisms, all of which are beneficial in wound healing but are extremely deleterious to prosthetic graft patency.

rHir, a 6,965 Da recombinant protein synthesized from the leech protein hirudin, is the most potent specific inhibitor of thrombin (84). rHir has demonstrated inhibition of thrombin's enzymatic, chemotactic, and mitogenic properties (8,85,86). rHir has also been shown to have potent antithrombin activity when covalently immobilized onto a Dacron surface (75) or to another biomolecule (87–89). This leech anticoagulant holds several advantages over heparin: (1) rHir inhibits thrombin directly, whereas heparin requires antithrombin III, (2) heparin enhances platelet aggregation (90), (3) rHir inhibits the uptake of thrombin into fibrin clots (91,92), and (4) heparin is regulated by platelet function (93). Thus rHir is an attractive agent for covalent attachment in order to reduce or eliminate the pseudointima formation on graft surface. Further, inhibition of thrombin via surface bound rHir may prevent smooth muscle cell proliferation and matrix production at the anastomoses.

### B. Recombinant Vascular Endothelial Growth Factor (VEGF)

The rationale for selecting a growth factor in order to promote cellular migration and proliferation was based upon the specificity of the growth factor for endothelial cells. VEGF, a 38 kDa homodimeric glycoprotein, has been shown to be a potent endothelial cell mitogen and vasopermeability factor (94–96). VEGF is produced by many different cell types both in tissue culture and *in vivo*. VEGF

binds to plasma membrane receptors on endothelial cells only with an extracellular transmembrane glycoprotein linked to an intracellular tyrosine kinase domain (94); thus VEGF is an endothelial-specific mitogen. These cell-specific, high-affinity receptors have structural similarities to both forms of the platelet-derived growth factor (PDGF) receptors (97). VEGF has been subsequently found in many tumors related to vascular angiogenesis (98), is responsible for vascular proliferation in the presence of hypoxia seen in diabetic retinopathy (99), and is shown to be involved in the normal development of the vasculature (100).

In vitro, VEGF expression can be increased by several mechanisms including stimulation by growth factors [basic FGF, TGF- $\beta$ , and PDGF (101)] and the cytokines tumor necrosis factor- $\alpha$  and interleukin-1- $\beta$  (102). VEGF mRNA expression is also increased by hypoxia in numerous cell lines, including endothelial cell and vascular smooth muscle cells (103). In addition, vascular growth factors PDGF and bFGF have synergistic effects on the induction of VEGF at moderate levels of hypoxia in vascular smooth muscle cells (104). Hypoxic induction of VEGF has been postulated to account for sustaining angiogenesis in tumor growth and in the induction of ischemic retinopathies such as diabetic retinopathy and central retinal vein occlusion (99).

In vivo, VEGF infused intra-arterially has been shown to improve collateral flow in a hindlimb model of ischemia (105) and mitigates the development of intimal hyperplasia observed after balloon catheter-induced arterial injury (106). The beneficial effect of VEGF following balloon denudation injury appears to result from an earlier, more extensive and more histologically normal reendothelialization of the vessel. Those portions of the vessel that were repopulated by endothelial cells had little or no neointimal growth (106). Of note, studies by Banai and Ibuki-yama demonstrated the efficacy of human VEGF at stimulating proliferation of canine endothelial cells (107,108), an important factor for future implant studies. In autologous vein grafts, VEGF mRNA expression has been shown to increase 2.5-fold 48 hours after bypass grafting as compared to control veins (109). This may, in part, explain the superior patency rates achieved with vein grafts over prosthetic arterial grafts in small vessel arterial reconstruction.

Thus VEGF is specific for endothelial cell activation and proliferation, resulting in endothelial cell infiltration in several clinical conditions. These characteristics establish VEGF as an ideal candidate for covalent linkage to a vascular graft in an attempt to facilitate neointima formation throughout the luminal surface of the conduit.

## IX. COVALENT BINDING OF rHIR TO THE DACRON SURFACE: IN VITRO AND IN VIVO RESULTS

### A. Covalent Linkage of $^{125}\text{I}$ -BSA with Various Sulfo-SMCC Ratios to HD Surfaces Via EDC Cross-linker

The second phase of the surface modification studies was to determine if a basecoat protein with binding sites could be linked to the surface (75). HD segments were placed in an EDC solution and reacted for 30 minutes at room temperature. CD segments were placed into 100% ethanol without EDC cross-linker and reacted under the same conditions. Concurrently, seven  $^{125}\text{I}$ -BSA solutions were prepared in PBS. One sample was utilized to establish the maximum binding control for this experiment as defined in our previous study (70), the incubation of HD segments with EDC followed by the addition of  $^{125}\text{I}$ -BSA with no sulfo-SMCC cross-linker. The other six samples were reacted with sulfo-SMCC in molar ratios of 1:5, 1:10, 1:20, 1:30, 1:40, and 1:50 for 20 minutes at 37°C and purified via gel filtration. The final concentration of the  $^{125}\text{I}$ -BSA and  $^{125}\text{I}$ -BSA-SMCC samples was adjusted to 14.8  $\mu\text{M}$ . CD and HD segments were then removed from their respective solutions after 30 minutes, shaken to remove excess ethanol/cross-linker, and incubated with the  $^{125}\text{I}$ -BSA/ $^{125}\text{I}$ -BSA-SMCC solutions for 2 hours at room temperature on the inversion mixer. Dacron segments were then individually sonicated in PBS with 0.05% Tween 20. This procedure was repeated three times, changing the wash buffer between sonications to remove any weakly adherent  $^{125}\text{I}$ -BSA on the surface of each segment. The segments with nonspecifically bound (CD +  $^{125}\text{I}$ -BSA and CD +  $^{125}\text{I}$ -BSA-SMCC) and covalently bound (HD- $^{125}\text{I}$ -BSA and HD- $^{125}\text{I}$ -BSA-SMCC)  $^{125}\text{I}$ -BSA were then gamma counted, and the amount of  $^{125}\text{I}$ -BSA bound (ng) per mg Dacron was determined.

The amount of  $^{125}\text{I}$ -BSA-SMCC covalently bound to HD segments via EDC was not significantly altered by any of the sulfo-SMCC ratios examined as compared to HD that was incubated with only EDC and  $^{125}\text{I}$ -BSA (Fig. 4). The amount of  $^{125}\text{I}$ -BSA covalently bound to the HD segments via EDC was significantly greater (6.7-fold difference in the highest  $^{125}\text{I}$ -BSA : sulfo-SMCC ratios to 11.4-fold difference for no cross-linker reacted with the  $^{125}\text{I}$ -BSA) than the amount of  $^{125}\text{I}$ -BSA or  $^{125}\text{I}$ -BSA-SMCC complex nonspecifically bound to CD segments. The amount of nonspecifically bound  $^{125}\text{I}$ -BSA to HD segments that were not incubated with EDC (data not shown) was slightly greater than the amount of  $^{125}\text{I}$ -BSA nonspecifically bound to the CD segments.

**Figure 24.4** <sup>125</sup>I-BSA and <sup>125</sup>I-BSA-SMCC (1:5–1:50 ratios) binding to HD in the absence or presence of EDC. The amount of <sup>125</sup>I-BSA covalently bound to HD segments via EDC was not significantly altered by any of the sulfo-SMCC ratios examined.

### B. Covalent Linkage <sup>125</sup>I-rHir to Dacron-BSA-SMCC Segments

In a separate series of experiments, the CD and HD segments were prepared without radiolabeling BSA in order to determine the amount of <sup>125</sup>I-rHir either nonspecifically or covalently bound to the surface. CD and HD segments, which were not exposed to BSA, also served as controls. <sup>125</sup>I-rHir was reacted in a 1:2 molar ratio with Traut's reagent for 20 minutes at 37°C in order to create sulfhydryl groups on rHir and purified via gel filtration. This <sup>125</sup>I-rHir-SH compound was then reacted with the modified Dacron segments overnight at 4°C. The segments were then washed and sonicated as described above. The nonspecifically bound <sup>125</sup>I-rHir segments (CD + <sup>125</sup>I-rHir-SH, HD + <sup>125</sup>I-rHir-SH, CD + BSA + <sup>125</sup>I-rHir-SH, and HD-BSA + <sup>125</sup>I-rHir-SH) and covalently linked <sup>125</sup>I-rHir segments (HD-BSA-SMCC-S-<sup>125</sup>I-rHir with various sulfo-SMCC ratios) were then gamma counted in order to determine the amount of <sup>125</sup>I-rHir bound (ng) per mg Dacron.

The amount of <sup>125</sup>I-rHir-SH covalently bound to the HD-BSA-SMCC segments increased with increasing sulfo-SMCC cross-linker (20, 39, 53, 77, 95, and 111 ng rHir/mg Dacron) (Fig. 5). These ng amounts of <sup>125</sup>I-rHir corresponded to 0.23, 0.45, 0.61, 0.89, 1.1, and 1.3 anti-thrombin units (ATU)/mg Dacron, with 1 ATU defined

**Figure 24.5** <sup>125</sup>I-rHir binding versus HD-BSA-SMCC with various SMCC ratios. The amount of <sup>125</sup>I-rHir-SH covalently bound to HD-BSA-SMCC segments increased with increasing sulfo-SMCC cross-linker.

as the amount of rHir necessary to inhibit 1 NIHU of thrombin. Conversely, CD (not shown), CD + BSA, and HD-BSA segments incubated with the <sup>125</sup>I-rHir-SH bound minimal but comparable amounts of the inhibitor (5 ng or 0.06 ATU/mg Dacron). Covalently bound <sup>125</sup>I-rHir on the HD-BSA-SMCC-S-<sup>125</sup>I-rHir segments resulted in 4-, 8-, 11-, 16-, 20-, and 22-fold greater <sup>125</sup>I-rHir binding as compared to control segments. The HD segments without BSA bound to the surface (not shown) had 1.7-fold greater (9 ng or 0.10 ATU/mg Dacron) nonspecific <sup>125</sup>I-rHir-SH binding than the other controls. Thus completion of these experiments resulted in a Dacron surface with a significant amount of <sup>125</sup>I-rHir bound to the surface. The next step was to determine which surface possessed optimum antithrombin activity.

### C. Initial Determination of Antithrombin Activity by Modified Dacron Surfaces

Determination of thrombin inhibition by these modified Dacron segments was then assayed using the chromogenic substrate for thrombin S-2238, a synthetically derived peptide that possesses an affinity for thrombin comparable to that of the natural substrate fibrinogen. Upon cleavage of S-2238 by thrombin, the chromophore para-nitro aniline (4-nitroaniline) or pNA is released, giving rise to color. Thus color change is directly proportional to proteolytic activity of thrombin.

CD + BSA +  $^{125}\text{I}$ -rHir-SH, HD-BSA +  $^{125}\text{I}$ -rHir-SH or HD-BSA-SMCC-S- $^{125}\text{I}$ -rHir (sulfo-SMCC ratios of 1:5 to 1:50) segments were placed flat into the bottom of 1 cm cuvettes. Thrombin (0.2 NIHU) was then added and equilibrated for 5 minutes at 37°C in a Beckman spectrophotometer. The thrombin assay was initiated by the addition of 1 mL of 50  $\mu\text{M}$  S-2238 and the change in absorbance per minute monitored at 15-second intervals for 10 minutes at 410 nm, thus measuring residual proteolytic activity of thrombin. Using this data, the amount of thrombin inhibited (NIHU) by surface-bound rHir was determined. These segments were then rinsed with PBS with 0.05% Tween 20, placed into a new cuvette, and rechallenge with another 0.2 NIHU thrombin.

The CD + BSA + rHir-SH and HD-BSA + rHir-SH controls inhibited 0.022 and 0.046 NIHU thrombin, respectively, upon the initial 0.2 NIHU thrombin challenge. These control segments had minimal remaining antithrombin activity (0.010 and 0.014 NIHU, respectively) when rechallenge with 0.2 NIHU. Conversely, the HD-BSA-SMCC-S-rHir samples that contained various sulfo-SMCC ratios (1:5, 1:10, 1:20, 1:30, 1:40, and 1:50) had substantial antithrombin activity (0.134, 0.142, 0.170, 0.172, 0.176, and 0.186 NIHU) with the 1:50 HD-BSA-SMCC-S-rHir segments having the greatest antithrombin activity. Upon rechallenge these segments with 0.2 NIHU, thrombin inhibition occurred but decreased in all segments (0.106, 0.130, 0.150, 0.158, 0.166, and 0.172 NIHU). Overall, the 1:50 segments possessed the best antithrombin activity and were further evaluated.

#### D. Characterization of Antithrombin Activity of the 1:50 HD-BSA-SMCC-S-rHir Segments

CD + BSA + rHir-SH, HD-BSA + rHir-SH and the 1:50 HD-BSA-SMCC-S-rHir segments were prepared as outlined above and evaluated for  $^{125}\text{I}$ -thrombin inhibition versus thrombin concentration and incubation time.  $^{125}\text{I}$ -thrombin was prepared and graft segments were challenged against 0.66, 2.80, 6.12, 10.10, 22.40, and 43.50 NIHU of  $^{125}\text{I}$ -thrombin. Test segments were reacted with  $^{125}\text{I}$ -thrombin for 5, 15, 30, or 60 minutes using a 37°C water bath shaker and transferred to the spectrophotometer for a 5-minute equilibration period. An increased concentration of chromogenic substrate (1 mL of 100  $\mu\text{M}$  S-2238) was utilized to initiate the assay in order to compensate for increased  $^{125}\text{I}$ -thrombin concentrations.

The maximum  $^{125}\text{I}$ -thrombin inhibited by either of the control segments (CD + BSA + rHir-SH and HD-BSA + rHir-SH) was 1.4 NIHU in the 2.80 NIHU challenge (Table 1).  $^{125}\text{I}$ -thrombin inhibition in the lower concen-

trations increased with increasing incubation times.  $^{125}\text{I}$ -thrombin inhibition by the control segments reacted with 6.12, 10.10, 22.40, or 43.50 NIHU samples was below the detectable limits of the assay. In the higher  $^{125}\text{I}$ -thrombin concentrations (6.12–43.50 NIHU), increasing incubation time did not alter the results.

In contrast, the 1:50 HD-BSA-SMCC-S-rHir segments showed significant thrombin inhibition over the 0.66–22.40 NIHU  $^{125}\text{I}$ -thrombin concentrations assayed with the inhibition greatest at the highest incubation times (30 and 60 minutes). The maximum  $^{125}\text{I}$ -thrombin inhibited by these segments was 20.43 NIHU, 14.6-fold greater than control segments. In the 5- and 15-minute incubation times for 22.4 NIHU challenge as well as for all the incubation times at 43.50 NIHU, accurate assessment of  $^{125}\text{I}$ -thrombin inhibition could not be determined due to saturation of the chromogenic assay with uninhibited  $^{125}\text{I}$ -thrombin.

After assaying the CD + BSA + rHir-SH, HD-BSA + rHir-SH, or HD-BSA-SMCC-S-rHir segments for  $^{125}\text{I}$ -thrombin inhibition, segments were removed from the cuvette, dipped into PBS with 0.05% Tween 20 in order to remove any weakly adherent  $^{125}\text{I}$ -thrombin, and gamma counted. Samples then underwent a more vigorous washing for 10 minutes in PBS with 0.05% Tween 20 on an inversion mixer and again gamma counted. The amount of  $^{125}\text{I}$ -thrombin remaining after washing was  $^{125}\text{I}$ -thrombin specifically bound to the material and the difference in  $^{125}\text{I}$ -thrombin binding between pre- and postwash samples was  $^{125}\text{I}$ -thrombin released.

$^{125}\text{I}$ -thrombin binding to HD-BSA-SMCC-S-rHir segments was 5.4-, 5.2-, 4.8-, 6.5-, and 8.3-fold greater than the CD + BSA + rHir-SH and HD-BSA + rHir-SH control segments at their respective  $^{125}\text{I}$ -thrombin concentration.  $^{125}\text{I}$ -thrombin binding to control segments was independent of the  $^{125}\text{I}$ -thrombin concentration applied, whereas binding to the HD-BSA-SMCC-S-rHir segments directly related to the  $^{125}\text{I}$ -thrombin concentrations applied between 0.66 and 22.4 NIHU. The maximum amount of  $^{125}\text{I}$ -thrombin specifically bound to this surface was 20.43 NIHU. Increasing the  $^{125}\text{I}$ -thrombin concentration to 43.5 NIHU yielded no further increase in binding, exhibited by an overlap of the 22.4 and 43.5 NIHU curves, suggesting saturation of available rHir surface binding sites.

Nonspecific binding to and release from the control segments was significantly greater than the HD-BSA-SMCC-S-rHir segments. The percent  $^{125}\text{I}$ -thrombin released from the controls after washing ranged from 26 to 62% over the various  $^{125}\text{I}$ -thrombin concentrations assayed. In contrast,  $^{125}\text{I}$ -thrombin release from the 1:50 segments was significantly lower, ranging from 1 to 12% across the  $^{125}\text{I}$ -thrombin concentrations assayed, and was independent of incubation time. These data demonstrated the highly spe-

**Table 24.1**  $^{125}\text{I}$ -Thrombin Inhibition (NIHU) Versus Incubation Time (Minutes) and  $^{125}\text{I}$ -Thrombin Applied (NIHU) by CD + BSA + rHir-SH, HD-BSA + rHir-SH and HD-BSA-SMCC-S-rHir Segments

cific nature of  $^{125}\text{I}$ -thrombin binding to surface immobilized rHir in comparison to the control segments in which  $^{125}\text{I}$ -thrombin was easily removed.

### E. In Vitro Flow Study

The in vitro pulsatile flow model was employed to determine structural stability of surface bound  $^{125}\text{I}$ -rHir and  $^{131}\text{I}$ -BSA on Dacron grafts (110). Both radiolabeled proteins were covalently linked to Cooley® Woven Dacron vascular grafts (3 cm × 0.6 cm). The grafts were perfused at a mean flow rate of 400 mL/min. Grafts were gamma counted at various times over seven days in order to determine pressure head to provide steady flow from the perfusate reservoir, through the heating coil that is used to maintain perfusate flow at 37°C, to the graft segment. Perfusate, which was 400 mL of a 5% albumin/PBS solution containing 200 units/mL penicillin, 0.2 mg/mL streptomycin, and  $^{131}\text{I}$ -thrombin (0.5–0.8 NIHU/mL),  $^{125}\text{I}$ -rHir and  $^{131}\text{I}$ -BSA loss from the graft surface.

Using pulsatile flow to assess structural stability of surface bound  $^{125}\text{I}$ -rHir and  $^{131}\text{I}$ -BSA at high-flow and high-shear arterial flow conditions, without  $^{131}\text{I}$ -thrombin present, resulted in 49.1% of the  $^{125}\text{I}$ -rHir and 21.6% of the  $^{131}\text{I}$ -BSA being removed from the surface after 7 days, with a majority of the protein release occurring after day 3. With a mean initial  $^{125}\text{I}$ -rHir density of 51.8 ATU/cm<sup>2</sup>, 26.4 ATU/cm<sup>2</sup> still remained covalently attached to the surface. Subjecting the  $^{125}\text{I}$ -rHir and  $^{125}\text{I}$ -BSA surfaces to constant flow did not significantly alter the total amount of protein released (data not shown).

The pulsatile flow system was then converted to a constant flow system, with only slight modifications, in order to evaluate  $^{131}\text{I}$ -thrombin interaction with each of these surfaces. The constant flow perfusion system (flow rate = 400 mL/min) employs a gravity then flowed through a Cooley® Woven Dacron vascular graft (3 cm × 0.6 cm) with either covalently bound  $^{125}\text{I}$ -rHir or  $^{125}\text{I}$ -BSA. These grafts were in the same inert encasement chamber as described earlier. Recirculation of the perfusate in the system was main-

tained via peristaltic pump. A second fluid reservoir was employed to isolate the test graft from the significant pressure and flow oscillations generated by the peristaltic pump. Grafts were gamma counted at various time intervals for 27 hours in order to determine the stability of  $^{125}\text{I}$ -rHir and  $^{125}\text{I}$ -BSA on the surface and the interaction of  $^{131}\text{I}$ -thrombin with each surface. Concurrently, 2 mL of the perfusate was drawn and assayed for  $^{131}\text{I}$ -thrombin activity using the chromogenic substrate assay previously described.

The effects of  $^{131}\text{I}$ -thrombin circulating under constant flow on surface-bound  $^{125}\text{I}$ -rHir and  $^{125}\text{I}$ -BSA were then evaluated (Table 2). Dacron grafts with covalently linked  $^{125}\text{I}$ -rHir on the surface bound significantly greater amounts of  $^{131}\text{I}$ -thrombin from the perfusate (23.8 NIHU) versus  $^{125}\text{I}$ -BSA coated grafts (3.9 NIHU). The  $^{125}\text{I}$ -rHir coated grafts were also more effective at inhibiting  $^{131}\text{I}$ -thrombin during the perfusate period (125 NIHU) versus the  $^{125}\text{I}$ -BSA coated grafts (3 NIHU).  $^{125}\text{I}$ -BSA removal from the graft surface was relatively similar in both the presence and the absence of  $^{131}\text{I}$ -thrombin. Conversely,  $^{125}\text{I}$ -rHir removal from the surface within the 27 hour perfusion period (36.4%) when exposed to  $^{131}\text{I}$ -thrombin was slightly less than the total  $^{125}\text{I}$ -rHir loss over the 7 day perfusion (49.1%).

A potential mechanism for increased  $^{125}\text{I}$ -rHir removal in the presence of  $^{131}\text{I}$ -thrombin may be a greater propensity for  $^{125}\text{I}$ -rHir to dissociate following  $^{131}\text{I}$ -thrombin binding due to the conformational changes that  $^{125}\text{I}$ -rHir undergoes upon binding. These changes may, in turn, reduce the stability of the sulfur bond between the Traut's and the sulfo-SMCC cross-linkers, thereby enhancing the release of  $^{125}\text{I}$ -rHir. The reduced stability may also be a result of the increased fluid drag forces associated with thrombin binding, which increases the mass of bound protein from 6.9 kDa to 43.5 kDa (3.4 fold). Overall, the  $^{125}\text{I}$ -rHir coated

grafts significantly inhibited and bound greater amounts of  $^{131}\text{I}$ -thrombin from the perfusate. Even though  $^{125}\text{I}$ -rHir was lost from the graft, the surface still possessed significant antithrombin activity after removal from the flow system.

#### F. In Vivo Assessment of a Dacron-BSA-SMCC-S- $^{125}\text{I}$ -rHir Surface in a Thoracic Aorta Patch Model

In order to evaluate if a surface with covalently bound  $^{125}\text{I}$ -rHir warranted long-term in vivo evaluation, an in vivo model was developed that would subject surface bound  $^{125}\text{I}$ -rHir to increased thrombus and shear force challenges within a relatively short time period (111). The thoracic aorta patch model is a nonheparinized high-flow and high-shear stress model that poses such a severe challenge to the  $^{125}\text{I}$ -rHir surface.  $^{125}\text{I}$ -rHir (test) and BSA (control) were covalently bound onto the surfaces of 3 cm  $\times$  2 cm Dacron patches. Prior to implantation, Dacron-BSA-SMCC-S- $^{125}\text{I}$ -rHir patches were gamma counted to determine the initial amount of  $^{125}\text{I}$ -rHir on each patch. For each animal, an unimplanted control containing covalently bound  $^{125}\text{I}$ -rHir was prepared in order to compare the postexplantation antithrombin activity of the patch.

Canines were tranquilized, intubated, and placed on halothane. A left thoracotomy was performed in order to expose the thoracic aorta. The aorta was then loosely dissected and major side branches ligated. A Satinski partial occluding vascular clamp was used to occlude a 2 cm  $\times$  4 cm segment of the thoracic aorta. At this point, a 3 cm  $\times$  2 cm Dacron patch containing either covalently bound BSA or  $^{125}\text{I}$ -rHir was sutured to the artery using 3-0 Prolene. The clamp was then removed and the patch area packed until bleeding was controlled. The clamp was then placed distally and the remaining patch was implanted.

**Table 24.2**  $^{125}\text{I}$ -rHir or  $^{125}\text{I}$ -BSA Loss From the Graft Surface,  $^{131}\text{I}$ -Thrombin Binding to the Dacron Graft and  $^{131}\text{I}$ -Thrombin Inactivation in Perfusate Under Constant Flow Conditions

	$^{125}\text{I}$ -rHir grafts (n = 6)	$^{125}\text{I}$ -BSA grafts (n = 3)	p value
Graft weight (mg)	200.0 $\pm$ 6.3	188.8 $\pm$ 7.2	
Initial $^{125}\text{I}$ -rHir concentration (ATU/cm <sup>2</sup> )	38.2 $\pm$ 1.8	—	
Final $^{125}\text{I}$ -rHir concentration (ATU/cm <sup>2</sup> )	28.7 $\pm$ 4.7	—	
Initial $^{125}\text{I}$ -rHir concentration ( $\mu\text{g}/\text{cm}^2$ )	—	7.4 $\pm$ 0.9	
Final $^{125}\text{I}$ -rHir concentration ( $\mu\text{g}/\text{cm}^2$ )	—	7.2 $\pm$ 0.7	
$^{125}\text{I}$ -rHir or $^{125}\text{I}$ -BSA loss from surface (%)	36.4 $\pm$ 5.4	1.9 $\pm$ 2.4	p < 0.01
$^{131}\text{I}$ -thrombin bound to graft (NIHU/cm <sup>2</sup> )	3.08 $\pm$ 0.61	0.64 $\pm$ 0.04	p < 0.01
Total $^{131}\text{I}$ -thrombin bound to graft (NIHU)	23.8 $\pm$ 2.6	3.9 $\pm$ 0.3	p < 0.001
Total $^{131}\text{I}$ -thrombin inactivation in perfusate (NIHU)	125 $\pm$ 8	3 $\pm$ 14	p < 0.005

**Figure 24.6** Macroscopic evaluation of the  $^{125}\text{I}$ -rHir patches after explantation (A); the patches had virtually no gross thrombus formation on the luminal flow surface. Control BSA patches had a dense carpet of thrombus that lined the entire flow surface (C). Microscopic assessment of these patches confirmed these results. The  $^{125}\text{I}$ -rHir surface had primarily a thin layer of platelets sealing the pores of the patches with minimal fibrin formation (B). Control BSA surfaces had dense, well-formed thrombus composed of fibrin and platelets (D).

After the second patch was implanted, blood was permitted to flow across the patch surfaces for 2 hours. After two hours, the aorta proximal and distal to both patches was clamped and the patches were retrieved. The  $^{125}\text{I}$ -rHir patches were then gamma counted. Both patches were cut in half: one half was placed into formalin for routine histology and the other half was placed into saline. The saline patch was assayed for residual antithrombin activity via the chromogenic assay previously described. Both unimplanted and explanted patch halves were cut into 1 cm<sup>2</sup> segments and challenged with thrombin concentrations of 1, 5, 10, and 15 NIHU for 1 hour at 37°C.

Upon macroscopic evaluation of the  $^{125}\text{I}$ -rHir patches after explantation, the patches had virtually no gross thrombus formation on the luminal flow surface (Fig. 6A). Some thrombus was observed near the suture site. In contrast, the control BSA patches had dense carpets of thrombus that lined the entire flow surface (Fig. 6C). These results were confirmed by routine histology that showed the  $^{125}\text{I}$ -rHir surface had primarily a thin layer of platelets sealing the pores of the patches with minimal fibrin formation (Fig. 6B). The control BSA surfaces had dense, well-formed thrombus composed of fibrin and platelets (Fig. 6D). The magnification used to identify the presence of fibrin on the surface of the  $^{125}\text{I}$ -rHir patches was signifi-

cantly greater than the magnification used on the control BSA patches.

Covalently bound  $^{125}\text{I}$ -rHir was released ( $20\% \pm 6.7$ ,  $n = 3$ ) from the patch surface subjected to 2 hours of this nonheparinized high-flow and high-shear thoracic aorta model. The  $^{125}\text{I}$ -rHir loss is comparable to the results seen in the in vitro flow studies. Evaluation of the  $^{125}\text{I}$ -rHir patches after explantation for antithrombin activity using the in vitro chromogenic assay resulted in 7 NIHU of thrombin inhibited in the 10 NIHU challenge that was incubated for 1 hour. The 15 NIHU challenge did not have any “detectable” thrombin inhibition. In contrast, the unimplanted  $^{125}\text{I}$ -rHir patch segments had significant antithrombin activity throughout all thrombin concentrations assayed. Overall, the  $^{125}\text{I}$ -rHir patches had platelet accumulation with minimal fibrin formation, whereas the BSA-coated patches had significant thrombus formation.  $^{125}\text{I}$ -rHir was released from the patch, but significant antithrombin activity remained on the surface. Thus covalently bound  $^{125}\text{I}$ -rHir had a significant impact on the interaction between the nonheparinized blood and the Dacron surface.

## X. COVALENT BINDING OF VEGF TO DACRON: IN VITRO AND IN VIVO MITOGENIC PROPERTIES

### A. Creation of Soluble VEGF Conjugate for Biological Activity Studies

Canine serum albumin (CSA) was utilized in the soluble conjugate studies in order to determine if covalent linkage of VEGF to another biomolecule would alter VEGF biologic activity (112). CSA, which has no cell adhesion properties, was selected for these studies over collagen in order to examine *only* the effects of modified VEGF. Creation of a soluble CSA- $^{125}\text{I}$ -VEGF conjugate required the use of both sulfo-SMCC and Traut’s reagent. CSA was reacted with sulfo-SMCC in a 1:50 molar ratio, and  $^{125}\text{I}$ -VEGF was reacted with Traut’s reagent in a 1:60 molar ratio ( $^{125}\text{I}$ -VEGF-SH). Both reactions were incubated for 20 minutes at 37°C with occasional mixing and purified via gel filtration. The two intermediate compounds were then mixed, incubated overnight at 4°C on an inversion mixer, and concentrated to 100  $\mu\text{L}$  using a Filtron 10K concentrator. The CSA-SMCC-S- $^{125}\text{I}$ -VEGF conjugate was then purified from the intermediate CSA-SMCC and  $^{125}\text{I}$ -VEGF-SH compounds utilizing a Superdex 75 HR10/30 gel filtration column. Fractions were collected and gamma counted in order to determine which peak fractions contained  $^{125}\text{I}$ -VEGF.

The CSA-SMCC-S- $^{125}\text{I}$ -VEGF conjugate eluted from the column as a broad peak at 15.8 minutes, with a

**Figure 24.7** Profile of CSA-SMCC-S- $^{125}$ I-VEGF conjugate purification using a Superdex 75 HR 10/30 gel filtration column. The CSA-SMCC-S- $^{125}$ I-VEGF conjugate eluted from the column as a broad peak at 15.8 minutes, with a shoulder off the front portion of the peak. A shift in the  $^{125}$ I-VEGF peak confirmed formation of the complex.

shoulder off the front portion of the peak (Fig. 7). The broadness of the peak suggests that multiple ratios of  $^{125}$ I-VEGF to CSA (i.e., 1:1, 2:1) were created. The CSA-SMCC (67 kDa) peak, which eluted at 18 minutes, was comparable to the CSA standard (data not shown), which eluted at 18.2 minutes. The unbound  $^{125}$ I-VEGF-SH peak (38 kDa), due to concentration, showed as a minor peak at 22.2 minutes. This retention time was in specific relation to the ovalbumin standard (43 kDa, data not shown), which eluted earlier at 20.4 minutes due to a 5 kDa difference in weight. Gamma counting the elution fractions confirmed that  $^{125}$ I-VEGF linkage to CSA did occur, as shown by the shift in the  $^{125}$ I-VEGF-SH peak from 38 kDa (fractions 22 to 24) to greater than 100 kDa (fractions 16 to 18). The total counts from this peak represented 54% of the applied  $^{125}$ I-VEGF. The free  $^{125}$ I-VEGF peak also correlated with the 22.2-minute absorbance peak. Thus VEGF could be covalently bound to another biomolecule using the described cross-linking techniques.

#### B. Comparison of Mitogenic Activity Between VEGF, VEGF-SH, and CSA-VEGF

The mitogenic activity of complex bound VEGF was then assessed. Bovine aortic endothelial cells (BAEC, passages = 1) were plated and grown to confluence in 10 cm dishes overnight in DMEM containing 10% calf serum. The media was changed to DMEM plus 2% calf serum for 24 hours prior to stimulation. The BAECs were stimulated for 5 minutes with 25 ng/mL of VEGF, VEGF-SH, or VEGF-CSA. Another well of BAECs was stimulated with 250 ng/mL VEGF. BAECs cultured without VEGF served as the negative control. The BAECs were then lysed in Laemmli buffer and boiled for 5 minutes. The lysates were centrifuged in an Eppendorf centrifuge at 14,000 rpm for 10 minutes. Aliquots of each cell extract, which had equivalent protein concentrations, were then loaded onto a 10% SDS polyacrylamide gel and separated. The separated proteins on the gel were then transferred to a nitrocellulose filter paper. Nonspecific binding of the antiphosphotyrosine anti-

**Figure 24.8** Determination of mitogenic activity using a MAP-kinase assay. BAECs exposed to PBS had minimal phosphorylation. In contrast, VEGF covalently linked to BSA (fractions 16–18.5) bound to and activated the transmembrane VEGF receptor as shown by intracellular phosphorylation by Erk 1 and 2 (MAP-kinases). VEGF, which was modified with Traut's reagent (fractions 22–23.5), also stimulated phosphorylation.

body was blocked via filter preincubation for 1 hour at room temperature using a blocking buffer that contained casein and Tween-20. The nitrocellulose blot was then incubated with the antiphosphotyrosine antibody (1  $\mu\text{g}/\text{mL}$ ), which was diluted using the blocking buffer, for 1 hour at room temperature. The bound antibodies were detected using an ECL kit in conjunction with a phosphoimager.

BAECs exposed to PBS had minimal phosphorylation (Fig. 8). In contrast, VEGF covalently linked to BSA (fractions 16–18.5) bound to and activated the transmembrane VEGF receptor as shown by intracellular phosphorylation by Erk 1 and 2 (MAP-kinases), a mechanism that is indicative of intracellular signaling activation. VEGF, which was modified with Traut's reagent (fractions 22–23.5), also stimulated phosphorylation comparable to the covalently bound VEGF. Native VEGF, the positive control, stimulated phosphorylation to a greater degree than both VEGF-SH and VEGF-CSA, possibly due to either lower concentrations of VEGF-SH/VEGF-CSA than calculated or a reduction in the mitogenic properties due to a modification of the VEGF.

### C. Comparison of Migration Properties of Native Versus Complex Bound VEGF

The chemotactic properties of complex bound VEGF were then examined using a Boyden Chemotaxis Chamber (113). This 48-independent well chamber consists of two sections. The lower section is employed to incorporate the stimulant or inhibitor agent of choice. The cell type to be

investigated is added to the upper section. A porous membrane is enclosed between these sections. Cells that migrate from the upper section onto the opposite side of the membrane were then counted. Advantages of this system are that sterility is not an issue since these are short-term studies and the chamber can be repeatedly used. Additionally, this type of apparatus permits simultaneous analysis of multiple agents at various concentrations.

For our study, BAECs were grown in DMEM with 10% FBS and then starved for 24 hours in DMEM containing 2% FBS. The BAECs were then trypsinized and diluted to a concentration of 100,000 cells/mL, and 50  $\mu\text{l}$  was added to each well in the upper section. Complex bound and native VEGF concentrations ranging from 50 to 200 ng/mL were added to bottom section. Wells containing DMEM with 2% FBS were used as a negative control. The BAECs were incubated 4 hours at 37°C (5%  $\text{CO}_2$ ). The apparatus was then disassembled, washed, fixed in ethanol, and stained with hematoxylin. BAECs bound to the porous membrane were then counted at 40 $\times$ .

BAECs exposed to DMEM with 2% FBS had an average 17 adherent cells/high-power field, demonstrating the migration properties of FBS (Fig. 9). Native VEGF had an average 23.9, 35.3, and 49.1 cells/high-power field for increasing concentrations of the growth factor. Complex bound VEGF had 25.9, 39.1, and 69 cells/high-power field over similar concentrations, results comparable to native VEGF. These results demonstrate that VEGF maintains biological activity when covalently bound to another biomolecule.

**Figure 24.9** Endothelial cells/high power field for  $^{125}\text{I}$ -VEGF and complex bound  $^{125}\text{I}$ -VEGF using the Boyden chemotaxis chamber. BAECs exposed to DMEM with 2% FBS had an average 17 adherent cells/high power field. Native VEGF had an average 23.9, 35.3, and 49.1 cells/high power field for increasing concentrations of the growth factor, comparable to complex bound VEGF (25.9, 39.1, and 69 cells/high power field).

#### D. Covalent Linkage of $^{125}\text{I}$ -Collagen/ $^{125}\text{I}$ -Collagen-SMCC to HD Segments

To evaluate if Type IV collagen bound in a similar fashion to albumin, a group of collagen binding experiments was performed. CD and HD segments ( $1\text{ cm}^2$ ) were cut and weighed. A stock  $^{125}\text{I}$ -collagen solution was prepared and divided in half. One half of the  $^{125}\text{I}$ -collagen solution was reacted with sulfo-SMCC in a 1:5 molar ratio. The other  $^{125}\text{I}$ -collagen solution had an equal volume of PBS added in order to maintain consistency between the two  $^{125}\text{I}$ -collagen solutions. Both  $^{125}\text{I}$ -collagen solutions were then placed into a  $37^\circ\text{C}$  water bath, incubated for 20 minutes with occasional mixing, and purified by gel filtration. Both the  $^{125}\text{I}$ -collagen/ $^{125}\text{I}$ -collagen-SMCC solutions, taking into account an approximate 50% loss in protein due to adhesiveness of the protein, were then brought up to a final concentration of  $6.4\ \mu\text{M}$ . Simultaneously, CD and HD controls were placed into 3 mL of 100% EtOH. The other set of HD segments was placed into 3 mL of a 10 mg/mL EDC solution in 100% EtOH. All segments were reacted for 30 minutes at room temperature on an inversion mixer. The CD and HD control segments as well as the HD test segment were then removed from their respective solutions after 30 minutes, shaken to remove excess solvent/cross-linker, and placed into 2.4 mL of a  $6.4\ \mu\text{M}$   $^{125}\text{I}$ -collagen. Another set of control and test segments was treated in a similar fashion, but these segments were placed into 2.4

mL of a  $6.4\ \mu\text{M}$   $^{125}\text{I}$ -collagen-SMCC. These segments were incubated for 2 hours at room temperature on an inversion mixer. The CD and HD segments were removed and washed/sonicated in PBS with 0.05% Tween 20 for 5 minutes. This procedure was repeated three times, changing the wash buffer between sonications, thereby removing any weakly adherent  $^{125}\text{I}$ -collagen on the surface of each segment. Segments with nonspecifically bound (CD +  $^{125}\text{I}$ -collagen, HD +  $^{125}\text{I}$ -collagen, CD +  $^{125}\text{I}$ -collagen-SMCC, HD +  $^{125}\text{I}$ -collagen-SMCC) and covalently bound (HD- $^{125}\text{I}$ -collagen and HD- $^{125}\text{I}$ -collagen-SMCC)  $^{125}\text{I}$ -collagen/ $^{125}\text{I}$ -collagen-SMCC were then gamma counted. Utilizing the specific activity, the amount of  $^{125}\text{I}$ -collagen bound (ng) per mg Dacron was determined.

Nonspecific binding of  $^{125}\text{I}$ -collagen to the CD segments (90 ng/mg) was significantly lower than the amount nonspecifically bound to the HD (429 ng/mg), thus creating a negative charge on the Dacron surface alone increased the binding by the positively charged  $^{125}\text{I}$ -collagen (Fig. 10). Nonspecific  $^{125}\text{I}$ -collagen-SMCC binding to CD (153 ng/mg) was 74% greater than with  $^{125}\text{I}$ -collagen. In contrast, nonspecific  $^{125}\text{I}$ -collagen-SMCC binding was 41% lower than with  $^{125}\text{I}$ -collagen alone (304 ng/mg), suggesting that removal of the positive charge groups by sulfo-SMCC linkage reduced the net charge of the protein, thereby decreasing  $^{125}\text{I}$ -collagen affinity for the HD surface. HD with EDC had significantly greater  $^{125}\text{I}$ -collagen linkage (531 ng/mg) and  $^{125}\text{I}$ -collagen-SMCC (571 ng/mg)

**Figure 24.10**  $^{125}\text{I}$ -collagen/ $^{125}\text{I}$ -collagen-SMCC binding (ng/mg Dacron) versus CD, HD, and HD reacted with EDC. Covalent binding of  $^{125}\text{I}$ -collagen to the HD surface was greatest utilizing the EDC cross-linker, and linkage of the heterobifunctional cross-linker sulfo-SMCC did not alter  $^{125}\text{I}$ -collagen immobilization to the HD surface.

than the HD controls and CD controls. No statistical difference was observed between the HD incubated with EDC in the presence of  $^{125}\text{I}$ -collagen or  $^{125}\text{I}$ -collagen-SMCC ( $p = 0.48$ ). Therefore covalent binding of  $^{125}\text{I}$ -collagen to the HD surface was greatest utilizing the EDC cross-linker, and linkage of the heterobifunctional cross-linker sulfo-SMCC did not alter  $^{125}\text{I}$ -collagen immobilization to the HD surface.

### E. Covalent Linkage of $^{125}\text{I}$ -VEGF to HD Segments

CD and HD segments were cut and weighed. CD and one group of HD segments were incubated with EDC followed by incubation with  $6.4\ \mu\text{M}$  collagen. The other set of HD segments was incubated with EDC followed by incubation in  $6.4\ \mu\text{M}$  collagen-SMCC. Removal of nonspecifically bound collagen/collagen-SMCC was performed via wash and sonication.  $^{125}\text{I}$ -VEGF ( $4.5\ \mu\text{M}$ ) was then reacted with 2-iminothiolane hydrochloride (Traut's) reagent in a 1:60 (mole:mole) ratio for 20 minutes at  $37^\circ\text{C}$  in order to create sulfhydryl groups on  $^{125}\text{I}$ -VEGF ( $^{125}\text{I}$ -VEGF-SH), purified by gel filtration and brought to a final concentration of  $0.52\ \mu\text{M}$ . This  $^{125}\text{I}$ -VEGF-SH complex was then reacted with the Dacron segments overnight at  $4^\circ\text{C}$  followed by the wash/sonication procedure. Nonspecifically bound (CD + EDC + collagen +  $^{125}\text{I}$ -VEGF-SH and HD-collagen +  $^{125}\text{I}$ -VEGF-SH) and covalently linked (HD-collagen-SMCC-S- $^{125}\text{I}$ -VEGF)  $^{125}\text{I}$ -VEGF segments were then gamma counted. The amount of  $^{125}\text{I}$ -VEGF bound (ng) per mg Dacron was determined.

$^{125}\text{I}$ -VEGF binding to the CD ( $2.9\ \text{ng/mg}$ ) and HD ( $7.0\ \text{ng/mg}$ ) controls was 5.6- and 2.3-fold less than the HD test segments ( $16.4\ \text{ng/mg}$ ) (Fig. 11). The HD control segments had 2.4-fold greater  $^{125}\text{I}$ -VEGF nonspecifically bound to the surface as compared to the CD segments, which could be the result of charge binding between the nonspecifically bound collagen and  $^{125}\text{I}$ -VEGF.

### F. Assessment of In Vivo Mitogenic Properties of Surface-Bound VEGF

A rat dorsal subcutaneous implant model was employed in order to evaluate the in vivo mitogenic properties of covalently immobilized VEGF (Fig. 12) (114). Segments ( $1\ \text{cm}^2$ ) of HD with covalently bound  $^{125}\text{I}$ -collagen ( $109 \pm 26\ \text{ng/mg}$  Dacron) and HD with covalently bound  $^{125}\text{I}$ -VEGF ( $76 \pm 18\ \text{ng/mg}$  Dacron) were prepared as previously outlined. CD segments were also utilized. Rats were anesthetized by intraperitoneal injection of pentobarbital, dorsum shaved, and prepared with betadine. A longitudinal incision was made for the subcutaneous insertion of the

**Figure 24.11**  $^{125}\text{I}$ -VEGF binding (ng/mg Dacron) for CD, HD, and HD reacted with EDC. Linkage to the CD ( $2.9\ \text{ng/mg}$ ) and HD ( $7.0\ \text{ng/mg}$ ) control segments was 5.6- and 2.3-fold less than the HD test segments ( $16.4\ \text{ng/mg}$ ).

**Figure 24.12** An illustration of the rat dorsal subcutaneous implantation model. This model permitted simultaneous evaluation of 8 segments, with each animal serving as its own control.

various Dacron segments. These segments were placed in random fashion by a single surgeon. Care was used to avoid subcutaneous hemorrhage, and skin was closed with staples. Rats were sacrificed at either 15 or 30 days after implantation via anesthetic overdose. Segments were explanted, gamma counted to determine the remaining amount of surface-bound protein, and fixed in buffered formalin for 24 hours prior to histological processing.

Formalin-fixed segments were processed for conventional histology, with sample sections performed every 0.5 mm in a serial manner. A total of six tissue sections were cut and analyzed for each Dacron segment, with 6 mm<sup>2</sup> of each Dacron segment represented. Sections were stained with hematoxylin phloxin saffron. Angiogenesis was quantified by counting the number of capillaries present in each segment under 40 $\times$  magnification. The average number of capillaries per unit area (mm<sup>2</sup>) was then determined.

Both time intervals showed a significant loss of protein from the Dacron surface. At 15 days, HD patches with <sup>125</sup>I-VEGF lost 91% of the protein from the surface. Similarly, loss from the HD patches with <sup>125</sup>I-collagen was significant at 88%. At 30 days, 99.7% of <sup>125</sup>I-VEGF and 97% of <sup>125</sup>I-collagen was released. Protein loss may have been caused by immune response to the immobilized human proteins (collagen and VEGF) as well as to the Dacron material. This hypothesis was further validated by morphological assessment of these segments, which showed granulation tissue and a mild inflammatory response that was evident in all segment types by 30 days. Gross microscopic observation of these segments revealed the greatest capillary formation in the HD-collagen-VEGF segments (Fig. 13).

**Figure 24.13** Histological examination of CD, HD-<sup>125</sup>I-collagen, and HD-collagen-SMCC-<sup>125</sup>I-VEGF segments after explant at 30 days. Segments with covalently bound <sup>125</sup>I-VEGF possessed the greatest amount of capillaries per area as compared to CD and HD-<sup>125</sup>I-collagen segments. All segments showed granulation tissue and a mild inflammatory response.

**Figure 24.14** Quantification of the number of capillaries/mm<sup>2</sup> for CD, HD-<sup>125</sup>I-collagen, and HD-collagen-SMCC-<sup>125</sup>I-VEGF segments. There was significant capillary ingrowth for HD with covalently bound VEGF at both 15 and 30 days (29/31 capillaries/mm<sup>2</sup>) as compared to HD-collagen (23/24 capillaries/mm<sup>2</sup>) and CD (20/21 capillaries/mm<sup>2</sup>).

Quantification of new microvessel formation confirmed the gross observations. There was significant capillary ingrowth for HD with covalently bound VEGF at both 15 and 30 days (29/31 capillaries/mm<sup>2</sup>) as compared to HD-collagen (23/24 capillaries/mm<sup>2</sup>) and CD (20/21 capillaries/mm<sup>2</sup>) (Fig. 14). The number of capillaries increased slightly for all groups at 30 days, with the segments with covalently bound VEGF possessing the greatest amount of capillaries. Therefore covalent linkage of VEGF to a Dacron surface can stimulate capillary formation from the surrounding tissue.

## XI. CONCLUSIONS FROM RESEARCH

Overall, this study demonstrates that a clinically accepted biomaterial (Dacron) can be modified using established textile techniques without altering the physical and chemical properties of the original biomaterial. This modification results in the creation of functional groups that can serve as “anchor” sites for covalent attachment of a specific basecoat protein, in an attempt to mask the adverse biomaterial properties. Using this basecoat layer in conjunction with heterobifunctional cross-linking agents, numerous target sites for a biologically active protein(s) can be created under controlled stoichiometric conditions. Anti-thrombin (rHir) and mitogenic (VEGF) agents have been independently attached to Dacron segments and have maintained biological activity in both in vitro and in vivo studies. Extensive in vivo studies still need to be performed

in a prosthetic grafting model in order to determine the ultimate utility of this technology. Protein loss from these surfaces in our preliminary in vivo trials suggests altering the cross-linking methodology or increasing species specificity of the immobilized proteins for the animal model in order to reduce the immune response to the surface. Additionally, a surface with both biological moieties immobilized onto the Dacron surface will also be investigated.

## XII. POTENTIAL FUTURE OF BIOMATERIAL RESEARCH

Thus far, most of research has focused on either altering an individual aspect of graft interaction within the vascular tree (i.e., thrombus formation, platelet activation, and cellular proliferation) or synthesizing a novel material in an attempt to promote host incorporation of the conduit. These studies have yet to yield a clinically suitable biocompatible prosthetic vascular graft. One possible reason that this problem has not been solved could be related to addressing this complex phenomenon with a single approach or so-called "magic bullet" theory. Also, research by a majority of these groups has been limited to their respective fields of expertise, so no collaborative exchange occurs in an area that requires a multidisciplinary approach. Our ultimate goal, using these foundation studies as well as a collaborative effort between academia and industry, is to design a prosthetic vascular graft that will possess multiple structural and biological properties that mimic those processes inherent to the native vessel.

## ACKNOWLEDGMENTS

This work was funded, in part, by grants from the National Institutes of Health (R01 21796) and the Whitaker Foundation. The authors would like to express their gratitude to Boston Scientific and Farmitalia for the generous donations of Dacron vascular grafts and rHir, respectively. Additionally, the authors would especially like to acknowledge Dr. Mauricio Contreras, Dr. Scott Berceci, Dr. Stephen Kubaska III, Dr. Eva Rzucidlo, Dr. David Stone, and Dr. Lloyd Aiello for their considerable time and effort dedicated to this extensive research project.

## Antithrombin–Heparin Complexes

Leslie R. Berry, Maureen Andrew, and Anthony K. C. Chan

*Hamilton Civic Hospitals Research Centre, Hamilton, Ontario, Canada*

### I. INTRODUCTION

Antithrombin is a serine protease inhibitor (serpin) that inhibits a number of plasma proteases. In particular, antithrombin functions as one of the major natural anticoagulants by irreversibly inhibiting a number of the enzymes formed during activation of the coagulation cascade in vivo (1). Antithrombin can form serpin–protease inhibitor complexes with activated factor (F) XII (FXIIa), FXIa, FIXa, FXa, and thrombin (1–3). Within this group of coagulant proteases, antithrombin has the fastest rate of reaction with thrombin, its preferred reactant (4).

Systemic generation of thrombin in vivo is dependent on a number of factors. These include plasma concentrations of pro- and anticoagulants, the presence of cell surface–associated stimulators (such as phospholipid, tissue factor) and inhibitors (thrombomodulin, tissue factor pathway inhibitor), and interactions with molecules in subendothelial and extravascular spaces (5). Ultimately, activation or inhibition of proenzymes or activated factors within the coagulation cascade affects the generation of thrombin from prothrombin, which, in turn, affects the conversion of fibrinogen to fibrin monomer that polymerizes to form a fibrin clot (see Fig. 1). Thrombin is the pivotal enzyme in the coagulation pathway (6). Once the initial amounts of thrombin are generated, thrombin causes feedback activation of its own formation by proteolytic cleavage of FV, FVIII, and FXI (Fig. 1) to produce FVa, FVIIIa, and FXIa,

respectively. Furthermore, thrombin reacts with FXIII, leading to the covalent cross-linking of fibrin monomers by FXIIIa. The resultant cross-linked fibrin polymer has more structural stability and integrity within the site of injury (7). Additionally, thrombin has other procoagulant functions within the vasculature. Thrombin activates platelets, thus facilitating their cell–cell or cell–clot interactions (8), and causes inhibition of fibrinolysis by reaction with thrombin activatable fibrinolysis inhibitor (9–13). Alternatively, when thrombin is bound to endothelial cell associated thrombomodulin, it can activate protein C, the active form of which (in association with protein S) inactivates FVIIIa and FVa, thus limiting thrombin production (14). Summarily, inhibition of thrombin is a critical step in the regulation of coagulant activities in vivo.

The reaction of thrombin with antithrombin can be significantly accelerated by the action of heparin and heparan sulfate glycosaminoglycans (GAGs). In fact, the rate of inhibition of thrombin by antithrombin is increased 1,000-fold in the presence of native unfractionated heparin (UFH) (15). The increase in inhibition rate is due to two reasons. First, UFH molecules bind to antithrombin via a specific GAG sequence (16). The binding of UFH causes an allosteric change in antithrombin that results in a conformation that is more reactive with thrombin. Second, UFH can also bind to thrombin, which allows for a combination of the serpin and protease in a tertiary complex. In effect, UFH can bridge both antithrombin and thrombin. Once an irre-

Figure 25.1 Plasma coagulation cascade for thrombin generation and inhibition.

versible covalent complex between thrombin and antithrombin (TAT) has been formed, the affinity of the antithrombin moiety for UFH decreases, which allows the GAG to dissociate and repeat the cycle of tertiary complex formation (17). By increasing the velocity of thrombin's reaction with antithrombin, UFH facilitates the inhibition of thrombin formed shortly after activation of coagulation. Thus the addition of UFH-like GAGs to plasma would sig-

nificantly reduce the concentration of free, active thrombin, which in turn would decrease the generation of thrombin due to feedback activation of the cascade.

Unfortunately, UFH has a number of limitations that are related to its pharmacokinetic and biophysical properties. The pharmacokinetic limitation of UFH is that it has a short, dose-dependent, intravenous half-life (18). UFH's rapid clearance from the circulation is due, in part, to non-

specific protein binding (19). As a consequence, basic plasma and cell surface-associated proteins compete with antithrombin for noncovalent binding to UFH. The concentrations and distribution of the UFH-binding proteins vary widely between individuals, which results in UFH having an unpredictable anticoagulant effect in vivo (20). In addition, UFH can readily pass through tissue layers and is lost from the circulation due to its small size, which prevents its sequestration within various vascular spaces (21). One of the biophysical limitations of UFH relates to its inability to inhibit a number of coagulation factors bound to surfaces. The antithrombin–UFH complex is ineffective at inactivating thrombin bound to fibrin (22,23) and factor Xa bound to phospholipid (24,25). Clot propagation is due, in part, to the activity of this clot-bound thrombin (23–25). Clinical evidence supports the importance of clot-bound thrombin and the consequences of the inability to inactivate this focus for coagulation. The early recurrence of unstable coronary artery syndromes after discontinuation of heparin is likely due to this mechanism (26). Finally, the use of high in vivo concentrations of heparin results in bleeding complications. Previously, it has been shown that UFH anti-factor Xa activity is directly proportional to bleeding time (27). Attempts to anticoagulate vascular devices by coating surfaces with heparin derivatives have also lead to problems. Leaching of weakly attached heparin, resulting in undesired systemic anticoagulation and reduced activity of the modified heparin bound to the surface, is one example of the difficulties involved with heparin coating of biomaterials. Furthermore, only  $\sim 1/3$  of starting commercial UFH preparations have anticoagulant activity because  $2/3$  of the molecules do not have high-affinity binding sites for antithrombin (28). Therefore biomaterials coated with heparin from mixtures derived from UFH would have the majority of their surface area covered by heparin with no antithrombin activity.

In order to address some of the problems associated with the clinical use of heparin, covalent complexes of antithrombin and heparin derivatives have been prepared. The rationale for construction of covalent antithrombin–heparin (ATH) is multifold. First, if heparin was irreversibly bonded to antithrombin, the serpin molecule should be fixed permanently in the active conformation. Thus the rate of thrombin inhibition will be increased compared to noncovalent antithrombin–heparin mixtures. Second, since the heparin component of ATH cannot dissociate from antithrombin, the intravascular pharmacokinetics would be expected to move towards that of antithrombin. Thus the half-life of the anticoagulant ATH should be significantly longer than heparin. Another aspect related to the transport and metabolism of ATH is that of endogenous protein binding in vivo. Because the antithrombin in ATH

will interact noncovalently with a significant portion of the heparin moiety (particularly in the case of ATH molecules which contain relatively short heparin chains), binding of plasma or cell surface proteins (or other molecules) with the heparin in ATH should be reduced compared to free heparin. A decreased heparin binding by intra- and extravascular proteins might lead to a more consistent clearance pattern and, consequently, a more predictable anticoagulant response. Furthermore, if ATH binding to cell surface receptors is decreased compared to uncomplexed heparin, risk of hemorrhagic side effects may be reduced. Third, both the technology and the resultant polymeric surfaces coated with ATH may be significantly improved compared to that for biomaterials coated with heparin. Attachment of heparin onto a variety of polymers would be facilitated by linking antithrombin to the GAG. Immobilization of ATH could be more readily optimized due to the increased range of functional groups and chemistries found in the amino acid R groups of the antithrombin. Also, surface linkage of ATH through the antithrombin moiety may allow for a high number of attached molecules in which the heparin chain is oriented outwards from the surface into the fluid phase. Again, since all antithrombin species in ATH should be permanently activated, ATH bound to surfaces of biomedical devices may all be active, whereas only a maximum of  $1/3$  of GAGs on UFH coated surfaces would possess anticoagulant activity. Given the potential number of desirable properties of ATH products compared to other UFH derivatives, methods for covalent complexation of antithrombin and heparin and analysis of the covalent conjugates have been investigated.

In this chapter, the development of permanently linked antithrombin–heparin complexes will be assessed. The format for this review will be as follows. Previous work on the structure–function relationships and clinical use of antithrombin will be discussed. Heparin's structure, activities, in vivo occurrence, and biochemistry will be covered in light of the long history of medical application. Analysis of the research on antithrombin and heparin will be followed by a broad introduction to the production of covalent ATH complexes. The overview of ATH complexes will include assessments of clinical advantages for conjugation of antithrombin and heparin, novel applications of ATH products, and an introduction to the range of ATH conjugates that are available. A detailed analysis follows for the various types of ATH that have been reported. Each ATH complex will be reviewed according to its synthetic chemistry, physicochemical properties, effect of conjugation on anticoagulant activities, performance in animal models, and particular clinical advantages (including possible use for anticoagulating materials that come into contact with blood). Discussion of the various ATH com-

pounds that have been produced will appear in the chronological order in which they have been reported. Finally, possible future directions for research on covalent serpin-GAG complexes will be presented.

## II. ANTITHROMBIN

### A. Antithrombin Chemical Structure

Antithrombin is a glycoprotein whose polypeptide moiety shares structural and functional homology with members of a large family of serpins (29–31). The degree of homology across the various proteins in this family is ~30%, indicating that the appearance of this molecular species may have been as early as 500 million years ago. In addition to primary sequence similarities, the serpins have a number of their tertiary structural features in common (32).

Antithrombin is produced within hepatocytes of the liver in mammals. The gene for antithrombin has been reported to reside entirely within the long arm of chromosome 1 (33). In addition, it has been shown that within this region, the human antithrombin gene extends over an unbroken stretch of ~19 kb including 7 exons and 6 introns (34,35). The open reading frame for human antithrombin contains 1396 nucleotides. At the 5' end of the reading frame there is a section of 96 nucleotides that code for a 32 amino acid segment called the signal peptide (35). This N-terminal peptide is removed prior to release from the cell. Within mammalian species 10% to 15% variation in primary sequence has been reported, but high conservation has been observed in the critical reactive site regions (36).

The antithrombin molecule is a single chain plasma glycoprotein with an approximate molecular mass of 60,000 daltons (37–39). The polypeptide chain in human antithrombin is composed of 432 amino acid residues (40). Upon folding into its native configuration, three disulfide bonds are formed between three pairs of cysteine residues in the polypeptide chain (40). Two of the disulfide bonds join a relatively unstructured stretch of 45 amino acid residues at the N-terminus to the third and fourth  $\alpha$ -helices of the molecule. Overall, the protein has a neutral to basic pI due to a preponderance of arginyl and lysyl residues, as opposed to the acidic residues. These positively charged amino acids contribute to the UFH binding regions on the serpin molecule (32,41). Analysis of the tertiary structure, as determined by peptide modeling of the primary amino acid sequence, has shown that human antithrombin has 31%  $\alpha$ -helix, 16%  $\beta$ -sheet, 9%  $\beta$ -turn and 44% random coil (42,43). Antithrombin has been crystallized recently, and the x-ray crystal structure determined to 3 Å resolution (44). Conformational studies of the topographic structure of antithrombin using x-ray diffraction show that the serpin can exist in two forms, one active and the other inactive (45). Analyses were made of dimers containing one active and one inactive molecule. Results showed that the active antithrombin consists of nine  $\alpha$ -helices and three  $\beta$ -sheets. A composite model for the three-dimensional structure of antithrombin, devised from various x-ray diffraction and chemical analyses that have been reported, is shown in Fig.2.

N-linked glycosylation occurs at specific asparagine residues that are flanked by sequences in  $\beta$ -sheet regions that are recognized by a glycosyl transferase during post-

Figure 25.2 Antithrombin tertiary structure.

translational modification *in vivo*. The number of glycan chains that are present on the native antithrombin polypeptide varies from three (46) to four (47), although up to five glycan chains have been reported (48). In addition, conditions such as carbohydrate-deficient glycoprotein syndrome have been shown to result in reduced levels of functional antithrombin due to decreased posttranslational glycosylation of the protein (49). Isoforms of plasma antithrombin, occurring as the three and four glycan chain containing molecules, have been designated as  $\alpha$ - and  $\beta$ -antithrombin, respectively. The fully glycosylated  $\alpha$ -antithrombin has glycan chains linked through N-amido glycosidic bonds to the R groups of asparagine residue numbers 96, 135, 155, and 192 (50). In the case of  $\beta$ -antithrombin, the glycan at position 135 is missing.

Post translational modification of antithrombin occurs in the Golgi apparatus by transfer of tetra-antennary, branched high mannose glycan structures from dolichol-phosphate onto the amino acid R group. These high mannose glycans are further processed by endoglycosidases to a core chitobiose-trimannose stub, which is the substrate for addition of further monosaccharide residues to produce the final “complex type” glycan structures. In addition to the major heterogeneity of glycan number described above, variations in structure within the glycans themselves (termed microheterogeneity) are observed. Complex N-linked glycans have been shown to occur in a number of forms that vary according to the number of branches extending out from the core region of the chain. Antithrombin molecules have been shown to exist as a group of populations in which the branching within glycans at the different glycosylation sites within the same polypeptide chain can range from mono- to bi-, tri-, and tetra-antennary forms (51,52). The glycans of antithrombin have been shown to vary in the level of N-acetylneuraminic acid residues present at the termini of the glycan chains (53). Additional groups may be added to the glycan structures in a heterogeneous fashion. For example, although fucosyl residues are present on the glycans at positions 96 and 192, a portion of glycans at position 155 was not fucosylated (51). Variations due to heterogeneity in antithrombin’s carbohydrate moieties have also been identified as having significant effects on its functional activities, as will be outlined below.

### B. Antithrombin Functional Biochemistry

The structural components that give rise to antithrombin’s functional activities have been delineated. Early studies showed that a circulating anticoagulant existed because thrombin, when added to plasma, lost its activity over time

(38,54). This plasma activity of the antithrombin molecule was given the name “progressive antithrombin activity.” With the subsequent isolation and clinical use of heparin, it was observed that heparin could inhibit thrombin rapidly when in the presence of an unidentified protein in plasma. The plasma protein responsible for this rapid thrombin inhibitory activity was designated “heparin cofactor” (55). Classification of the biological antithrombin activities was proposed in the 1950s by Seegers (56). Removal of plasma thrombin activity by binding to a fibrin clot was given the notation antithrombin I, while heparin cofactor and progressive antithrombin activities were called antithrombin II and antithrombin III, respectively. Isolation and further characterization of the native plasma thrombin inhibitor in the 1960s and 1970s showed that the protein responsible for the progressive antithrombin activity and that responsible for the heparin cofactor activity were identical (38). Afterwards, the term antithrombin III was used for the progressive antithrombin with heparin cofactor activity, which later became shortened to antithrombin.

Antithrombin, as well as a most of the other serpins, inhibits serine proteases (such as thrombin) by a stress-release mechanism. Within the antithrombin molecule, a reactive center loop exists that is towards the C-terminus of the polypeptide chain. Thrombin interacts noncovalently with antithrombin through the recognition of certain amino acids close to the reactive center. The thrombin-binding region has been mapped out by the natural occurrence of amino acid substitution mutations in the protein, which give rise to expression of molecules with reduced antithrombin activity. The mutations ala<sup>382</sup>  $\rightarrow$  thr<sup>382</sup> (antithrombin Hamilton) (57) and pro<sup>407</sup>  $\rightarrow$  leu<sup>407</sup> (antithrombin Utah) (34) have indicated that the thrombin-binding region extends to at least include amino acid residues 382 and 407. Alternatively, investigations using thrombin mutants have illuminated structural components of the enzyme that are involved in the noncovalent interaction. Gly<sup>226</sup> in the thrombin polypeptide has been shown to protrude into the antithrombin specificity pocket, since substitution of a valine at this position removed inhibitory activity (58). Molecular modeling indicated that the larger valine side chain would not allow enough space for the antithrombin P<sub>1</sub> arg<sup>393</sup> R group. Once thrombin binding through weak interactions occurs, a more stable covalent bond is formed. Members of the serpin family have specific peptide bonds in the reactive center that are susceptible to enzymatic cleavage by the target protease. Two amino acids make up the reactive center peptide bond, and the peptide is designated as P<sub>1</sub>-P<sub>1</sub>’. The P<sub>1</sub> amino acid residue in antithrombin (arg<sup>393</sup>) provides the inhibitor with selectivity towards thrombin and the other coagulation factors (31). Other resi-

dues to the N-terminal side of the P<sub>1</sub> arg<sup>393</sup> give further enzyme selectivity and structural elements, such as in the case of the P<sub>2</sub> gly<sup>392</sup>, which is preferred for reaction with FXa and is important for preventing release of FXa from the inhibitor complex (59). The role of the P<sub>1</sub>' in antithrombin (ser<sup>394</sup>) is not entirely clear.

Thrombin initially treats antithrombin as a substrate by attacking the inhibitor's arg<sup>393</sup> C-terminal amide carbonyl via the protease active serine residue. Thus thrombin forms a covalent ester bond between the hydroxyl oxygen of the active serine and the arg<sup>393</sup> carboxyl carbonyl. The active noncleaved antithrombin exists in an S-configuration where the two amino acids of the reactive center are in the middle of a stressed loop (60). Within antithrombin, the reactive center loop connects strand 4 of  $\beta$ -sheet A (central sheet in the serpin ordered numbering system) to strand 1 of  $\beta$ -sheet C (61). In this stressed configuration, the reactive center loop of antithrombin is under some tension and the resultant surface topology is such that the reactive center is readily available for reaction with thrombin. Once the arg<sup>393</sup>-ser<sup>394</sup> has been cleaved, leaving thrombin and antithrombin remaining linked by a covalent ester bond, a radical conformational change occurs leading to a relaxed or R-configuration (60). Several studies of thrombin-antithrombin inhibitor complexes and postcomplex cleaved antithrombin have been done that have helped elucidate the structural properties of the relaxed configuration of the antithrombin within the complex. Antibodies have been produced that do not bind to native antithrombin but recognize either the consumed inhibitor or the inhibitor when it is bound to a tetradecapeptide corresponding to the P<sub>14</sub> to P<sub>1</sub> residues of the reactive center loop (61-68). These experiments, in conjunction with x-ray studies, strongly suggested that upon reaction of antithrombin with thrombin, the reactive center loop becomes embedded into the  $\beta$ -sheet A, which exposes new epitopes that are not present at the surface of the intact inhibitor. Model-building studies based on crystal structures and biochemical analyses of protease complexes with normal and mutant antithrombins have suggested that the reactive center loop is inserted into  $\beta$ -sheet A as far as P<sub>12</sub>, strand s1C is absent from the  $\beta$ -sheet C, and the conformation of the C-terminus has changed so that it interacts with thrombin (69). In fact, an intact noninhibitory (latent) conformer of antithrombin exists with a structure where the P<sub>14</sub> to P<sub>3</sub> residues of the reactive center are completely inserted into  $\beta$ -sheet A (70). However, experiments with an antibody, that did not bind to native, latent, or reactive center cleaved antithrombins, recognized antithrombin neopeptides in either stable thrombin-antithrombin complexes or antithrombin complexed to a synthetic peptide corresponding to the P<sub>14</sub> to P<sub>9</sub> sequence. Therefore only part of the reactive center may

be imbedded in the antithrombin  $\beta$ -sheet A within the inhibitor complex (71). Regardless, insertion of the reactive center loop positions the thrombin reactive site close to or within the  $\beta$ -sheet A pocket. Thus the thrombin moiety becomes irreversibly trapped as a reaction intermediate covalently linked to antithrombin (72).

Interaction of antithrombin with heparin and heparan sulfate glycosaminoglycans accelerates the thrombin inhibition reaction. Activation of antithrombin by heparin binding has been verified by the concomitant increase in protein intrinsic fluorescence, as a result of a conformational change. Research involving antithrombin trp  $\rightarrow$  phe mutants has shown that trp<sup>225</sup> and trp<sup>307</sup> each account for ~37% of the heparin-induced fluorescence enhancement (73). A spectral shift in trp<sup>49</sup> towards the blue suggests partial burial due to contact with heparin, while a red shift for trp<sup>225</sup> (along with fluorescence enhancement) indicates the increased access to the solvent due to heparin-induced movement of contact residue ser<sup>380</sup>. The main heparin binding region on antithrombin has been shown (according to mutant studies) (74-77) to reside towards the N-terminus of the molecule (32,78). A second heparin-binding region on antithrombin was proposed to exist at residues from positions 107 to 156 (79). Ultimately, high resolution of the heparin-binding site was achieved by alanine scanning mutagenesis in a baculovirus expression system, which gives a normal product that is highly similar to plasma  $\beta$ -antithrombin (80). Mutant antithrombins were screened for heparin affinity by gradient elution from heparin columns. It was determined that only a subset of residues (lys<sup>11</sup>, arg<sup>14</sup>, arg<sup>24</sup>, arg<sup>47</sup>, lys<sup>125</sup>, arg<sup>129</sup>, and arg<sup>145</sup>), which line in a 5 nm groove along antithrombin's surface, are critical for heparin binding (80). A few other residues have been proposed to be significant points for heparin binding (70,72). Molecular modeling has suggested that interaction of heparin with these amino acid R groups would induce the breakage of salt bridges between  $\alpha$ -helix D and  $\beta$ -sheet B, thus facilitating movement of s123AhDEF to give a species that is conformationally primed for reactive center loop uptake by  $\beta$ -sheet A (80). X-ray studies have confirmed that binding of heparin pentasaccharide to certain of the key antithrombin residues gives an increased affinity between the GAG and antithrombin, which accompanies the change in conformation (70). In addition, peptides representing P<sub>14</sub>-P<sub>3</sub> are able to inhibit formation of the conformation that would be induced by heparin binding to antithrombin (81). Finally, once antithrombin has been cleaved by thrombin, heparin affinity for the serpin in the inhibitor complex dramatically decreases. Model studies using immobilized heparin have shown that although native antithrombin readily bound to the heparin, upon covalent linkage to thrombin (cleavage) the serpin (as part of an

inhibitor complex) dissociated from the GAG (17,82). Undoubtedly, conformational changes resulting from insertion of the reactive loop peptide into the  $\beta$ -sheet A of cleaved antithrombin disturb the heparin binding site channel.

Variation in glycosylation on the antithrombin molecule has substantial effects on the ability of heparin to catalyze antithrombin's inhibition of thrombin. It has been shown previously that human  $\beta$ -antithrombin, which lacks the carbohydrate side chain at asn<sup>135</sup>, has higher affinity for heparin than the fully glycosylated (4 glycan)  $\alpha$ -antithrombin (83). Previously, glycoforms of antithrombin produced in either BHK or CHO cells that had a 10-fold difference in heparin-binding affinity (52,84) were found to vary in the glycosylation at asn<sup>155</sup> (85). Increased binding of heparin to  $\beta$ -antithrombin might be expected, given that the glycan position at asn<sup>135</sup> is directly within the heparin-binding site residues lys<sup>125</sup>, arg<sup>129</sup>, and arg<sup>145</sup> of the serpin. Rapid kinetic studies of heparin binding to  $\alpha$ - and  $\beta$ -antithrombin demonstrated that, although the asn<sup>135</sup>-glycan moderately interfered with the weak initial binding of heparin, the rate constant for the conformational change induced by heparin was significantly lower for  $\alpha$ -antithrombin than for  $\beta$ -antithrombin (83). Thus there is a higher energy required for inducing the activated conformation in  $\alpha$ -antithrombin, leading to a decrease in heparin-binding affinity. Since heparin-like GAGs exist *in vivo*, the variation in binding affinities by the antithrombin glycoforms may have physiological importance. In fact, evidence has been presented showing that  $\beta$ -antithrombin tends to be bound to vessel wall heparin/heparan sulfate, while  $\alpha$ -antithrombin resides more commonly in the plasma phase (46). These data suggest specialized functions for the antithrombin glycoforms where  $\beta$ -antithrombin may be vital for controlling thrombogenic events arising from vessel wall injury, while  $\alpha$ -antithrombin may be largely responsible for inhibition of fluid phase thrombin.

### III. HEPARIN

#### A. Heparin Chemical Structure

Heparin is a member of the GAG family of molecules that occur not only in mammals but in most multicellular, as well as some single-cell, organisms (86). This group of molecules includes heparin, heparan sulfate, dermatan sulfate, chondroitin-4-sulfate, chondroitin-6-sulfate, keratan sulfate, hyaluronic acid, and a number of minor subclasses (87). GAGs are straight chain polysaccharides that are composed of repeating uronic acid–hexosamine disaccharide units (88). Hyaluronic acid is of extremely high molecular weight and forms the structural matrix for many

tissues, as well as molecules associated with the other GAGs. Heparin and heparan sulfate contain glucosamine derivative residues, whereas dermatan sulfate and the other chondroitins contain galactosamine (88). The uronic acid present in GAGs are either glucuronic or iduronic. Generally, both types of uronic acids appear in heparin and heparan sulfate, while dermatan sulfate and the other chondroitins contain solely iduronic acid or glucuronic acid, respectively (88,89). Saccharides in GAG chains are extensively modified during and after glycosidic polymerization. Galactosamines in dermatan sulfate and chondroitins are N-acetylated and variously O-sulfated. In the case of heparin and heparan sulfate, glucosamine residues can be N-acetylated or N-sulfated. However, while >80% of the glucosamines are N-sulfated in heparin, approximately equal amounts of N-sulfated and N-acetylated glucosamines have been detected in various sources of heparan sulfate (90). Furthermore, whereas there are  $\geq 2$  O-sulfates per disaccharide unit in heparin (91), O-sulfation per disaccharide in heparan sulfate has been found to range from 0.2 to 0.75 (90). Thus, from these and other structural observations, it has been concluded that heparin and heparan sulfate represent separate groups of N-sulfated GAGs.

GAGs are ubiquitous in mammals. Heparin as well as other GAGs are produced in mast cells by biosynthetic attachment to a protein core. Each core protein may contain as many as 10 heparin chains, of molecular weights ranging from 60,000 to 100,000, linked via O-glycosidic bonds to serine residues in a glycine–serine sequence repeat (92). Heparin GAG is synthesized by glycosyltransferase addition of monosaccharide residues. An initial xylose-galactose-galactose-glucuronic acid linkage region sequence is built up, with the terminal xylose linked through serine to the polypeptide backbone (93). Within the growing polysaccharide, uronosyl- $\beta$ -1  $\rightarrow$  4-glucosaminosyl units are joined by  $\alpha$ -1  $\rightarrow$  4 bonds (94). During polysaccharide chain formation, numerous functional group modifications are performed, in a somewhat concerted fashion, on the monosaccharide residues within the nascent oligosaccharide. Glycosyltransferases (95), N-acetylases (96), N-deacetylases (96), O-sulfotransferases (97), N-sulfotransferases (98), and glucuronosyl-5-epimerases (97) have been isolated and characterized which are involved in anabolism towards the final heparin product *in vivo*. Segments of glucuronosyl–glucosaminosyl oligosaccharide chain are initially produced which are partially N-unsubstituted, N-acetylated, or N-sulfated (99). Following (and during) (99) this stage, the growing chain is acted upon by a combination of a N-deacetylase and a N-sulfotransferase to yield a much greater N-sulfate containing stretch (96,99). Shortly after N-sulfation, a glucuronosyl-C5-epimerase causes conversion of the chain-end glucuro-

nosyl residue to an iduronosyl residue (97). However, the epimerase reaction is one in which an equilibrium exists between glucuronosyl and iduronosyl residues, with the net equilibrium being towards the iduronosyl form. If O-sulfation occurs at either the C6 of the glucosaminosyl or the C2 of the iduronosyl residue in question, conversion of the iduronosyl back to a glucuronosyl does not occur (97). Chronologically, C2-O-sulfation of iduronosyl residues is carried out in the absence of C6-O-sulfation of neighboring glucosaminosyl residues, while C6-O-sulfation of glucosaminosyls occurs readily in the presence of 2-O-sulfates on adjacent iduronic acid units (100). However, if further glycosyl transfer occurs before C2-O-sulfation of the terminal uronic acid in the nascent chain, that uronic acid remains nonsulfated throughout subsequent modification reactions (100). Analyses of heparin samples has shown that ~78% of uronic acids are in the form of iduronic acid (94), of which ~75% are 2-O-sulfated (94,101). No significant amount of 2-O-sulfated glucuronic acid residues have been detected (94). Termination of the biosynthesis of each polysaccharide on the core protein varies, which yields (as mentioned above) side chains ranging in length (molecular weight). Chain size and monosaccharide modifications are not directed by transcriptional expression but are affected by factors within the milieu, such as substrate availability and cell status (102,103).

Studies of heparin metabolism in mastocytoma cells have shown that the newly synthesized heparin proteoglycan chains are partially depolymerized by an endoglucuronidase and stored in cytoplasmic granules (104,105). Due to this cellular processing, commercial heparin prepared from intestinal mucosa or lung mast cells are free GAG chains ranging in molecular weight from 5,000 to 30,000. Primary source commercial heparin, without isolation of any subpopulations, is called unfractionated heparin (UFH, as above). Within the last few decades, low molecular weight heparins (LMWHs) have been prepared via various methods (106). Partial depolymerization of UFH has been carried out by limited treatments with  $\text{HNO}_2$ , heparinases, heparitinases, and base elimination following partial esterification of uronic acid carboxyls (106,107). Molecular weights of LMWHs produced vary from 1,800 to 12,000 (106). Apart from variation in chain size, LMWHs have a number of pharmacokinetic and biological properties that separate them from their UFH parent compound.

## B. Heparin Functional Biochemistry

Heparin (both UFH and LMWH) provides two major functions in vivo. First, heparin (and other GAGs), mainly in the proteoglycan form, acts as an extracellular matrix com-

ponent for structural organization and as a chemoattractant in tissue (108,109). Second, via particular sequences, heparin can operate as an anticoagulant. Heparin's anticoagulant activities are based on its ability to bind to either plasma heparin cofactor II or antithrombin and catalyze their inhibition of thrombin (heparin cofactor II or antithrombin) or other coagulation factors [antithrombin (see above)] (110).

Reaction of antithrombin with various coagulation factors is catalyzed by heparin in vivo (111). Heparin's physiological anticoagulant activity resides particularly in facilitating antithrombin's inhibition of FXa and thrombin (112,113). However, heparin's augmentation of thrombin inhibition by antithrombin has been shown to be a major basis for the clinical use of heparin (particular UFH) (114). Regulation of in vivo FXa and thrombin inhibition by heparin relies on the presence of a particular pentasaccharide sequence in the GAG molecule that binds to antithrombin (115). This pentasaccharide antithrombin binding site has been shown to occur in the GAG chains of the proteoglycan form of heparin obtained from rat skin mast cells (which conserve intact proteoglycan) (116). Analyses indicated that while most proteoglycans contain no heparin chains with antithrombin binding sites, a small proportion of proteoglycans had chains with heparin pentasaccharide sequences numbering from 1 to 5 (average of 3) per polysaccharide unit (117). In the case of commercial UFH, on the average, only about 1/3 of the molecules have been found to have high-affinity antithrombin binding (118). Interestingly, though, some molecules of commercial UFH have been shown to contain two high-affinity antithrombin binding sites per molecule (119). On the other hand, pentasaccharide antithrombin binding sites in LMWH are reduced in number due to the degradative cleavages used to make LMWH molecules (112,120). It has been shown that the pentasaccharide antithrombin binding sequence occurs somewhat randomly along the chain in UFH molecules (121). However, reports have indicated that there may be a bias for the antithrombin binding sites to be located towards the nonaldose half of UFH chains (122,123).

The biosynthetic and structural aspects of the pentasaccharide antithrombin binding site in heparin have been elucidated. Previously, it was reported that an unusual 3-O-sulfate group was present on an internal glucosamine group within the pentasaccharide sequence (124). Further work has indicated that the 3-O-sulfated glucosamine residue was critical to the high-affinity antithrombin binding and anti-FXa activity (125). Final characterization and chemical synthesis of the complete pentasaccharide sequence has been accomplished (126) and is shown in Fig. 3. Important elements of the structure are the appearance of nonsulfated glucuronic acid and 3-O-sulfated glucos-

**Figure 25.3** Heparin pentasaccharide high-affinity antithrombin binding sequence.

amine at positions 2 and 3 from the nonaldose terminus of the sequence. Binding of heparin to antithrombin, through the pentasaccharide, involves a two-stage mechanism that corresponds to the structural activation events that occur in the serpin. Evidence for the mechanism of activation of antithrombin by heparin pentasaccharide has come from experiments involving binding of various mono-, di-, tri-, and tetrasaccharide derivatives to antithrombin (127–129). Initially, residues 1, 2, and 3 (Fig. 3) of the heparin pentasaccharide bind to antithrombin via charge and hydrogen-bond interactions. Binding of the first three residues from the nonaldose end of the pentasaccharide is relatively weak but induces a conformational change in the antithrombin that is very similar to the heparin activated form (127). The 2-O-sulfated iduronic acid (residue 4, Fig. 3) has been shown to have a flexible capability to convert from a chair to a skew boat conformation (129). Upon binding of pentasaccharide residues 1–3 to antithrombin, movement of the polypeptide due to the trisaccharide-induced conformational change causes amino-acid R groups, particularly arg<sup>47</sup> (130), to come into contact with the remaining pentasaccharide residues 4 and 5. The skew boat conformation of the 2-O-sulfated iduronic acid also allows the 3-O-sulfate on the central glucosamine and a putative charge cluster on pentasaccharide residues 4 and 5 to interact with the polypeptide after antithrombin's change in conformation (129). This binding of charge groups from pentasaccharide residues 4 and 5 gives the high affinity binding with antithrombin that locks the GAG and serpin in place (128,129). No additional conformational activation of antithrombin occurs due to the locking interactions with residues 4 and 5 of the pentasaccharide (130).

It is now well understood that, although activation of antithrombin by heparin pentasaccharide binding is fairly sufficient to accelerate inhibition of FXa, a larger stretch of heparin chain is required for maximal inhibition of thrombin (115). For heparin catalysis of antithrombin's reaction with thrombin, both the serpin and the enzyme must bind to the GAG. It has been determined that effective ter-

nary complexes of antithrombin, thrombin, and heparin require a heparin pentasaccharide sequence to bind the inhibitor and a total chain length of 18 to 22 monosaccharide residues in order also to accommodate interaction with thrombin (131).

Heparin binding to thrombin involves an anion binding exosite on the protease (132). However, although significant negative heparin charge density is important (133), a specific binding sequence in heparin for thrombin has never been found. Since binding to both antithrombin and thrombin by heparin has a minimum chain length requirement, certain LMWH molecules would be unable to catalyze thrombin inhibition. This has been borne out by the fact that LMWH preparations have a lower antithrombin-to-anti-FXa activity ratio. The importance of heparin's ability to catalyze thrombin activity has been implicated by reduced *in vivo* antithrombotic activity of various LMWHs compared to UFH (112). In fact, the lowest antithrombotic activity (as indicated by *in vivo* fibrin deposition) has been found with the pentasaccharide (134). These findings would appear to suggest a reduced clinical usefulness for LMWHs compared to UFH. However, the intravenous half-life of LMWHs is significantly longer than UFH (135). The difference in pharmacokinetics is due to two main reasons. First, nonspecific protein binding by LMWH molecules is reduced compared to UFH (136). Since LMWH has reduced affinity for other proteins *in vivo*, there is a reduction in pathways by which LMWH activity can be either pacified or removed from the circulation. Second, although UFH can be either metabolized by uptake into the liver or lost through the kidneys, plasma disappearance of LMWH occurs only via renal elimination (131). This single-phase elimination of LMWH is much slower and less variable than the concave–convex pattern seen with UFH. As a result of the reduction of pathways for LMWH's pharmacokinetics *in vivo*, LMWH produces a more predictable anticoagulant response than UFH, which gives a decreased risk of bleeding (137,138). Nevertheless, since different preparations of LMWH exhibit differing

amounts of activity against thrombin (possibly due to contaminating higher molecular weight chains, varying charge density, etc.) (139), a narrow window of dosage and regimen exists for their application that must be evaluated for each type of LMWH (107). Furthermore, unlike UFH, LMWHs cannot be completely neutralized by protamine (administered to prevent bleeding if plasma levels become too high during treatment) (140). Thus development of a heparinoid with the thrombin inhibitory potency of UFH and the increased half-life of LMWH would be desirable.

#### **IV. COVALENT ANTITHROMBIN- HEPARIN COMPLEXES: OVERVIEW**

##### **A. Limitations of Currently Available Anticoagulants**

Limitations in the control of thrombin by heparin administration, as well as major adverse side effects induced by heparinization, have led to the development of new anticoagulants for clinical use. Deficiencies in heparin's efficacy for thrombin regulation stem from either loss of heparin activity within the plasma compartment or the inability of heparin to accelerate inhibition of thrombin bound to different surfaces. Loss of plasma heparin activity occurs due to removal of heparin molecules from the circulation (disappearance) or neutralization. Pharmacokinetic loss of UFH is due to binding and uptake of heparin by cells, such as hepatocytes of the liver, or by glomerular filtration through the kidneys (131). In both elimination mechanisms, removal of UFH from the circulation requires the dissociation of UFH from antithrombin. That antithrombin UFH complexes break up prior to UFH elimination *in vivo*, is borne out by the fact that noncovalent mixtures of UFH and antithrombin have significantly different intravenous half-lives when injected as a bolus (118). It has been determined that the intravenous half-life of UFH in humans is dose dependent and ranges from 0.3 to 1 hour (131). UFH's short half-life makes it necessary to administer UFH either by intravenous infusion (which assures a constant delivery of UFH) or by subcutaneous injection (which provides a depot of heparin for slow release into the intravascular space) (141).

Subcutaneous UFH injection gives peak plasma concentrations at 4 hours (142). LMWHs have been shown to have longer intravenous half-lives than UFH (143). Interestingly, LMWH administered subcutaneously in humans at therapeutic doses gave peak plasma levels by 3 hours with plasma activity being undetectable after 12 hours (137). Apart from the disappearance of heparin from the plasma compartment, heparin's activity can be altered due to binding to other fluid phase or cell surface molecules

within the lumen. It has been shown that plasma proteins (144,145), platelets (146), and endothelium (147) can bind UFH. Binding to plasma proteins, other than antithrombin and heparin cofactor II, is nonselective and based on charge (148). When bound to plasma proteins, UFH exhibits reduced activity (144), which can be regained following displacement from these basic heparin-binding proteins (149). However, dissociation of UFH from nonanticoagulant plasma proteins (part of the heparin rebound effect) results in variation of heparin activity levels and the regimen used to stop treatment by administration of protamine (149). Again, binding of UFH to basic plasma proteins involves dissociation of the heparin from antithrombin. As stated earlier, heparin has reduced efficacy at inhibiting fibrin-bound thrombin (22,23). In fact, at therapeutic levels, heparin promotes the binding of thrombin to fibrin polymer (150), which, in turn, protects thrombin from inactivation by antithrombin · UFH noncovalent complexes (151). The mechanism by which fibrin accretion of thrombin protects the protease from inactivation by antithrombin + heparin has been investigated. Fibrin, thrombin, and UFH interact to form a ternary complex (152). Once in this ternary complex, the action of thrombin against its substrates is altered (153), which causes decreased reaction of the protease with incoming antithrombin-heparin (151). Although LMWH has been found to have reduced nonselective plasma protein binding (154,155), both UFH and LMWH are unable to inactivate clot-bound thrombin (156). Numerous adverse side effects have been associated with heparin administration. Approximately 3% of adults receiving heparin develop heparin-induced thrombocytopenia (a condition in which antibodies are developed by the patient against platelet-bound heparin molecules) (157), and the use of UFH on a long-term basis results in osteoporosis in 17–36% of patients (158,159). Review of heparin use has indicated that the most significant problem is the risk of bleeding (160). Thus careful monitoring is required to ensure that UFH's anticoagulant activities remain within the therapeutic range to minimize the risk of recurrent disease while preventing hemorrhagic complications (161). Since heparin is rapidly cleared from the circulation, constant infusion or frequent subcutaneous injections are required to control the efficacy/bleeding ratio (162). From data in acute coronary syndrome patients, it has been suggested that LMWH may have a lower risk of heparin-induced thrombocytopenia than UFH (160). However, since LMWHs cross-react with 80% of antibodies generated during UFH exposure, LMWH is not recommended for the treatment of established heparin-induced thrombocytopenia (160). Furthermore, in clinical practice, there is no evidence that bleeding complications are reduced with LMWHs compared to UFH (163,164).

Non-heparin-related anticoagulants have been developed to improve on clinical therapy and to overcome problems with treatments involving heparin. Examples of new and effective anticoagulants include LMWHs (as discussed above), hirudin, hirulog, and PPACK (165–168). Hirudin is a small (7000 MW) direct, reversible thrombin inhibitor produced by the leech (169), and hirulog is the C-terminal portion (residues 53–65) of hirudin covalently linked to a short peptide active site inhibitor (170). Investigations have determined that hirudin can inhibit clot-bound thrombin, since clot growth did not occur even long after hirudin had been cleared from the circulation (171). However, the intravenous half-lives of hirudin ( $\beta$ -phase  $\leq 1$ h, terminal half-life = 2.8 h) (172) and hirulog (36 min) (173) in humans are not significantly longer than that of UFH. Furthermore, it has been shown that persistent formation of thrombin occurs during declining plasma levels of hirudin after administering potent dosages, suggesting that thrombin generation is not blocked (174). PPACK (phe-pro-arg-chloromethyl ketone) is a modified tripeptide substrate that reacts selectively and rapidly with thrombin. Again, PPACK is very effective at irreversibly inhibiting clot-bound thrombin, as has been demonstrated in animal models (175). Given its small size, it is not surprising to note that PPACK's half-life is extremely short (176), which has led to bleeding risk at therapeutic treatment doses (177). Thus the potency/bioavailability/bleeding issues that are concerns for heparin use have not been ameliorated by the development of alternative anticoagulant agents.

### B. Potential Advantages of Covalent Antithrombin–Heparin Complexes

To address the aforementioned limitations of UFH, LMWH, and other anticoagulants, researchers have studied the possibility of stabilizing the interaction of antithrombin with heparin by covalent bonds. The rationale for producing a covalent antithrombin–heparin conjugate (ATH) was severalfold. First, if ATH molecules could be produced in which the antithrombin in the complex was able to interact with a pentasaccharide on the heparin component of the same complex, the ATH antithrombin would be activated for rapid reaction with thrombin. Reaction of ATH with thrombin should be faster than noncovalent mixtures of heparin + saturating amounts of antithrombin because the reaction step of antithrombin + heparin binding would be eliminated. In fact, previous workers have shown that antithrombin + heparin binding is the rate determining step in heparin-catalyzed inhibition of thrombin by antithrombin (178). Second, if antithrombin cannot dissociate from the heparin, the antithrombin would be per-

manently activated. Thus, wherever and whenever ATH appears at locations in the body, the antithrombin would always be in the conformation of a very potent anticoagulant towards thrombin, FXa, and other coagulant molecules of the cascade. Permanently activated antithrombin would not rely on any particular conditions to react rapidly with thrombin, which may be necessary for the prevention of noncovalent antithrombin · heparin complex dissociation. Third, depending on the methodology used, covalent ATH complexes may be prepared in which a selection takes place (prior to covalent linkage) for only the heparin molecules that have pentasaccharide sequences. That is, a mechanism for ATH synthesis may be possible in which antithrombin first binds heparin ionically, through the high-affinity sites on the GAG, followed by covalent bonding. In this way, the ATH formed would be a preparation in which all of the molecules would contain serpin species activated by heparin pentasaccharide sites. The heparin in ATH produced by preselection of the heparin component by the antithrombin component would have GAG that is a much more potent anticoagulant than the starting heparin, since only  $\sim 1/3$  of commercial UFH (and even fewer for LMWH) have pentasaccharide containing molecules (118). Fourth, ATH may have the capability to inhibit fibrin-bound thrombin. Since the antithrombin and heparin in ATH do not dissociate, ternary complexes of fibrin/heparin/thrombin cannot form. Given that the antithrombin must remain attached to the heparin chain, it is expected that the heparin moiety in ATH will be less likely also to accommodate fibrin and thrombin compared to free heparin. Fifth, if antithrombin were permanently linked to heparin, the heparin moieties would not dissociate and be lost from the circulation through a renal mechanism. Given the increased size of an ATH complex, glomerular filtration of such a compound should be prohibited, or at least vastly reduced, compared to the much smaller low molecular weight species in polydisperse UFH (even more so for LMWH preparations). Sixth, since the antithrombin in ATH may cover (by noncovalent interaction or steric hindrance) a significant portion of the heparin chain in the complex, binding of the ATH GAG moiety by other plasma and cell surface proteins could be reduced. This reduction in nonselective protein binding would decrease both the removal of active compound from the circulation (via cell surface interactions, cell uptake, and cell matrix binding) and neutralization of anticoagulant activity (basic plasma protein, platelet factor 4 receptor, etc.). Seventh, close interaction of the heparin in ATH complexes with the conjugated antithrombin should sterically inhibit attack by proteases or glycosidases that may be released into the plasma environment. Therefore, by maintaining antithrombin and heparin as a complex, the serpin and GAG may,

to a degree, inhibit degradation. Eighth, immune response against ATH may be much less compared to other anticoagulant modalities. For example, if human antithrombin is used to make ATH, no antibodies should be raised directly against the serpin during clinical application (unlike hirudin, hirulog, and PPACK). Also, since part of the heparin molecule permanently interacts with the antithrombin in ATH, the ATH heparin chain may interact with other proteins in a manner similar to that of LMWH (only a small part of the heparin in ATH is available for binding). Thus heparin-induced thrombocytopenia may be decreased for ATH (as it is for LMWH) (160), compared to UFH. Additionally, if binding between the antithrombin and heparin in an ATH preparation is very close, linking agents may be sterically hidden as epitopes for recognition for immune response. Ninth, ATH may not promote osteoporosis as readily as UFH. It has been shown previously that LMWH causes less osteopenia than UFH because it only decreases the rate of bone formation and does not increase bone resorption (179). ATH, again, would only have a portion of its heparin component available (free from the bound antithrombin) and therefore may interact poorly with osteoclasts to effect bone loss. Tenth, for the same reasons as those given for increased inhibition of fibrin-bound thrombin and reduced promotion of osteoporosis, ATH molecules may induce fewer hemorrhagic side effects than either UFH or LMWH. Platelet binding by ATH may be reduced compared to free heparin, since the covalently linked antithrombin may not allow heparin either to bridge receptors on the membrane or to interact with single protein molecules via the required geometry. Finally, ATH may combine many of the positive attributes exhibited by either UFH or LMWH, without a number of their deficiencies. For example, if ATH is prepared from UFH, the product should have high activity against thrombin (unlike LMWH) but have an increased intravenous half-life (decreased cell surface protein binding compared to UFH). In effect, ATH may be the optimum heparinoid.

### C. Potential Uses of Covalent Antithrombin-Heparin Complexes

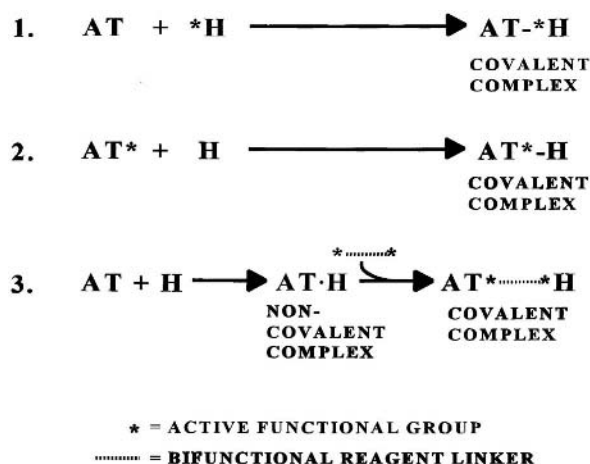

ATH has characteristics that make it attractive for use in a range of clinical indications. The rapid inhibition of thrombin, that should occur if antithrombin is permanently activated by covalently linked heparin, would be highly advantageous for anticoagulant prophylaxis. The low levels of thrombin, which need to be inactivated during ongoing prophylactic treatment, would be quickly complexed by ATH before feedback activation of FV, FVIII, or FXI can occur. Also, since ATH is likely to have a prolonged half-life compared to free heparin, it may be possible to

give a single intravenous bolus injection of the conjugate to achieve safe protection against thrombosis. Monitoring of the ATH may be less critical if ATH has a reduced bleeding risk profile. Another possible application of ATH is administration of the complex as an antithrombotic treatment. As suggested above, although UFH and, to a lesser extent, LMWH have reduced activity against clot-bound thrombin, ATH may have good reactivity with thrombin associated with fibrin clots. Thus, in addition to an increased half-life for *in vivo* inhibition of thrombin generation, ATH may be able to pacify the procoagulant activity on thrombi. Rapid inhibition of clot-based procoagulant activity is critical to the prevention of myocardial infarction and stroke, and ATH may be a treatment that could reduce this risk in two ways. By inactivating thrombin on the surface of the polymerized fibrin, clot extension should not occur, since there will be no further activation of fluid phase coagulation by the clot (23–25). Thus fibrin accretion would be reduced if not eliminated. In addition, due to its increased potency and half-life compared to UFH and LMWH, ATH could be used at dosages that would not cause significant risk of hemorrhage. Another novel utilization of ATH involves the likelihood that its permeability from one compartment to another would be reduced compared to free heparin. The molecular size of ATH is much greater than that of heparin alone, which would prevent its percolation through small pores in cross-linked sections of the extracellular tissue matrix. Therefore ATH should be retained within the compartment or space in which it is placed. This property can be advantageous in situations where an anticoagulant must have potent direct activity in a confined space, without it being lost from that compartment. An example of a disease that would be best treated by sequestration of covalent serpin-GAG complex is respiratory distress syndrome (RDS). RDS, particularly in neonates, is characterized by intrapulmonary coagulation. Neonatal and adult RDSs are typified by leakage of plasma proteins of varying sizes into the airspace (180–182), which leads to interstitial and intra-alveolar thrombin generation with subsequent fibrin deposition. In fact, extravascular fibrin deposition is a hallmark of RDS (183,184), a common complication of premature birth. Furthermore, the success of surfactant therapy for RDS has not resulted in decreasing either the incidence or the severity of chronic bronchopulmonary dysplasia, which continues to be a problem for survivors of prematurity (185–191). Thus if an agent could be placed in the alveolar airspace that would eliminate thrombin activity, without being lost into the intravascular system, neonates could be treated prophylactically so that chronic effects of RDS would be prevented. ATH is a strong candidate for RDS treatment and prevention of chronic fibrotic lung disease. Coagulation in the

lung space may occur where there is a paucity of antithrombin for thrombin inhibition. ATH would provide potent direct inhibition of pulmonary thrombin generation, even in the absence of antithrombin from the patient (a requirement for UFH and LMWH). Due to its size, ATH should slowly, if at all, disappear from the lung into the circulation. Therefore there would be little bleeding risk systemically from intratracheally instilled ATH. Finally, once ATH forms a complex with thrombin generated in the alveolar airspace, the serpin–GAG conjugate itself would be neutralized and unable to participate in any further, undesired reactions. In conclusion, prophylaxis, systemic antithrombotic treatment, and anticoagulation of selected compartments by sequestration are significant applications in which the particular characteristics of ATH may make it a superior agent compared to other available drug technologies.

#### D. Concepts for Producing Covalent Antithrombin–Heparin Complexes

There are only three general approaches to permanent linkage of antithrombin and heparin. Bonding can occur if heparin is activated to make it reactive, followed by interaction with antithrombin to effect covalent bond formation. Conversely, antithrombin can be preactivated and then incubated with heparin to obtain a stable complex. Finally, antithrombin and heparin can be conjugated by allowing the two macromolecules to interact noncovalently, followed by addition of a bifunctional reagent, one end of which bonds to the serpin and the other end of which reacts covalently with the GAG. The three synthetic schemes for ATH preparation are outlined in Fig. 4. In the first two

**Figure 25.4** General approaches for covalent linkage of antithrombin and heparin.

methodologies, it is theoretically possible that the heparin or antithrombin may possess groups that, under the appropriate conditions, are already reactive enough to form a bond with the other macromolecule. Furthermore, in a number of procedures, care must be taken (by selective chemistry, appropriate reagent stoichiometries, or particular reaction conditions) to prevent linkage of either heparin to itself or antithrombin to itself.

Functional groups on heparin that may be activated (or have active or activatable groups attached to them) are carboxyl, sulfonyl, hydroxyl, amino, and acetal. Apart from the acetal and amino groups, attachment through heparin's other functional groups would be within the chain of the molecule. Only linkage through acetals, or aldehydes formed at the reducing terminus, would result in end-point attachment of heparin to antithrombin, which more closely resembles the structure of the glycosidically bonded chains in the proteoglycan form of heparin (93). An example of conjugation that occurs by reaction of antithrombin with a preactivated heparin follows. Heparin carboxyl groups are reacted with a carbodiimide followed by incubation with a diaminoalkane to form amide-linked groups with a free amino. Further reaction of the amino-substituted heparin with a diisothiocyanate then gives a heparin derivative with a free isothiocyanate group that can form thiourea bonds with the N-terminal or lys -amino groups of antithrombin. This type of mechanism for joining heparin to antithrombin has been carried out previously and will be discussed in further detail later (192).

Activation of antithrombin for covalent reaction with heparin is more problematic. Proteins not only have a greater number of different functional R group types than those on heparin, but the same type of amino acid R group can exist in a range of environments, either on the surface or within the tertiary structure. Thus more finely tuned chemistries may be required to obtain significant yields of purified ATH (containing linkages with heparin that are at the same point on the antithrombin molecule) resulting from the initial activation of the antithrombin. One possible example for this type of synthesis would involve activation of antithrombin with N-hydroxysuccinimidyl-4-azidobenzoate (formation of benzoyl amide with antithrombin lys  $\epsilon$ -amino), followed by interaction with heparin in the presence of light to cause photochemical linkage between the benzoyl derivative and heparin. Additionally, the antithrombin carbohydrate residues could be modified to act as linkage points for heparin conjugation. Reaction of antithrombin with  $\text{NaIO}_4$ , under mild conditions, only produces aldehydes on the terminal sialic acids of the glycans. Aldehyde-containing antithrombin can be reacted with diaminoalkane +  $\text{NaBH}_3\text{CN}$  to form alkyl-amino antithrombin. Reaction of the alkyl-amino groups on the

antithrombin with N-hydroxysuccinimidyl-4-azidobenzoate (as above) would then be preferred, compared to other amino groups on the antithrombin, since the amino groups are very prominent (essentially on a spacer arm). Conjugation of such a modified antithrombin with heparin should then be possible. The likely advantages for linkage of antithrombin to heparin through the serpin glycan termini are that the number of linkage points on the antithrombin may be more controlled and there would be no perturbation due to modification of the polypeptide.

ATH synthesis involving simultaneous bonding of antithrombin and heparin with an intermediate agent is likely to be more sophisticated than procedures in which initial activation of either heparin or antithrombin is carried out. All of the functional groups that are present on heparin exist on antithrombin as well. Therefore it would be fortuitous to use heterobifunctional agents that have one functional end that would only react with a functional group found solely on antithrombin. An example would be use of a linking agent that contains one reactive group that would selectively link with the guanidinyll group of antithrombin arg residues (vicinal dione functional group) while the other end of the linker has a photoactivatable group ( $-N_3$ ) with a neighboring plus-charged group ( $-N(CH_3)_3^+$ ) to form a covalent bond with the negatively charged heparin chain. One disadvantage of this approach is that more than one link between antithrombin and heparin may occur, which may result in denaturation of the protein. On the other hand, allowing native antithrombin and heparin to interact prior to covalent modification would give the opportunity for the most active non-covalent antithrombin-heparin complexes to form prior to conjugation.

Investigations into ATH synthesis have been reported before. The vast majority involve the first method (discussed above and illustrated in Fig. 4) in which heparin is activated prior to interaction with antithrombin. The evolution of ATH compound investigation is reviewed below.

## V. COVALENT ANTITHROMBIN-HEPARIN COMPLEXES: DEVELOPMENT

### A. Chemistry, Physicochemical Properties, and In Vitro Activity

The chronological development of ATH products shows an evolution over time of more sophisticated, selective chemistries that are concomitant with higher anticoagulant activities. A number of studies have reported preparations in which noncovalent complexes of antithrombin and heparin have been produced (193–196). Such complexes are useful for short-term treatment but are not practical for

long-term thrombin regulation or anticoagulation at surfaces where binding by the heparin moiety may cause dissociation of the antithrombin-heparin. As the various attempts to join antithrombin and heparin are described, the type of synthetic methods utilized will be related to the structure of the final product in order to explain the observed physical properties and anticoagulant activities.

Initial investigations in the construction of a permanently activated antithrombin relied on chemical linkage of GAGs, particularly heparin, to chromatographic matrices and other macroscopic surfaces. Conjugation of heparinoids to albumin has been accomplished in a manner similar to the methods employed for preparation of ATH compounds, but that literature will not be covered in detail. However, covalent attachment of heparin to other proteins (such as albumin) (197,198), natural polysaccharides (199), and synthetic polysaccharides (199) has added to the knowledge base for coupling of heparin to macromolecules. Modification of functional groups on heparin has been done over most of this century, and characterization of the broad range of reactions used eventually contributed to devising final methods for the conjugation of antithrombin and heparin. Some of the earliest attempts to form ATH were carried out by Ceustermans et al. (192). UFH was activated with CNBr at pH 10 according to the procedure of Cuatrecasas et al. (200), followed by reaction with antithrombin. These experiments failed to produce significant amounts of conjugate. Activation of heparin with CNBr may involve the formation of iminocarbonate or cyanate groups with the hydroxyl groups on heparin but, more likely, CNBr reaction requires the presence of amino groups, of which there are fewer than one per heparin molecule on the average (192). In addition, the amino groups on the heparin molecules may be at locations distal to the antithrombin that is interacting with the GAG pentasaccharide binding site. Further experiments were undertaken to form conjugate through the bifunctional reagent, 1,5-difluoro-2,4-dinitrobenzene (192), according to the methods of Zahn and Meienhofer (201,202). Again, no ATH was produced. Since 1,5-difluoro-2,4-dinitrobenzene would require the presence of heparin amino groups for nucleophilic substitution on the benzene ring to take place, lack of product was probably due to the same reasons as those for CNBr experiments. Modification of heparin with 4-fluoro-3-nitrophenyl azide or 4-azido-phenacyl bromide, followed by reaction with antithrombin via photoactivation of the  $-N_3$  group, has been carried out according to the experimental conditions reported previously (203–206), but with negative results.

Successful linkage of antithrombin and heparin was finally obtained by Ceustermans et al. (192) using tolylene-2,4-diisocyanate according to the procedure of Clyne et al.

(207–209). In order to increase reactivity of aminos (or hydroxyls) with the isocyanate groups, reactions were carried out under basic conditions. However, the amount of conjugate obtained was  $\leq 5\%$ . The yield of ATH decreased rapidly due to the facile hydrolysis of isocyanate groups on the substituted heparin during incubation on ice in pH 9.5 borate buffer, just prior to interaction with the antithrombin. Thus the more stable tolylene-2,4-diisothiocyanate (TDTC) reagent was substituted in further attempts to couple antithrombin and heparin. Heparin was modified with TDTC using the procedure of Edman and Henschen (210), followed by reaction with antithrombin in pH 8.5 bicarbonate buffer (192). A yield of 30% was obtained for ATH using the heparin modified with TDTC.

In order further to improve yield and quality of the product with the TDTC reagent, ATH was synthesized following TDTC reaction with heparin that had amino groups introduced into it, either by deblocking amino groups on the glucosamine residues or by modifying the carboxyl groups with an amino-containing spacer arm (192). The resultant product was purified and structurally characterized, and its functional activities were assessed. A scheme for the reaction used to produce ATH with antithrombin linked to amino group modified heparin is shown as reaction 1 in Fig. 5. The high-affinity fraction of UFH passed over an immobilized antithrombin column was used as starting material for all of the ATH prepared from amino-substituted heparin. Partial N-desulfation was performed by incubation of the pyridinium salt of the acid form of heparin (prepared by passage of heparin through Dowex 50) in 95% dimethylsulfoxide for 0.5 h at 23°C (211,212), followed by adjustment of the pH to 9.5 and dialysis versus H<sub>2</sub>O for 2 days. Introduction of aminos by carboxyl modification was achieved by incubation of high-affinity heparin with 1,6-diamino-hexane in the presence of a carbodiimide condensing agent. Either of the two amino-modified heparins was reacted with excess TDTC (to prevent cross-linkage of the GAG), after which the activated heparin was reacted with antithrombin via the remaining isothiocyanate group. Chemical analyses of the modified heparins and corresponding ATH products are found in Table 1. Partial N-desulfation of heparin resulted in an approximate two-fold increase in isothiocyanate groups incorporated per activated GAG molecule. Isothiocyanate substitution was improved by a factor of 2.9 in (hexyl-amino)-containing heparin compared to reactions with starting heparin. Yield of ATH (in terms of either starting heparin or antithrombin) was  $\sim 30\%$  using either partially N-desulfated heparin or hexyl-amino heparin. Furthermore, up to 25% of the ATH obtained contained two antithrombin molecules per heparin molecule (heparin/antithrombin molar ratio Table 1) (192). Activity measurements of N-desulfated or hexyl-

amino heparin were determined using an activated partial thromboplastin time (APTT) clotting time measurement or anti-FXa inhibition assay (Table 1). After partial N-desulfation, heparin APTT activity decreased by 35%, and anti-FXa activity was reduced by 24%. Hexyl-amino heparin had 44% and 39% lower APTT and anti-FXa activities, respectively, compared to starting high-affinity heparin (Table 1). The anti-FXa activities represent the ability of the heparin species to catalyze the inhibition of FXa by exogenous antithrombin (excess added antithrombin that is not covalently bound to heparin). Significant loss of activity occurred in both partially N-desulfated heparin and heparin with diamino-hexyl groups linked to the uronic acid residues, which is not surprising given that it has long been known that the N-sulfate and carboxyl groups are critical for heparin's anticoagulant activity (213). Anti-FXa measurements of the ATH complexes produced using partially N-desulfated heparin were not reported (192). Direct, noncatalytic reaction of the hexyl-amino containing ATH complexes with FXa was studied. Determinations of the reaction velocity revealed that the second-order rate constant for this ATH (Table 1) was  $2.1 \times 10^6 \text{ M}^{-1}\text{s}^{-1}$  ( $\sim 3$  times lower than that for noncovalent mixtures of unmodified high-affinity heparin + saturating amounts of antithrombin) (192). Addition of heparin to the ATH doubled the rate of direct FXa inhibition, suggesting that not all ATH heparin was coupled so that the antithrombin was in the active conformation (192). Thus exogenous heparin increased the activity for these nonactivated molecules. ATH prepared from the amino-modified heparins had been purified by combinations of anion exchange, gel filtration, and sepharose-antithrombin affinity chromatographies (192). Further purification of hexyl-amino heparin-produced ATH on sepharose-concanavalin A allowed removal of residual free heparin and possibly some inactive complexes (214). The highly purified ATH was tested in reactions with thrombin, and a second-order rate constant of  $6.7 \times 10^8 \text{ M}^{-1}\text{s}^{-1}$  was measured (Table 1). A bimolecular rate constant for reaction with thrombin of  $2.2 \times 10^8 \text{ M}^{-1}\text{s}^{-1}$  was determined with high-affinity heparin in the presence of saturating amounts of antithrombin (compared to  $2.5 \times 10^8 \text{ M}^{-1}\text{s}^{-1}$  for inhibition of thrombin by ATH) (214). Thus ATH that was an isolate of highly active covalent complexes of one amino-hexyl-thiourea-tolylene-isothiocyanate heparin molecule and one antithrombin molecule had direct inhibitory reactivity with thrombin that was essentially the same as that for inactivation of thrombin with noncovalent mixtures of heparin + saturating amounts of antithrombin. No specific antithrombin activity values have been reported for the hexyl-tolylene linkage-containing ATH. Hoylaerts et al. have also prepared ATH from high-affinity hexyl-amino containing heparin using

2. Hexyl-amino substituted high-affinity heparin conjugated to antithrombin with tolylene-2,4-diisothiocyanate. (*Source:* Refs. 192, 236, 214.)
3. Reductive alkylation of antithrombin with high-affinity anhydromannose-terminating heparin and NaBH<sub>3</sub>CN. (*Source:* Refs. 215, 217.)
4. Conjugation of antithrombin to CNBr-activated heparin. (*Source:* Refs. 218, 219.)
5. Incubation of antithrombin with aldose-terminating unfractionated heparin to form a Schiff base between an antithrombin lysyl amino group and the heparin aldose aldehyde, which undergoes an Amadori rearrangement. (*Source:* Refs. 118, 230, 233.)

LMWH obtained by HNO<sub>2</sub> treatment of UFH [followed by size fractionation to give LMWH with chain lengths of 10–14 monosaccharide units ( $M_r = 3,200$ ) or 14–18 monosaccharide units ( $M_r = 4,300$ )] (214). However, second-order rate constants for reaction with thrombin were significantly reduced for the LMWH containing ATH ( $3 \times 10^5 \text{ M}^{-1}\text{s}^{-1}$  and  $2 \times 10^7 \text{ M}^{-1}\text{s}^{-1}$  for 3,200 and 4,300  $M_r$  heparin containing ATH, respectively), compared to the corresponding ATH with standard molecular weight ( $M_r = 15,000$ ) heparin.

Almost coincident to the ATH prepared by Ceustermans et al., Björk et al. produced ATH using end-group attachment to the heparin moiety (synthetic scheme 2, shown in Fig. 5) (215). UFH was treated with HNO<sub>2</sub> to cause partial deaminative cleavage. High-activity LMWH fragments were obtained by immobilized-antithrombin affinity chromatography, followed by covalent linkage to antithrombin by reduction of the Schiff base formed between the aldehyde group of the LMWH anhydromannose termini and lysyl amino groups on the protein (reductive alkylation) (215). Conjugate was isolated by gel filtration to separate ATH and antithrombin from unreacted LMWH, followed by heparin agarose affinity chromatography to separate ATH from free antithrombin. After completion of the purification procedures, determinations showed that

~40% conversion of the original antithrombin to ATH occurred. The molecular weight of heparin prepared by this partial deaminative cleavage method has been shown to range from 3,700 (215) to 10,000 (216). Unlike heparin in the hexyl-tolylene linked ATH, the LMWH generated by HNO<sub>2</sub> treatment of UFH has only one active group per molecule located at the terminal anhydromannose residue (Table 1). Therefore only one type of orientation of the heparin on the antithrombin can occur (end-point attachment). Analyses showed that ATH preparations, formed by reductive alkylation of antithrombin with high-affinity anhydromannose-terminating heparin, had an average of 0.7 moles of GAG chain conjugated per antithrombin (Table 1). LMWH obtained by HNO<sub>2</sub> for conjugation (prior to isolating the high-affinity fraction) was determined to have an anti-FXa activity of 140 units/mg, which is slightly lower than the UFH starting material (217). Titration with FXa showed that the Björk et al. ATH complex had an activity which was 98% of that for the high-affinity LMWH material used in the preparation (Table 1). Interestingly, although the anti-FXa activity of noncovalent mixtures of LMWH + antithrombin could be neutralized by high NaCl concentrations (1 M) or polybrene, reactivity of the Björk et al. ATH with FXa was only slightly decreased by high salt or polybrene (215). Therefore it may

be concluded that covalent linkage of the  $\text{HNO}_2$ -produced LMWH to antithrombin prevents removal of the activating heparin species from the serpin by ionic media. Thus the Björk et al. ATH complex is at the same time potent in a variety of conditions and difficult to reverse if used for clinical treatment. Unfortunately, both the LMWH prepared using  $\text{HNO}_2$  and the resultant ATH had no measurable antithrombin activity (217). The lack of activity against thrombin is not surprising, given that short-chain LMWH cannot provide the template required for binding both antithrombin and thrombin (115,131).

Further development of ATH by conjugation of heparin and antithrombin using CNBr was accomplished by Mitra and Jordan (reaction scheme 3, Fig. 5) (218). UFH was activated at pH 10.7 with  $\sim$  a 57-fold molar excess of CNBr for 40 min at 23°C, after which excess CNBr was removed by dialysis under basic conditions. A cyanate/imino-carbonate/N-nitrile active group-containing heparin was then incubated with 0.02 moles of antithrombin per mole of GAG at pH 9.4 for 18 h at 5°C. Separation of free heparin from ATH and free antithrombin was accomplished by chromatography on immobilized Concanavalin A, and isolation of ATH from antithrombin was done using a heparin-sepharose column (218). A yield for ATH of 40% (in terms of antithrombin) was estimated. Complexes with antithrombin were also produced using LMWH (obtained by fractionation of UFH on gel filtration columns), but no further characterization of the products was done. Data on the products of this CNBr-based synthetic procedure are shown in Table 1. No information on the number of activating groups formed on the heparin molecules by CNBr (cyanate/imino-carbonate/N-nitrile) was given (218). However, given the molar ratios involved and that Mitra and Jordan suggest the use of glycine to block any excess active groups after conjugation to antithrombin (218,219), it is likely that more than one reactive group per GAG chain was obtained and that  $\geq 1$  heparin was conjugated to each antithrombin in the ATH complexes. Titrations of Mitra and Jordan ATH with thrombin and FXa suggested that essentially all of the complex had rapid, direct inhibitory activity. Also, the increased intrinsic fluorescence of heparin-activated antithrombin was observed with the Mitra and Jordan. ATH, which was not further enhanced by addition of UFH. The ability of CNBr-conjugated ATH to catalyze inhibition of either FXa or thrombin by added antithrombin (exogenous to the antithrombin in the covalent complex) was not clearly investigated. However, description of thrombin and FXa inhibition assays of the complex in plasma suggests that the inhibitory capacity was only that of the covalent complex (no significant catalytic activity) (218,219). The rate of reaction of the Mitra

and Jordan ATH with thrombin was investigated by generating inactivation time curves with equimolar enzyme and inhibitor concentrations (which allow for bimolecular rate constant calculation) (218). Results showed that the conjugate reacted with thrombin at a bimolecular rate of  $6.7 \times 10^7 \text{ M}^{-1}\text{s}^{-1}$  (Table 1). Interestingly, noncovalent mixtures of antithrombin + high affinity heparin gave a bimolecular rate constant for reaction with thrombin of  $2.0 \times 10^7 \text{ M}^{-1}\text{s}^{-1}$ , which was 3.3 times lower than that for ATH. The authors suggested the possibility that the ATH may react with thrombin at a faster rate than noncovalent antithrombin + heparin because certain equilibrium constraints which apply to the free component system (such as association of the serpin with the GAG) are circumvented by the covalent complex. Unfortunately, since the rate measurements were not done under first-order conditions (reactants not at 5-to-10-fold higher concentrations with respect to the enzyme being inhibited), comparison of absolute values for reaction rates of the noncovalent and covalent complexes cannot be done. No measurement of the rate of inhibition of FXa by the Mitra and Jordan ATH was reported.

More recently, a new approach has been put forward by Chan et al. (118) that utilizes the chemistry of glucose and plasma proteins occurring in diabetics (see Fig. 5). It has long been known that hemoglobin and various plasma proteins undergo Schiff base formation between the aldehyde function on  $\text{C}_1$  of plasma glucose and the  $\epsilon$ -amino of lysyl residues of the protein (220). This intermediate product is metastable and in equilibrium with the starting materials. However, as shown in Fig. 5, over time, a tautomeric rearrangement (Amadori) between protons and groups on  $\text{C}_1$  and  $\text{C}_2$  occurs to form an ene-ol-amine and finally a stable keto-amine (220). The formation of Amadori rearrangement products is dependent on glucose concentration, pH, temperature, and availability of amino functions. However, once formed, nonenzymatically glycosylated proteins have been shown to survive in diabetic tissue from weeks to years after hyperglycemic exposure (220). Reports have indicated that nonenzymatic glycation can have effects on protein function (221). In the case of antithrombin, brief increases in blood glucose concentration have been shown to result in short alterations of antithrombin activity without loss of protein (likely due to nonenzymatic labile Schiff base formation) (222). Significant decreases in antithrombin activity due to longer term glycation has been noted (223), which may explain some of the pathogenesis for thrombosis in severe diabetics (224). Moreover, nonenzymatic glycation of antithrombin in vitro (225) and in vivo (225) has been found to inhibit heparin-catalyzed antithrombin activity. Even more fascinating was that glycation-induced effects on heparin-catalyzed

antithrombin activity were completely reversed by incubation with excess Na heparin before assay (225). Therefore reaction of glucose with a particular antithrombin lysyl residue may be occurring to produce Schiff base/Amadori products that can be displaced by a large excess of heparin. Further evidence of selective glycation of antithrombin can be seen in that even in the presence of up to 5 mM glucose for 10 days, only 0.6 moles of glucose can be covalently bound per mole of protein (224). Although other literature has shown that a number of regions of the antithrombin molecule may form the keto-amine adducts, only one glucose per protein molecule could be yielded during incubations with up to 0.5 mM sugar (226)! Thus once one glycation site is affected, the probability of further glycation is drastically reduced. Given the effects of heparin on glycated antithrombin, the possibility arises that heparin molecules containing aldose residues of their own might be responsible for reversing (competing with) the Schiff base/Amadori structures being formed. Thus if UFH contained significant numbers of aldose-terminating molecules, it may be possible to form covalent ATH by simple incubation of unmodified UFH and antithrombin under the appropriate conditions. Previous work had shown that Schiff base/Amadori rearrangement of insulin by the disaccharide maltose can proceed (227). However, numerous workers had concluded that even Schiff base formation between polysaccharide aldoses and amino groups would be extremely limited because the aldose terminus represented a very small part of the sugar residues in the polymer, the equilibrium would be highly in favor of the hemiacetal (masked aldehyde) form, and significant steric hindrance for the approach of macromolecular amines seemed likely (228).

Chan et al. decided to test the hypothesis of ATH formation via Schiff base/Amadori rearrangement of UFH and antithrombin. It had been determined before that in commercial UFH preparations, approximately 10% of all molecules terminated in a free aldose (229). Since it would be desirable to have ATH complexes in which the antithrombin was activated by the covalently linked heparin, incubation conditions would need to be designed so that antithrombin molecules could have the opportunity to select for heparin with noncovalent pentasaccharide binding sequences that were close to the aldose end of the chain (118). Feasibility studies showed that nonenzymatic glycation of polypeptides by polysaccharide aldose was possible, but yields were greatly variable for a number of reasons (230). A format for ATH production via Schiff base/Amadori rearrangement was established. UFH and antithrombin from various sources were mixed in physiological buffer and heated for up to 16 days. Purification of the

ATH formed was by a two-step procedure of hydrophobic chromatography (to remove unbound heparin), followed by separation of unbound antithrombin on DEAE sepharose (118). Since it had been shown that incubation of antithrombin with monosaccharide aldose could increase the temperature for thermal denaturation ( $T_d$ ) (231), interactions at different temperatures were studied. Yields of conjugate (in terms of antithrombin) were observed to be ~5% at 37°C, while ~50% conversion of antithrombin to complex was observed at 40°C (230). Properties of the Chan et al. ATH are found in Table 1. Analyses indicated that ~ one molecule of heparin was combined with each antithrombin in the complex (118). This would be in agreement with the binding of a heparin chain to the antithrombin binding site (through the high affinity pentasaccharide), followed by Schiff base/Amadori rearrangement of the aldose terminus with a lysyl residue in the vicinity. Since no prior modification of the heparin was used before conjugation, the number of activating groups, anti-FXa activity, and anti-IIa activity of the heparin in the coupling reaction were those of the starting UFH. Surprisingly, the Chan et al. ATH was found to possess catalytic activity for the inhibition of either FXa or thrombin by exogenous antithrombin (Table 1) (118). Furthermore, the catalytic anticoagulant activity of the covalent complex was greater than that for either the starting UFH or heparin with high affinity for antithrombin (118). This startling result was proposed to be due to the selection, during incubation with antithrombin, of not only heparin chains with a pentasaccharide but some GAG molecules with more than one pentasaccharide unit. The presence of more than one high-affinity antithrombin binding site in a subpopulation of UFH molecules (1–3%) has been described before (119,232). Selection of this minor subpopulation of UFH chains by antithrombin was made possible by using a vast molar excess (>200 fold) of UFH to antithrombin during the synthesis (118). It was posited that, since the interaction of incubating antithrombin and UFH would initially be via noncovalent binding to pentasaccharide sequences, heparin chains with more than one high-affinity site might be preferred because the intramolecular mean distance of diffusion would be less than the intermolecular mean free distance of diffusion, and there is a higher probability that at least one site may be close to the aldose terminus (where covalent linkage would occur). Further studies confirmed that, in fact, the Chan et al. ATH did contain a significant number of molecules with more than one pentasaccharide (233). Given that formation of Chan et al. ATH involved simple incubation of unmodified heparin with the antithrombin, it was not surprising to find that direct reaction of the inhibitor with thrombin proceeded with a second-

order rate constant ( $3.1 \times 10^9 \text{ M}^{-1}\text{s}^{-1}$ ) that was one of the fastest ever recorded (118).

## B. In Vivo Performance

Further studies have been accomplished that investigated the in vivo properties of many of the ATH compounds described above. Investigations ranged from determination of pharmacokinetics to antithrombotic treatment of disease models in animals. Data for the different ATH products are given in Table 2.

ATH produced from the high-affinity fraction of UFH, according to the technique of Ceustermans et al. (192), has been tested for a number of characteristics in animals. Initial studies showed that, in rabbits, ATH joined to partially N-desulfated high-affinity heparin disappeared from plasma in a biphasic pattern with a short first phase ( $\alpha$ ) and a longer second phase ( $\beta = 0.65 \pm 0.06 \text{ h}$ ) (192). Further studies were carried out to characterize ATH made by joining hexyl-amino-substituted high-affinity heparin to antithrombin using diisothiocyanate. Using antithrombin linked to high-affinity hexyl-amino containing heparin (from UFH), disappearance from the circulation in rabbits could be described by a single phase with half-life of  $0.89 \pm 0.26 \text{ h}$  (192). Neither of these ATH complexes had half-lives that were more than  $\sim 3$ -fold longer than UFH in rabbits (single phase =  $0.23 \pm 0.03 \text{ h}$ ), and both were well short of the half-life of antithrombin ( $11.0 \pm 0.4 \text{ h}$ ) (192). As with UFH, covalent complexes of the hexyl-

amino containing heparin with antithrombin may be eliminated by binding of the heparin moiety to basic plasma and cell surface proteins; since it was shown that these conjugates could also bind to histidine-rich glycoprotein (148). In order to extend longevity in the circulation, ATH from high-affinity hexyl-amino substituted LMWH (3,200 and 4,300 MW, produced by partial depolymerization with nitrous acid) was prepared and the turnover parameters in rabbits measured (234,235). Both LMWH ATH complexes were lost from plasma with  $\beta$ -phase half-lives of  $\sim 7$ – $8 \text{ h}$  (Table 2). This disappearance rate for the high-affinity hexyl-amino LMWH ATH complexes was 30 times longer than that for UFH in rabbits ( $0.25 \pm 0.04 \text{ h}$ ). However, the half-lives of the unbound 3,200 and 4,300 starting high-affinity heparins were  $2.35 \pm 0.17 \text{ h}$  and  $2.50 \pm 0.18 \text{ h}$ , respectively, only  $\sim 3$  times shorter than the corresponding conjugates with antithrombin (234). In addition, it was claimed by the authors that the covalent complexes (Ceustermans et al. ATH prepared from high-affinity UFH or LMWH) possessed the ability to catalyze reactions with the animal's own antithrombin. Thus, even with an increased half-life, any antithrombotic properties might be determined by their rate of consumption by activated coagulation factors, as opposed to how long the compound or its metabolites remained in the circulation. The antithrombotic properties of ATH prepared from either high-affinity hexyl-amino UFH or LMWHs were tested in a Wessler rabbit thrombus prevention model (235,236). Anesthetized rabbits, injected with test compounds, were injected with

**Table 25.2** In Vivo Characteristics of Covalent Antithrombin–Heparin Compounds

Compound	Intravenous half-life (h)		Basic plasma protein binding	Bleeding characteristics	Antithrombotic activity (given equal mass concentration doses)
	$\alpha$ -Phase	$\beta$ -Phase			
1	<0.5	$0.65 \pm 0.06$	ND	ND	ND
2	$0.89 \pm 0.26$	—	Yes	ND	Same as noncovalent mixtures
3	1	$7.85 \pm 0.18$	ND	ND	Same as noncovalent mixtures
4	1	$7.63 \pm 0.75$	ND	ND	Same as noncovalent mixtures
5	>UFH?	—	ND	ND	ND
6	<3	—	ND	ND	ND
7	2.6	13	Low	Similar to UFH	Efficacy superior to UFH

*Definitions:* UFH = Commercial unfractionated heparin; ND = Not determined.

*Synthetic Methods:*

- Partially N-desulfated high-affinity heparin conjugated to antithrombin with tolylene-2,4-diisothiocyanate. (*Source:* Ref. 192.)
- Hexyl-amino substituted high-affinity heparin conjugated to antithrombin with tolylene-2,4-diisothiocyanate. (*Source:* Refs. 192, 214, 236.)
- Hexyl-amino substituted high-affinity low molecular weight heparin (MW = 3,200) conjugated to antithrombin with tolylene-2,4-diisothiocyanate. (*Source:* Refs. 234, 235.)
- Hexyl-amino substituted high-affinity low molecular weight heparin (MW = 4,300) conjugated to antithrombin with tolylene-2,4-diisothiocyanate. (*Source:* Refs. 234, 235.)
- Antithrombin reductively alkylated with anhydromannose-terminating heparin. (*Source:* Refs. 215, 217.)
- Antithrombin conjugated to CNBr-activated heparin. (*Source:* Refs. 218, 219.)
- Antithrombin coupled to heparin by Schiff base/Amadori rearrangement. (*Source:* Refs. 118, 230, 233.)

glass-activated plasma and stasis of a 2 cm length of isolated jugular vein induced for 10 min, followed by semi-quantitative analysis of the number and size of thrombi expressed within the vessel segment (236). Both effects of dosage and time delay from treatment to insult were examined. Results, up to 45–60 min after administration of anticoagulant, showed that all covalent complexes showed similar antithrombotic effects compared to that for injection of the same mass concentrations of the corresponding noncovalent mixtures of antithrombin + heparinoid. However, antithrombotic effects (reduction in size or number of thrombi) could be detected up to 60–120 min for the conjugates, due to the increased half-lives of ATH compounds compared to the corresponding free heparins (236). Hemorrhagic properties of Cuestermans et al. ATH produced from either UFH or LMWH have not been reported.

Information of *in vivo* use of Björk et al. ATH compounds is scarce. Dawes et al. have prepared ATH according to the method of Björk et al. and injected it, by intravenous bolus, into 12-week-old mice (217). Although no *in vivo* pharmacokinetic data were reported, administration of only three injections of small amounts of conjugate were necessary to obtain antibodies against the human antithrombin in the complex. Furthermore, interaction of radiolabelled ATH with hybridoma cells *in vitro* showed very low nonspecific binding to cell surface molecules (217). These data may suggest that the Björk et al. ATH complex has a low affinity for binding to proteins *in vivo*, which would enhance the half-life. Unfortunately, assay of the anti-FXa activity of the conjugate gave a very low activity (5.2 U/mg) and no definite indication exists of its antithrombotic properties.

Mitra and Jordan have tested their ATH *in vivo* (218,219). Rabbits were given intravenous infusions of 84 or 200 anti-FXa U/kg using either ATH or UFH, respectively, at rates of 2 mL/kg. On completion of infusion, blood samples were taken over time and the supernatant plasma tested for anticoagulant activity. It was noted that, compared to the UFH group, animals receiving ATH had a significant prolongation of functional activity (as measured by activated partial thromboplastin time assays) for up to 3 h after discontinuation of treatment (218). This result would suggest that, at lower doses, a longer period of anticoagulant prophylaxis can be achieved with the Mitra and Jordan covalent ATH conjugate compared to use of free UFH alone. It is likely that this effect would be due to a longer intravenous half-life of ATH prepared from CNBr-activated heparin, since elimination of UFH from the rabbit circulation at this dosage would be less than 3 h (237), and lower activity of ATH than UFH was administered. Nevertheless, direct determination of the loss of ATH compound by mass analyses of the plasma time sam-

ples were not reported, and antithrombotic efficacy was not investigated.

A significant number of experiments have been performed to evaluate the *in vivo* character of ATH produced by Chan et al. Bolus injection of the (keto-amine)-linked ATH into rabbits gave an intravenous  $\alpha$ -phase (two-compartment model) half-life of 2.5–2.6 h for both anticoagulant activity and mass (compared to 0.32 and 13 h for UFH and antithrombin, respectively) (118). Using a three-compartment two-exponential decay model,  $\beta$ -phase half-lives of 13 h and 69 h were calculated for loss of the ATH and antithrombin, respectively, from rabbit plasma. This terminal phase half-life was the longest ever reported for any ATH complex *in vivo*. Single subcutaneous injection of Chan et al. ATH resulted in systemic appearance of complex, which had peak concentrations at 24–30 h and could be detected up to 96 h after administration (118). However, only a small portion of the injected ATH was recovered in the plasma, indicating a very poor bioavailability of the subcutaneously administered Chan et al. compound. Given the long intravenous half-life of Chan et al. ATH, a likely explanation for the low total plasma levels of the subcutaneously administered adduct is that the large molecular size of ATH drastically reduced its permeability through extravascular tissue. This hypothesis led to the suggestion that Chan et al. ATH may be useful as an anticoagulant in sequestered spaces. One possibility is for anticoagulant treatment of respiratory distress syndrome in the lung (180,238–241), where administration of heparin is not useful due to ready loss of GAG to the circulation (21). Intratracheal instillation of keto-amine conjugated ATH into the lung airspace in rabbits led to significant anticoagulant activities and antithrombin antigen concentrations for up to 48 h after administration (118). Furthermore, no ATH protein could be measured in the plasma of the treated rabbits, indicating that ATH was retained in the lung without any leakage systemically. Functional activity of Chan et al. ATH as an anticoagulant on the alveolar surface of the lung is likely. Inhibition of thrombin generation in plasma on the surface of fetal distal lung epithelial cells *in vitro* was shown to be much more efficient with Chan et al. ATH than with similar concentrations of noncovalent mixtures of UFH and antithrombin (242). The superior efficacy of ATH on inhibition of epithelial-based plasma thrombin generation was due, in part, to the very rapid direct inactivation of initial thrombin feedback activation for the conversion of prothrombin to thrombin (242). Further tests to evaluate the antithrombotic potential of Schiff base/Ama-dori prepared ATH were carried out. ATH was compared to noncovalent mixtures of UFH + antithrombin in a rabbit treatment model of preformed jugular vein thrombi. Results showed that administration of a single intravenous

bolus of Chan et al. ATH caused a reduction in clot mass and fibrin accretion, whereas similar (by mass) injections of noncovalent mixtures of UFH + antithrombin led to an increase in clot size (237). Parallel experiments using a rabbit bleeding ear model showed no significant difference in cumulative blood loss between covalent complex and noncovalent mixtures of UFH and antithrombin (237). Thus Chan et al. ATH was not only a highly potent antithrombotic but could be used effectively at safe doses. Data from the thrombosis treatment model were suggestive of the possibility that the conjugate tested may function via the direct noncatalytic inhibition of clot-bound thrombin. As stated earlier, noncovalent antithrombin · UFH has significantly reduced activity against fibrin-bound thrombin compared to that against fluid-phase thrombin. Further investigations with soluble fibrin have shown that the keto-amine adduct of antithrombin and heparin can directly inhibit fibrin-bound thrombin with a similar rate constant to that of thrombin in buffer only (243). This finding has major implications regarding possible indications for the clinical use of ATH. One rationale for the lack of effect of fibrin on the inhibition of thrombin by Chan et al. ATH is that binding of the ATH heparin chain to fibrin is reduced, due to steric hindrance by the covalently linked antithrombin. In that case, ATH heparin would not be able to form a ternary complex with fibrin and thrombin. Additionally, it has been noted, from comparison of the catalytic anti-FXa and antithrombin activities of ATH in either plasma or buffer, that the effects of nonselective plasma protein binding on the anticoagulant properties of Chan et al. ATH are reduced compared to those of UFH (private communication from the author). Given the Schiff base/Amadori mechanism by which antithrombin and commercial UFH combine to form Chan et al. ATH, the fascinating possibility presented itself that such a reaction may, in fact, occur spontaneously during the clinical use of UFH. Attempts were made to isolate ATH from plasmas of rabbits and a human injected subcutaneously with UFH (230). Using preparative procedures similar to that employed by Chan et al. for purification of their ATH, covalent adducts of heparin and antithrombin were detected in plasma samples of UFH-treated rabbits and humans (230). Thus given that endogenous, nonprotein linked heparin chains are known to circulate in humans (244–246), it is apparent that Chan et al. ATH may be a natural product.

## VI. COVALENT ANTITHROMBIN-HEPARIN COMPLEXES: ATTACHMENT TO POLYMER SURFACES

### A. Biochemical and Chemical Overview

Biomaterials that come into contact with blood have a number of limitations. First, cells such as platelets and

polymorphonucleocytes can bind to the foreign surfaces and become activated (247,248). Second, binding of plasma proteins can cause modification of the surface properties towards other molecules or cells. The noncovalent plasma protein absorption encourages cells and other materials to bind in a layered effect that may even lead to constriction or change in the laminar flow characteristics of the blood. Third, interaction of some biomaterials with the blood cells or surrounding tissue can invoke inflammatory processes (249). In this case, inflammation can be the result of a plethora of factors such as providing a surface for infectious agents that induce inflammation, damaging blood cells or tissue that respond by arachidonic acid metabolism, and generating products at the biomaterial surface that are secondary to the inflammatory pathway. Fourth, the polymer composition or functional groups within the matrix of biomaterials may either contain epitopes or react with the blood to produce epitopes that cause an immunogenic response. Induction of complement activation by surface membranes, such as those used in dialysis, may actually exacerbate recovery of the patient (250). Finally, the surface may be procoagulant. Of all the problems listed above, surface-induced activation of the coagulation cascade is probably the most common difficulty encountered with blood-contacting materials. Materials are often coated on the polymeric surface in order to decrease the procoagulant nature of the foreign agent. However, such coatings frequently suffer from either incomplete anticoagulation of the entire surface or long-term instability, whereby the coating becomes modified to render it inactive, or some of the coated molecules are lost to the circulation (leaving part of the material unprotected and producing a systemic anticoagulant effect).

Covalently coupled antithrombin and heparin is an agent that may provide a surface covering that could overcome a number of the inherent blood incompatibilities of synthetic products. First, since antithrombin is often found noncovalently bound to the heparan sulfate (heparinlike) proteoglycans on the luminal surface of blood vessels (251), ATH could be a very good model for the native vein or artery. Second, since the heparin portion of ATH already has permanently attached antithrombin, it is less likely that absorption of other proteins in the blood will occur, for steric reasons. Third, both antithrombin and heparin have been shown to have anti-inflammatory properties. Heparin coated surfaces have long been known to possess reduced inflammatory effects due to decreased humoral, cellular, and complement activation by this very negative polymer (252). More recently, however, antithrombin has also been identified as having an anti-inflammatory effect in such conditions as septic shock (253). Fourth, since both antithrombin and heparin are natural products occurring in the human vascular system, very little immune response

should be engendered by their combination. Low antigenicity should certainly be possible for the ATH produced by Chan et al., given that it is produced by spontaneous Schiff base/Amadori rearrangement of unmodified, native antithrombin and UFH. As would be expected, ATH should have potent anticoagulant activity for the direct inhibition of thrombin. However, once the covalently linked antithrombin in ATH is consumed by thrombin, FXa, etc., any further anticoagulant activity of a biomaterial coated with the conjugate would have to come from the heparin moiety. Thus not all ATH products may be as effective in providing a long-term, highly potent anticoagulant surface. Again, the high catalytic activity of the Chan et al. ATH towards inhibition of thrombin by plasma antithrombin in the patient would be a significant advantage for ongoing pacification during insults leading to thrombin generation near or at a biomaterial surface.

One ancillary advantage for the coating of biomaterials with ATH compared to heparin involves technical issues. Since antithrombin has a greater variety of functional groups than heparin, there is a wider range of chemistries available for covalent as well as noncovalent attachment of the serpin than that of the GAG. Carbamate, guanidinium, imidazole, indole, and phenolic groups on the protein allow for selective linkage of ATH through antithrombin, instead of the heparin chain. In addition, antithrombin's 37 lys residues (human) provide a very enriched amino content compared to heparin (192). Thus coupling reactions involving  $\text{NH}_2$  functions would be strongly biased towards selection of  $\epsilon$ -amino groups on antithrombin, as opposed to the serine amino or the small number of glucosamine residues on heparin. Since the  $\text{NH}_2$  group has itself a large number of reactivities, connection of the surface or surface-spacer arm to ATH via primary amino functions on antithrombin would be an easy operation with the number of commercial reagents and conditions available. As alluded to above, noncovalent binding of biomaterial surfaces to the antithrombin of ATH is feasible. It has been shown that the Chan et al. ATH and antithrombin can be separated from free heparin by hydrophobic chromatography on butyl-agarose (118), which verifies that hydrophobic surface absorption of ATH would be through the serpin and not the GAG component. Again, this is advantageous in that it is preferable to bind ATH to the blood-contacting surfaces through the antithrombin, thereby allowing the heparin to be directed out into the fluid phase. Stronger attachment of active molecules to biomaterials, using antithrombin as the link point, would result if multiple covalent bonds from the surface to ATH are formed. The number and variety of amino acid R groups in the ATH protein lend a greater efficacy for joining the conjugate to the surface by several bonds, which would give a more stable coating that is less likely to be removed in vivo. Moreover,

if heparin were joined to the biomaterial surface through many link-points, the likelihood that the pentasaccharide sequence will be adversely affected would increase significantly. Also, surface binding of heparin by bonds at several positions will almost certainly cause steric problems for the approach of either plasma antithrombin or thrombin during catalytic inhibition (the orientation of the heparin is improper). In fact, this is the major reason for the significantly superior commercial performance of blood-contacting products that have end-point-linked heparin, compared to those that do not. One other factor that makes coating with ATH advantageous is, simply, the dual functioning of the conjugate. Covering polymer surfaces can be done with either direct (hirudin) or indirect (heparin) thrombin inhibitors. In favor of the direct (noncatalytic) inhibitors is the rapid reaction with thrombin that is not limited by the requirement of a secondary molecule (is not affected by the metabolic environment of the patient to supply an inhibitor or cofactor). On the other hand, surface-bound indirect (catalytic) inhibitors would not be limited to a single knockout of thrombin but could, essentially, enable the inhibition of limitless amounts of ongoing thrombin generation, as long as they are supplied with plasma phase inhibitor molecules. Chan et al. ATH combines both very rapid noncatalytic and potent catalytic inhibition of thrombin in the same molecule. Therefore coatings with Chan et al. conjugate may, in the short term, quickly eliminate small amounts of thrombin that cause feedback activation when biomaterials are first in contact with blood, as well as catalyze the reaction of plasma antithrombin + thrombin for long-term patency.

## B. Characteristics of Coated Surfaces

At present the only ATH product that has been attached to a biopolymer is the Schiff base/Amadori rearrangement or keto-amine linked conjugate prepared by Chan et al. Preliminary testing of the material, in vitro and in vivo, has shown promise for the conjugate when covalently linked to grafts composed of synthetic polymers that are found in commercial use.

ATH has been linked to two types of polyurethane. One is a polymer of polycarbonate with urethane extenders and the other material is an ester-grade polyurethane. The polycarbonate urethane tubing used was composed of a finely threaded material that in some cases was woven around a flexible stainless-steel wire mesh in order to provide further elasticity for application as an endoluminal vascular graft. This polycarbonate urethane came in several diameters and was produced by Corvita Corporation under the trade name Corethane™. The other material utilized in investigations was composed of a pure polyurethane that contained no plasticizers and low levels of extractables.

Pure polyurethane tubing was a clear, flexible, impermeable product that had resistance to fuels, oils, and a number of hydrophobic solvents. Developed by Nalgene, pure polyurethane conduit came in several wall thicknesses and was ideal for quick assessment of results from the different chemistries tested for graft polymers prepared to covalently link ATH to devices, etc.

Chan et al. ATH was attached to polymer surfaces and tested for various properties (254). Attachment was covalent and involved linkage to a graft poly/oligomer on the two types of polyurethane tubing described above. Chemical bonding was performed in three stages and is shown schematically in Fig. 6. Polycarbonate urethane was activated by reaction with NaOCl, after which the resultant N-chloro urethane groups were incubated with an initiator (i.e.,  $\text{Na}_2\text{S}_2\text{O}_4$ ) and a functional group containing monomer (allyl glycidyl ether). After reaction with the activated urethane surface, the tubing was washed and there was incubation with ATH for covalent linkage between the graft epoxide groups and lysyl amino groups of antithrombin in the ATH. Under the conditions employed, it has been shown previously that oligomers of the grafted species containing from 1 to 4.6 monomer units per urethane group can be obtained on the average (255,256). This polymer chemistry is based on the general mechanisms of radical-initiated polymerization on poly(N-chloroamide) donor

**Figure 25.6** Covalent coating of antithrombin-heparin conjugates onto polyurethane.

surfaces (257). Literature reviews have concluded that surface coating relies on a number of parameters such as surface area and mode of drug attachment (258). Therefore all steps in the process must be appraised. Preliminary tests on the pure polyurethane Nalgene surfaces verified that grafting of the epoxide materials had occurred. After reaction had taken place with the allyl glycidyl ether, the pure polyurethane tubing became cloudy, and a fine film could be observed that was strongly bound to the surface. Pre-reaction of NaOCl activated polyurethane followed by addition of the monomer (no initiator) did not result in coated surfaces nor did omission of any one of the reaction components. Epoxide group activity on the pure polyurethane grafted with propyl glycidyl ether was evident by the quenching of colored 2-nitro-5-thio-benzoic acid. Thus active surfaces could be prepared for covalent coupling of ATH. Coating of polycarbonate urethane with ATH was verified by staining of the protein or GAG present on the surface (259).

Immobilization of heparin and hirudin (one of the most potent direct thrombin inhibitors known) onto surfaces has been studied for some time. Hirudin has been bound to clinically used biomaterials by a number of methods (260,261). Significant coating densities with hirudin have been achieved with a surface character that gave efficient thrombin binding and inhibition. However, because hirudin-thrombin complexes are not covalent and only one thrombin can be inactivated per hirudin molecule, attempts have also been made to investigate the properties of heparinized biomaterials. Very ingenious methodologies have been developed to adapt heparin for use in a wide range of synthetic clinical devices. Only one such example is the bonding of heparin to bileaflet valves using a coating of graphite-carbon and benzalkonium chloride (262). However, the most viable structures for anticoagulating surfaces with heparin have been shown to require end-point attachment of heparin chains (263). This conclusion is consistent with the concept that active heparin molecules must be directed away from the surface in order to prevent surface activation of coagulants from the blood flow or surrounding tissue. In fact it has been deduced that the critical action of heparinized biomaterials is to mediate inhibition of the coagulation cascade leading to prothrombin activation (thrombin feedback reactions?) (263). Unfortunately, simple end-point binding of heparin chains to the polymer surface is not sufficient for good thrombin inhibition. A series of experiments have demonstrated that heparin that was directly covalently linked to polystyrene containing hydrophilic groups could not efficiently catalyze formation of thrombin-antithrombin complexes (17). In order to effect optimum anticoagulant activity of heparin on the surfaces, end-point attachment of the GAG to spacer arms

(>2,000 MW) is necessary (17). As a final caveat, in an attempt further to fortify heparinized surfaces, either free heparin has been coimmobilized on the same surface with antithrombin (264), or surfaces with covalently bonded heparin have been presaturated with free antithrombin (265). Although a mild improvement for thrombin inhibition has been noted, optimum arrangement of the antithrombin and heparin have not been achieved. Thus surface coating with a significant density of antithrombin and heparin that yields rapid, high-capacity inhibition of thrombin is desirable. Analysis of the ATH coated polycarbonate urethanes presented an excellent opportunity for testing the viability of attaching high-activity heparin to the surface through antithrombin itself.

Higher substitution of Chan et al. ATH on polycarbonate urethane was observed than that with either heparin alone (259) or hirudin (254). This verifies that covalent ATH has superior chemical features for attachment of the heparin containing anticoagulant. Storage properties of the ATH coated surface are favorable, since treated biomaterial could be utilized as an endoluminal graft *in vivo* after incubation in sterile saline at 4°C for minutes to months, with similar results (259). Even though ATH was likely covalently bonded through the antithrombin moiety to the propyl glycidyl linker on the surface, the immobilized ATH exhibited significant direct noncatalytic activity against thrombin (254). Thus polymer surfaces could be created with ATH coatings that have long-term rapid inhibitory action towards thrombin, which does not require a supply of antithrombin from the patient. However, binding experiments with labeled antithrombin indicated that significant surface concentrations of pentasaccharide sites were readily accessible on polycarbonate urethane coated with the Chan et al. ATH (259). High-affinity binding of antithrombin to the surface strongly suggests that ATH coated material can potentiate the reaction of plasma antithrombin with thrombin. Given the high catalytic anticoagulant activity reported for the keto-amine conjugated ATH, significant surface-associated catalysis of antithrombin reaction with thrombin would be expected from ATH coated biomaterials, provided that the coating process had oriented the heparin away from the polymer. The exogenous antithrombin binding results suggested that the ATH covered polycarbonate urethane product likely possesses the desired catalytic capacity (259).

*In vivo* experiments were performed to examine if the ATH coated endoluminal grafts had biological effectiveness that corresponded to the substitution density and antithrombin activity results observed *in vitro*. Endoluminal tubing (treated and nontreated) was deployed by a wire plunger through a narrow-gauge catheter into the jugular veins of anesthetized rabbits. No anticoagulant was admin-

istered to the animals and, after 3 h, the tubing segments were recovered and the weight of clot adherent to the device determined. Significant improvement with respect to tubing anticoagulant properties resulted from coating with ATH. A four- to fivefold reduction in weight of clot generated on the tubing was observed with ATH coated compared to nontreated surfaces (254). This improvement in antithrombogenicity of the biomaterial was not gained due to the presence of grafted propyl glycidyl groups, since tests with these control surfaces (no ATH attached) were negative (259). Furthermore, *in vivo* experiments with polycarbonate urethane coated with antithrombin gave results similar to those with surfaces that were reacted with allyl glycidyl ether alone. Thus, not surprisingly, the heparin moiety of the surface bound ATH was critical. Finally, hirudin was bonded to polycarbonate urethane in a fashion similar to that of ATH, followed by testing in the rabbit jugular vein. *In vitro* analyses of the tubing showed that most of the hirudin bound to the endoluminal graft could inhibit thrombin directly. However, significantly more clot was generated in the hirudin tubing than in the ATH tubing *in vivo*. Therefore ATH coated surfaces have greater potency than surfaces that are coated only with highly active direct thrombin inhibitors. The dual noncatalytic and catalytic anticoagulant activities of ATH may represent a new generation of pacified biomaterials.

## VII. THE FUTURE

ATH is an agent that, either in fluid phase or surface immobilized form, pacifies the coagulation system *in vivo*. The fact that, with optimum methodologies, the highest activity heparin can be selected by antithrombin during conjugation, gives a significant advantage for prevention and treatment of coagulation, as well as the construction of highly anticoagulant surfaces for clinical use. A number of investigations are necessary in order to realize fully the potential applications of ATH. Long-term use of fluid-phase ATH in animals needs to be evaluated for its application as a prophylactic. Furthermore, a number of clinical procedures could be studied to determine the value of ATH treatment during surgery. ATH may also be efficacious for the treatment of deep vein thrombosis and RDS. Animal models of these pathological states exist that could be used to challenge the viability of ATH as a treatment agent. Linkage of the conjugate to a variety of polymers must be done to determine the optimum type of biomaterials for coating with ATH. In conjunction with the type of surface material is the investigation of other more sophisticated chemistries that could link to the antithrombin in ATH via amino acid R groups other than that of lysine. Although the lysine ε-

amino is a standard for protein immobilization, the heparin in ATH may tie up some of the key residues. Once the chemical details on ATH attachment to biomaterial surfaces have been determined, in vivo experiments in a number of animal models will be required to evaluate the best indications for use. Finally, clinical trials will be necessary before commercial use of either fluid-phase ATH or ATH coated biomaterials is possible.

## Adhesives for Medical Applications

Iain Webster and Peter J. West

*Smith & Nephew Group Research Centre, York, England*

### I. INTRODUCTION TO MEDICAL ADHESIVES

The area of medical adhesives is very broad and encompasses a variety of technologies that can be applied to a wide range of medical products and procedures. This technology already has a long and well-documented history, but, not surprisingly, as a result of the advances in health care, there are many new adhesives emerging to meet our demands for the future.

In this chapter we discuss medical adhesives for use in products that are applied directly to the body or used in surgery inside the body. This covers the areas of pressure-sensitive adhesives (PSAs) and tissue adhesives, which can be further divided into synthetic and biological adhesives. The scope of this chapter is shown in Fig. 1.

Investigations in pressure-sensitive adhesive technology have concentrated in recent years on materials that can do more than simply adhere medical dressings to a wound. Since the gradual replacement of rubber resin-based adhesives for medical applications with synthetic polymers, researchers have utilized the wide range of possible formulations to tailor adhesive properties to meet specific needs. Having a greater understanding of the skin as an adhesive substrate, formulators have been able to produce PSAs that form a vital part of modern wound dressings.

The use of surgical tissue adhesives in medicine has developed considerably over the last 40 years, and the list of applications is now increasing every year. Traditionally, the area of tissue reattachment or repair following surgery

or trauma has been dominated by sutures, staples, and wiring, but recently the huge commercial potential for tissue adhesives has sparked a minirevolution in medical practices. Ultimately the general acceptance of new tissue adhesives will mark a step change in clinical practice.

The approach to developing new adhesives relies on understanding the different and often complicated requirements of various tissue types and a large number of surgical procedures. This understanding can only be gained by researchers working closely with medical professionals in hospitals and clinics. Equally, medical practitioners need to be prescriptive about their needs and be willing to contribute to, and ultimately accept and promote, new and exciting developments. With this challenge in mind, it is becoming possible to provide better products for us all as potential patients.

### II. PRESSURE-SENSITIVE ADHESIVES

#### A. Introduction

Typically, pressure-sensitive adhesives have been used for adhering wound dressings to skin. PSAs have glass transition temperatures ( $T_g$ ) or softening temperatures in the range  $-20^{\circ}\text{C}$  to  $-60^{\circ}\text{C}$ , which means they are soft materials at room or skin temperature. These soft polymers are able to flow and “wet out” on to a surface and are formulated to be permanently tacky to enable adherence to that surface. The bond formed between PSA and substrate is not permanent and can be broken with a measurable force,

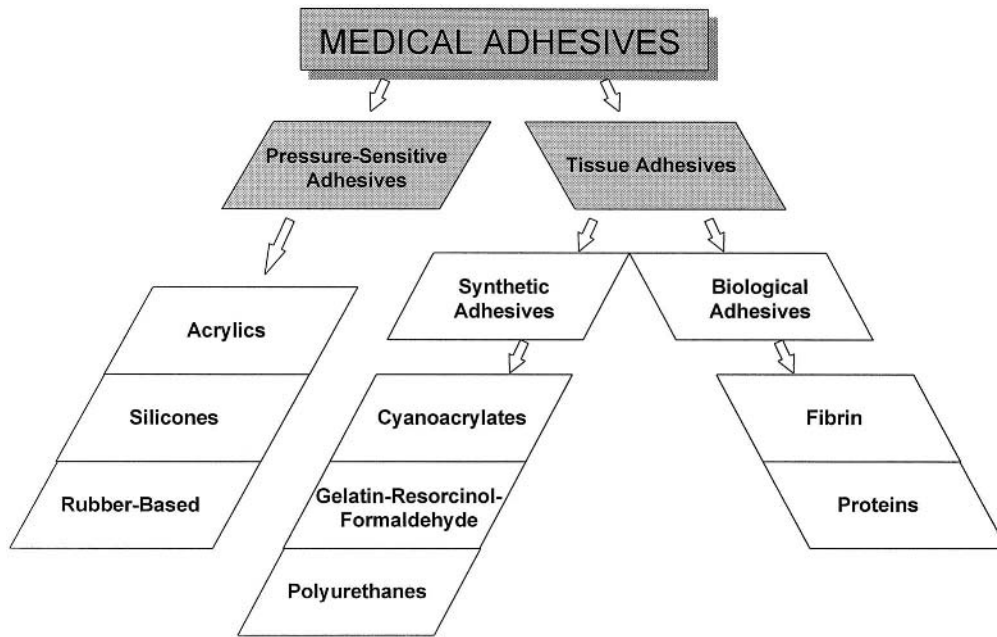

Figure 26.1 The scope of medical adhesives.

leaving the substrate relatively free from damage. Since the mid-19th century, when the first adhesive plasters were reported (1), the hospital and first aid applications of dressings have become more demanding, and the polymers used for PSAs have consequently undergone significant devel-

opment (2) (Fig. 2). Early adhesive formulations were based on blends of natural rubber and resins derived from wood rosin, which act as tackifiers. However, a PSA is required to be more than just sticky. The adhesive should be permanently and aggressively tacky, adhere with only

Figure 26.2 The development of first aid dressings; from early elastic adhesive bandage sold under the trade name *Elastoplast* to the modern day waterproof, breathable, absorbant, conformable dressings that also act as bacterial barriers.

slight finger pressure, form a strong bond with surfaces, and have sufficient cohesiveness that it can be removed without leaving a residue.

The properties for medical PSAs are made yet more demanding by the requirements for skin contact. Foremost is the need to be chemically and biologically acceptable to the skin, with the adhesive causing no irritation or sensitization. Skin is also very variable, both between individuals and even between different sites on the same individual. The roughness, elasticity, and surface energy of the skin must be taken into account, which means that adhesives must have sufficient flow to ensure intimate surface contact (3). Additionally, medical adhesives must be able to cope with moisture and sebum exuded by the skin without severely compromising performance. Finally, once securely adhered to the skin, medical PSAs should be easily removed with minimal trauma to the skin. Although this may appear to be a contradiction, recent developments in PSA technology have endeavored to solve this problem.

The last thirty years have seen the gradual replacement of rubber adhesives with acrylic copolymers, which now dominate the medical adhesive market. These acrylic copolymers are naturally tacky materials and have eliminated the need for the large number of components present in rubber PSAs, such as natural rosins. This reduction in potential for introducing irritant and sensitizing agents has led to a broad acceptance of acrylic PSAs within health care due to their natural hypoallergenicity (4).

Although polyacrylates are used widely and generally for medical PSAs, typically the polymer selected for a

given PSA is directed by the application for which it is required (5) (Table 1). This section therefore describes the range of indications that require formulated medical grade adhesives and the properties required of the polymeric materials used. We will also detail the polymer types that are used to formulate these adhesives.

## B. Indications and Adhesive Requirements

### 1. Adhesion To Skin

Skin is a very demanding and variable substrate for adhesive bonding, and consequently the properties of medical grade PSAs have to be adaptable. Skin is a rough surface, which requires the PSA to have good flow characteristics to enable it to form a good bond. Skin also flexes, which results in the adhesive being subject to various stresses as well as changing the angle of peel when tapes are removed. Furthermore, sebum and moisture exuded by skin may affect not only its surface energy but also its adhesive properties. Many studies have been made of the physical properties required of a PSA to produce good skin adhesives (3,6–8). The main properties that dictate adhesive performance are the surface energy of the PSA compared to that of skin and also the bulk rheological properties of the adhesive polymer.

#### a. Surface Properties

In order to provide a satisfactory bond, an adhesive must wet the skin surface. This requires that the surface energy

**Table 26.1** Polymers Used in the Formulation of Medical Grade PSAs

Polymer	Application	Property
Silicone	Transdermal drug delivery	Chemically inert Biocompatible High drug permeability
Polyvinyl ether	Skin patches/surgical dressings	Moisture permeability
Polyvinyl pyrrolidone	Ostomy	Moisture absorption
Polyacrylate	Transdermal drug delivery	Chemically inert Good drug release properties
	First-aid dressings	Quick adhesion Adhere during normal daily activity
	Electromedical devices	Good, long-term adhesion
	Surgical dressings	Moisture permeability
	Incise drapes	Sterilizable Wet stick
Hydrophilic gels	Surgical tape	Sterilizable
	Electromedical applications	Electrical conductivity Moisture absorption
Rubber resins	First-aid dressings	Quick adhesion Adhere during normal daily activity

**Table 26.2** Variation of Surface Energy of Human Skin with Temperature and Relative Humidity

Temperature (°C)	Relative humidity (%)	Total surface energy (J/m <sup>2</sup> )
23	34	0.038
23	50	0.042
28	60	0.054
32	56	0.051
33	51	0.057
36	50	0.057

of an adhesive must be lower than that of the skin. The surface energy of skin increases with increasing temperature and relative humidity, as sweating produces a high-energy surface (8). This is illustrated in Table 2. The surface energy of a commercially available medical grade acrylic PSA is shown in Table 3 for comparison; it can be seen that humidity does not significantly affect the adhesive. The incorporation of polar monomers into acrylic PSAs has been shown to provide improved adhesion to skin during sweating, when the surface energy is higher (8). This is thought to be enhanced due to interfacial interactions between the adhesive and the skin surface.

#### b. Adhesive Peeling from Skin

The peeling of a PSA spread tape from a standard substrate is the most common assessment made of adhesives. This involves the measurement of the force required to peel an adhesive, spread onto a flexible backing, from a substrate following adhesion under controlled conditions of pressure and buildup time. The force required is dependent on the peel angle (typically 180° or 90°) and peel rate (estimated for removal of PSA tapes from skin as between 12 and 200 inches per minute). Although this type of test allows differences between adhesives to be identified, it is unrepresentative of how any given PSA will peel from skin.

**Table 26.3** Variation of Surface Energy of Acrylic Medical-Grade PSA with Relative Humidity

Relative humidity (%)	Total surface energy (J/m <sup>2</sup> )
10	0.027
20	0.027
42	0.028
52	0.026
81	0.027
100	0.025

Skin, as a peeling substrate, is rough, has a variable surface energy, and is flexible, whereas most data for peel adhesion has been determined using stainless steel as the substrate. The difficulty in reproducing skin as an *in vitro* substrate is demonstrated by the lack of suitable models developed over the years. Attempts have been made to model the surface energy and roughness using embossed polypropylene plaques (3) or a hydrated cross-linked gelatin/lipid substrate (9) with varying degrees of success.

#### c. Skin Stripping and Trauma

The requirements that a medical-grade PSA should adhere well to skin and yet be easily removed with minimal trauma are obviously contradictory. When an adhesive tape is removed, a layer of skin is also removed, because the separation is not at the skin–adhesive interface but deeper into the stratum corneum (4,10). The stripping of this surface barrier compromises the skin's ability to regulate fluid balance as well as its ability to protect from chemical, mechanical, and microbial effects (11). Research has been carried out for many years to devise a PSA that can be removed without causing damage or trauma to the skin while giving sufficient adhesion when required. However, a fundamental understanding of the interaction between the skin and adhesive is required to allow solutions to be explored (12).

Studies carried out using occlusive and nonocclusive tapes have shown that the buildup of moisture behind occlusive tapes results in hydration and therefore weakening of the stratum corneum. This means that the levels of adhesion between the outer layers and the adhesive are greater than the internal strength of the stratum corneum. Hence when tapes are peeled, layers of skin are also removed with the adhesive (4). Repeated application of a tape to the same site produces higher peel forces as the deeper epidermal cells have increased cohesion (Fig. 3). When more porous tapes and adhesives are used (i.e., changing from a hydrophobic rubber resin to a more hydrophilic acrylic adhesive), the moisture content of the skin is maintained and therefore so is its strength. This type of approach has enabled the development of adhesive dressings that can be removed with less trauma to the skin based on thin polyurethane films coated with moisture vapor permeable adhesives. Dressings based on this theory, typically surgical drapes and tapes, do not therefore cause maceration of the skin but do allow moist wound healing.

## 2. Wound Management Indications

The largest segment of the medical adhesive market is that for the protection of wounds. This diverse sector includes adhesive bandages, surgical drapes, ostomy bag mounts,

**Figure 26.3** Force of removal of adhesive tapes peeled from a defined area of human back skin. (Graph reproduced from Ref. 4.)

intravenous needle attachments, electromedical procedures, microporous tapes, and transdermal drug delivery (5) (covered more extensively in Section II.B.3). The adhesives used in the majority of wound care applications are based on acrylic copolymers, although rubber-based PSAs (natural or synthetic) are still used where high levels of adhesion are required and skin irritation is not a major concern. The backing materials used with the adhesives range from foams to porous materials such as nonwovens, cotton and fabric, and polymeric films such as polyethylene and polyurethane.

Ostomy appliances require a PSA to perform two roles, firstly to provide a good seal around the device to prevent leakage of fluids around the stoma, and secondly to secure the device to the body. The adhesive must also be designed to allow prolonged and repeated application to the same site without causing significant skin deterioration by mechanical or chemical irritation. Acrylic adhesives were often found to be unsuitable for this application, as they did not provide a good seal around the stoma (5). However, several patents exist that describe soft acrylic PSA copolymers that provide good adhesion over prolonged wear times (13,14). The advent of acrylic hot melt PSAs has provided new materials suitable for this purpose. Other adhesive types include blends of acrylic/rubber components (15), polyisobutylenes (16), and vinyl ether copolymers (17).

PSAs for electromedical applications are used to provide an electrical connection between the skin and an electromedical device (5). Traditionally, a conductive gel in contact with a metal electrode was used and held in contact with the skin by a pressure-sensitive tape. However, more

recent developments have seen the adhesive designed to both hold the electrode in place and provide a conductive medium (18,19). Typically, adhesives for this application are cross-linked hydrophilic polymers swollen with water (20). Examples include an ultraviolet curable PSA synthesized from acrylic acid and a multifunctional acrylate as cross-linking agent (21), an electron beam curable composition of polyvinyl pyrrolidone, polyethylene glycol, and water (22), and a PSA comprising cross-linked sodium carboxymethyl cellulose and polyisobutylene swollen with water (23). A hydrophilic PSA has also been described that comprises a zwitterionic polymer blended with a plasticiser (24). It is claimed that the zwitterionic functionality imparts high conductivity to the adhesive, making it suitable also for use as a matrix for iontophoretic delivery of drugs (Section II.B.3).

The acceptance of moist wound healing as most appropriate for rapid healing (25) has led to the development of occlusive thin film dressings capable of maintaining the correct wound environment (26). The first dressing of this type was introduced in 1971 by Smith & Nephew under the tradename *OpSite*<sup>™</sup>, which comprised a polyurethane film spread with a vinyl ether adhesive (27). Other semiocclusive dressings were developed along similar lines based on polyurethane or copolyester backing films with an acrylic PSA. Moist wound healing was found to enhance the rate of experimentally induced wound resurfacing by up to 40% compared to air exposed wounds (28). It was therefore important that the dressing was capable of striking the balance between exudate handling and maintaining a moist environment. The moisture vapor transmission rate (MVTR) of the dressing and therefore the PSA played an important role in achieving this, as the thin film dressing could not absorb much moisture from the wound. The adhesive was required to have a MVTR (measured according to ASTM E96) greater than that of skin, which varies depending on the body site and skin condition (Table 4) (28). Changes in the polarity, porosity, and thickness of the ad-

**Table 26.4** MVTR for Intact Skin and Varying Wound Types

Body site/wound type	MVTR (g/m <sup>2</sup> /hr)

Tegaderm™ HP	3M	450	1300

hesive provide control of the MVTR. Dressings based on the moist wound healing principle were required to cope with both lightly exuding wounds, requiring a low MVTR film and PSA, and high levels of moisture such as that experienced with invasive catheter fixation (Table 5) (28). *OpSite™* IV 3000 (Fig. 4) used a specially developed emulsion-based acrylic PSA that was pattern spread to cover 75% of the film area to ensure optimum MVTR while maintaining good skin adhesion.

### 3. Transdermal Drug Delivery

PSAs have been used in transdermal delivery devices since the 1970s and have been found to offer many advantages over conventional methods for the controlled delivery of drugs (29). Transdermal drug delivery involves the delivery of an active ingredient through the skin and into the blood vessels before delivery to the target organ. This provides a constant rate of drug delivery that leads to stable levels within the blood that correlate more closely to those obtained for intravenous drug infusion (30). This technique allows the use of lower doses of drug than with oral medication and avoids the variable blood level profiles typically

**Figure 26.4** Catheter fixation using *OpSite™* IV 3000\* film dressing. (\*Trademarks of Smith & Nephew.)

seen with other systems. Transdermal drug delivery therefore allows more effective and safe dosing to achieve the desired therapeutic result. Patient compliance is also likely to be higher, as the dosing regime may require only a single dressing change per week, and the delivery can be stopped by removing the adhesive patch.

Conventional uses of transdermal delivery systems have included patches for the release of nitroglycerin for antian-ginal products (31), scopolamine (motion sickness), clonidine (hypertension), glycol salicylate (analgesia), and nicotine patches for smoking cessation. Such developments produced an industry generating annual sales of \$1.7 billion in 1998, sales are estimated to continue growing as new drugs are proposed for transdermal delivery (29).

Transdermal drug delivery patches may be split into two basic types (29,30,32) with the drug being held either in a reservoir by a permeable membrane and adhered to the skin using a PSA, or in a matrix system where the drug is incorporated directly into the adhesive polymer (Fig. 5).

The adhesive chosen for transdermal applications must not only display the characteristics of a good skin adhesive but also be compatible with the drug so as not to alter its characteristics and, in the case of the matrix design (Fig. 5b), have the correct drug/adhesive solubility relationship. The polymers that meet these criteria tend to be silicones, acrylic copolymers (33), and polyisobutylene (29,32). Silicones, although the more expensive of these options, tend to offer the highest drug diffusion rates as well as being easily formulated to give the right adhesive properties. Acrylate copolymers can also be easily modified to optimize drug solubility, by controlling the hydrophilic nature of the polymer, diffusion, and adhesion. Polyisobutylenes provide more of a challenge to tailor their properties to transdermal drug delivery, but they are particularly suited for use with drugs of low solubility or polarity.

Many studies have compared the relative performance of these three polymer types for their suitability as drug delivery vehicles. Firstly, the ability of an adhesive to provide long-term adhesion is essential in order to complete the dosing regime required (34). Typical values of tack and

**Figure 26.5** Transdermal drug delivery patch designs. (a) Reservoir system; (b) matrix system.

peel adhesion of PSAs loaded with drugs (progesterone and indomethacin) have been given as 60–70 g/cm<sup>2</sup> and 500–520 g/cm<sup>2</sup> respectively (35). The efficiency of adhesives to release drugs has also been widely studied with respect to drug solubility in the adhesive, drug release kinetics, and skin permeation (36–38). Drug solubility may be related to the hydrophilicity of the adhesive; trends such as those shown in Table 6 are observed for examples of the three adhesive types.

Drug release is dependent on the T<sub>g</sub> of the PSA and the functionalities on the adhesive polymer chain. The low T<sub>g</sub> of silicone PSAs, for example, results in a very flexible and open polymer structure that gives high permeability values for a variety of molecules. Figure 6 illustrates the release profiles of four drugs from acrylic copolymers of 2-ethylhexyl acrylate with either acrylic acid or acrylamide, a silicone PSA, and a PSA blend of high and low molecular weight polyisobutylenes (38). These profiles demonstrate how the good flow characteristics of the silicone PSA results in a high rate of release for all of the drugs studied, whereas the potential for interaction between the acrylics and the drug produced varying release profiles depending on the drug type. The polyisobutylene gave fairly consistent release results for all drugs, as these polymers have no functional groups to cause differentiation.

Skin permeation of drugs does not however always follow the trends established for drug release in water. Skin permeation data, generated using human cadaver skin for the determination of skin flux of fentanyl, showed that the two properties do not necessarily give the same ranking (Table 7) (37). When released into phosphate buffer solution, the general ranking of fentanyl release by polymer type was acrylate > silicone > polyisobutylene. This order was changed, however, for skin permeation with a ranking of silicone 2920 (Dow Corning) > polyisobutylene (Exxon Chemical) > silicone 2675 (Dow Corning) > acrylate (Gelva-737, Monsanto) (silicone 2920 is moderately more hydrophobic than silicone 2675).

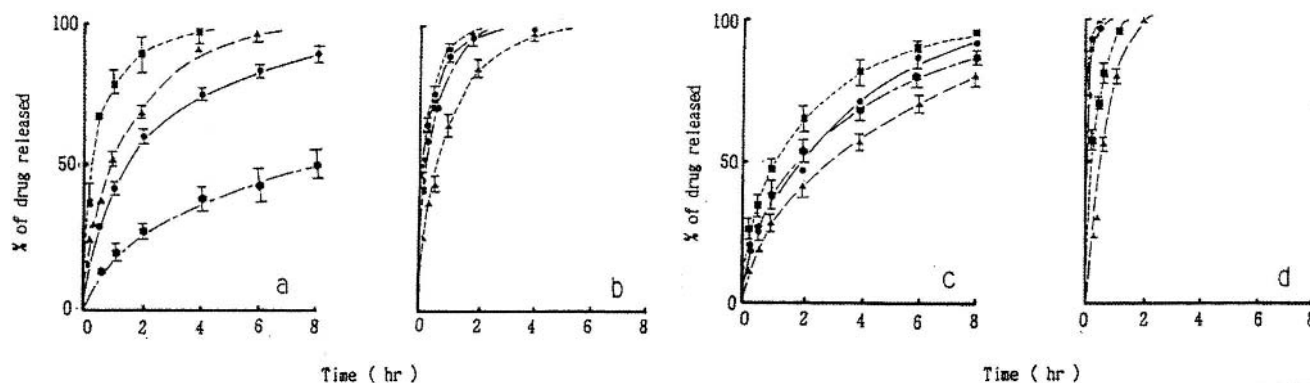

The future of transdermal drug delivery technology will be directed by the development of current delivery systems to allow extended wear times (39), biphasic drug delivery profiles, generic drug patches, and combination drug patches (29). A further challenge lies in the need to deliver higher molecular weight drugs through a skin barrier designed to prevent penetration of foreign molecules. Therefore external stimuli systems such as

*Iontophoresis*, where a conductive PSA and miniature battery set up an electrical potential to admit ionically charged drug into the skin (40,41)

**Table 26.6** Drug Solubility (mg/mL) in Acrylic, Silicone, and Polyisobutylene PSAs

PSA	Fentanyl	Aminopyrine	Dipropylphthalate	Lidocaine	Ketoprofen
Acrylic copolymer	21.9	95.1	223.7	438.6	61.3
Silicone	20.0	39.6	12.9	81.0	4.2
Polyisobutylene	0.8	48.3	62.7	62.4	0.8

*Sonophoresis*, where sound waves disrupt the stratum corneum to increase drug delivery rates

*Electroporation*, where pores within the skin are opened to create channels of low resistance

are being developed to allow the controlled delivery of high molecular weight compounds (29). The development of more hydrophilic PSAs such as hydrogels, polyurethanes, and modified acrylics has also led to enhanced drug delivery rates (42).

#### 4. Trauma-Free Removal

A number of approaches have been taken to producing adhesives that initially adhere well but can be removed easily without causing trauma to the skin. Typically these have involved deactivation of the adhesive by some stimulus. One such development by Smith & Nephew has involved the use of light to deactivate, or switch off, an acrylic adhesive by deadening its tack and reducing the level of adhesion (43,44). The PSA was formulated using acrylic monomers (*n*-butyl acrylate, 2-ethylhexyl acrylate, and acrylic acid) copolymerized with either itaconic anhydride or vinyl azlactone. These adhesives were then further reacted with hydroxyethyl methacrylate to produce methacrylate

functional polymers capable of free-radical cross-linking (Fig. 7). When formulated with a suitable visible light photoinitiator, the adhesive cross-links on exposure to light, resulting in reduced peel forces on removal from a substrate.

Analysis of their performance on skin, as part of a volunteer trial, demonstrated the benefits of switching (deactivating) the adhesive. Results showed that 60% reductions in peel strength were possible when the adhesive was exposed to light. This in turn gave significant reductions in perceived pain, skin erythema, and skin stripping (45) (Fig. 8).

Other methods for deactivating adhesives to give trauma-free removal of dressings include the use of water and temperature. Adhesives Research Inc. have developed a PSA for use on wound care products that can be deactivated when more than 25–30% water is absorbed (46). The adhesive is based on a hydrophilic polymer comprising a mixture of a vinyl ether/maleic acid ester copolymer (e.g., Fig. 9) and a polyvinyl alkyl ether, such as polyvinyl methyl ether. The base polymer is blended with a water-soluble tackifier to produce a PSA that is coated onto a nonwoven backing. When the adhesive absorbs excess moisture, the tackifier separates from the base polymer, causing a loss of adhesion (Fig. 10).

Adhesives are also known that perform as well as conventional PSAs but can be thermally deactivated by either heating or cooling during removal (47). This technology uses side chain crystallizable polymers combined with conventional acrylic medical grade PSAs to produce materials that have their adhesion controlled by the ambient temperature. The “Cool Off” adhesive was shown to lose 60% of its initial adhesion to skin when switched with ice or a cold compress (48). Similarly, the “Warm Off” adhesive gave reductions in peel strength of 70–90% with little stripping of the stratum corneum.

**Table 26.7** Release Rates into Aqueous Medium and Skin Permeation of 2% Fentanyl from Various PSAs

PSA type	Release rate constant $k$ ( $\text{min}^{-1/2}$ )	Skin flux ( $\mu\text{g}/\text{cm}^2/\text{hr}$ )
Acrylic copolymer	3.6	$0.9 \pm 0.2$
Silicone 2675	1.3	$1.1 \pm 0.2$
Silicone 2920	2.1	$6.3 \pm 0.7$
Polyisobutylene	1.3	$3.1 \pm 0.3$

**Figure 26.7** Synthesis of methacrylate functional PSAs using (a) itaconic anhydride and (b) vinyl azlactone containing copolymers reacted with hydroxyethyl methacrylate for the formation of light switchable PSAs.

Many medical grade PSAs are designed to overcome the problem of trauma on removal by the use of cross-linking (covalent, hydrogen bonding or physical) or incorporation of hard monomers, such as acrylic acid (12,49–53). This is designed to control the buildup in adhesion once a sufficient bond has been formed between

the adhesive and the skin. Therefore, by limiting the long term flow of the adhesive polymer, the ultimate bond strength is controlled and the cohesive strength of the adhesive is also increased. This results in reduced pain on removal with little or no adhesive residue left on the skin (54).

### C. Adhesive Types

#### 1. Acrylic Polymers

Acrylic polymers are the most widely used materials for medical PSAs due to their hypoallergenicity, natural tackiness, and wide scope for formulation/property tailoring. They are typically copolymers composed of “hard” monomers that produce homopolymers with a high Tg and “soft” monomers that yield low Tg homopolymers (Table 8) (55,56). Acrylates are esters of acrylic acid and have the general structure shown in Fig. 11. The nature of the alkyl group, R, can be used to dictate the adhesive properties by varying the chain length and the hydrophilic/hydrophobic nature of the group (57). The length of the R group affects the Tg as shown in Fig. 12, where it can also be seen that the addition of a CH<sub>3</sub> group (R') to produce a methacrylate leads to increased steric hinderance and therefore higher Tgs (56). The contribution made to adhe-

**Table 26.8** Glass Transition Temperatures of Acrylic Homopolymers Derived from Typical Monomers Used in Medical PSAs

Monomer	Homopolymer Tg	Remarks
<i>n</i> -Butyl acrylate	-54°C	Soft segment
2-Ethylhexyl acrylate	-70°C	Soft segment
Acrylic acid	+106°C	Hard segment
Vinyl acetate	+30°C	Hard segment
<i>n</i> -Butyl methacrylate	+20°C	Hard segment

**Figure 26.11** General structure of (meth)acrylic monomers.

sive properties by varying the polarity of the acrylic monomers is also highlighted in Table 9.

Polymerization is normally carried out by a free-radical mechanism producing random copolymers of molecular weight typically in the range 200,000–1,000,000. The Tg of the resultant polymer can be controlled by the ratio of hard and soft monomers, which will in turn affect the adhesive properties. Varying the functionality of the monomers allows particular properties to be imparted on the adhesive:

**Figure 26.10** Relationship between tack of a moisture switchable PSA and moisture content. (Adapted from U.S. patent 5,032,637 assigned to Adhesives Research Inc.)

**Figure 26.12** Effect of alkyl chain length on the Tg of poly(alkyl) acrylates and methacrylates. (Adapted from Ref. 56.)

*High MVTR.* A high proportion of ether oxygen atoms can be incorporated into the polymer to increase the MVTR. Monomers such as methoxybutyl and butoxyethyl acrylate therefore give increased MVTR to the PSA, as does decreasing the alkyl chain length (58–60).

*Sebum tolerance.* An alkyl chain length of at least C<sub>6</sub> is required to dissolve sebum, e.g., 2-ethylhexyl acrylate.

*Tack.* Low Tg acrylic monomers are required with chain lengths of C<sub>4</sub>–C<sub>12</sub> (61). These acrylates have lower Tgs than corresponding methacrylates (Fig. 12).

*Wet stick.* Changing the surface energy by varying the adhesive polarity (e.g., acrylic acid content) may affect the

wet stick ability of the PSA (62–64). Increasing the alkyl chain length (e.g., *n*-butyl to *n*-lauryl acrylate) may also increase the wet stick ability.

*Cohesive strength.* Increasing the molecular weight by chain propagation or slight cross-linking will increase the cohesive strength of the adhesive.

Although the majority of acrylic adhesives are solvent based, there is a growing move towards solvent-free systems such as water-borne or hot-melt acrylics. Developments in water-borne PSAs have generally concentrated on acrylic dispersions, which offer several advantages over solvent-based PSAs such as higher coating speeds, reduced impact on the environment (although water has a higher evaporation enthalpy than most solvents used), and greater resistance to aging.

The major development in this area concerns the surfactants used for emulsion polymerization. Typically, non-polymerizable surfactants were used in PSA formation, which left the adhesives sensitive to water due to extraction of the surfactant. However, in order to maintain good adhesion to skin it is essential that water does not significantly affect adhesive properties. To this end, polymerizable surfactants based on acrylic esters have been developed that overcome this problem (Fig. 13) (65). Therefore a PSA based on 2-ethylhexyl acrylate, *n*-butyl acrylate, and *n*-butyl methacrylate was produced that adhered well to human skin under dry and wet conditions as well as to sweaty skin.

Hot-melt adhesives are increasing in importance due to environmental pressure on solvent-based systems and the performance shortcomings of aqueous systems. The use of

**Table 26.9** Adhesive Properties of Acrylic Monomers

Monomers	Adhesive property
<i>Hydrophobic</i>	<i>Present as a large proportion of the copolymer in order to</i>
2-Ethylhexyl acrylate	Impart low Tg
Isooctyl acrylate	Provide pressure sensitivity
<i>n</i> -Butyl acrylate	Impart sebum tolerance
<i>Hydrophilic</i>	<i>Present as a smaller proportion of the copolymer in order to</i>
(Meth)acrylic acid	Increase cohesive strength
Vinyl acetate	Provide surface polarity
Methyl acrylate	Enhance wear performance on skin
Vinyl caprolactam

Methoxybutyl acrylate	
Butoxyethyl acrylate	

**Figure 26.13** Polymerizable surfactant based on acrylic esters (M = metal).

hot-melt coating technology also offers superior economics to solvent- or water-based coatings.

The major health care applications of hot-melt PSAs (HMPSAs) are in adhesive tapes, bandages, and transdermal drug delivery systems. HMPSAs are particularly suited for use as combined adhesive/drug matrix media for drug delivery, as they can be formulated to contain little or no chemical functionality (66). This reduces the possibility of medication/adhesive interactions. Hot melts are also less prone to swelling when in contact with the alcohols used in certain medications, this being a particular problem with acrylics.

The major disadvantage of using hot-melt adhesives in skin contact applications is the high peel force required for removal due to their low cohesive strength and hence aggressive nature. Various examples do exist, however, of high cohesive strength HMPSAs formulated for medical use. Adhesives composed of soft acrylate (such as *n*-butyl acrylate) and hard methacrylate (such as isobutyl methacrylate) polymers containing methyl-3-oxa-4-oxo-5-azanonyl methacrylate as comonomer have been found to have high adhesive strength to human skin but only negligible adhesive transfer to the skin on removal (67,68). This is believed to be due to the ability of the comonomer to form hydrogen bonds and thus enhance cohesive strength.

Another approach to improving the cohesive strength of the adhesives is to introduce cross-links. The technique most suitable for cross-linking hot melts is radiation-induced cross-linking, as thermally activated cross-linking would occur prematurely during premelting. The polymerization of an ultraviolet (UV) photoinitiator into an acrylic PSA formulation has provided a novel route to a UV curable hot melt PSA (69). The copolymerized acrylic esters with substituted benzophenone terminal groups cross-link on UV irradiation to produce PSAs with a range of properties that remain constant with no post-curing (Fig. 14).

## 2. Rubber-Based PSAs

Rubber-based PSAs only find limited use in the modern medical field, as acrylic adhesive copolymers have been

**Figure 26.14** Cross-linking mechanism of UV curable hot melt PSA.

developed. Early medical adhesives, however, were most commonly based on natural rubber, an early composition is described as (1)

India rubber	5 lb
Gum of southern pine	1 lb
Balsam of Peru	6 oz
Ground litharge	1 lb
Extract of Capsicum annum	4 oz
Solvent—turpentine	

A more general formulation for a surgical tape adhesive is given as (70)

	Parts by weight
Natural rubber	100
Colophony or ester gum	100
Lanolin	20
Zinc oxide	50

These natural rubber-based formulations have largely been superseded by synthetic elastomers such as polyisoprene and polyisobutylene (Fig. 15). Polyisobutylene tends to pack tightly on a molecular level, which results in low air and moisture permeability. The low T<sub>g</sub>s of these polymers produce flexible materials that are naturally tacky, but because of their low polarity, adhesion of polyisobutylenes to many surfaces is weak and tackifiers are often used to impart a degree of polarity to the formulation (42). Low molecular weight polyisobutylenes may also be incorpo-

**Figure 26.15** Repeat unit of polyisobutylene.

rated into the formulation in order to give suitable adhesive properties. These lower molecular weight polyisobutylenes (~50,000–100,000 molecular weight) are naturally tacky materials and provide the PSA with softness and flexibility, allowing the polymer to wet out on the skin surface. A typical polyisobutylene-based PSA formulation is described as (71)

Polyisobutylene (80,000)	50
Factice	29
Glyceryl ester of hydrogenated rosin	24
Liquid polyisobutylene	35
Lanolin	20
Beeswax	9
Titania	14
Hydrated alumina	62
Antioxidant	1.5

(Factice is used to limit the cold flow of the adhesive mass.)

### 3. Silicones

Silicone-based PSAs have been used in medical applications since the mid-1960s and have been utilized for tapes, dressings, and bandages. More recently, silicone adhesives have found use in transdermal drug delivery systems, which offer controlled entry of a pharmaceutical into the blood. Silicone PSAs are typically formulated from silicone resins and polydimethyl siloxane gum (72) (Fig. 16). In order to impart sufficient cohesive strength to these systems, the polymer and resin are cross-linked to form a network. The properties of the final adhesive can be controlled by varying the ratio of components and the cross-link density (73).

The properties attainable from silicones are summarized in Table 10 and illustrate why they are suitable for transdermal drug delivery. Firstly, silicones have excellent skin compatibility as they contain no tackifiers, plasticisers, an-

**Figure 26.16** Silicone PSA components—polydimethyl siloxane polymer and silicate resin.

**Table 26.10** Typical Properties of Silicone Polymers for Transdermal Drug Delivery

Biocompatibility	Biologically inert Low level of extractables Nonsensitizing and nonirritating
Adhesion	Low glass transition temperatures Good formulation control
Permeability	High gas permeability Permeable to a variety of pharmaceuticals
Chemical stability	Chemically inert to many substances Compatible with pharmaceuticals

tioxidants, or stabilizers and therefore have low levels of potential extractables (74). As well as satisfying the standard requirements for a medical PSA, it is especially important for drug delivery devices that the adhesive is biocompatible so as to be nonirritating and nonsensitizing as well as to produce no systemic toxicity. This is enhanced in silicone polymers by their surface activity and hydrophobic nature, which limits their interactions with body fluids (73). However, it is their high permeability to a wide variety of pharmaceuticals and their chemical resistance that allow controlled rates of delivery of an active ingredient to a patient (35).

## III. TISSUE ADHESIVES

### A. Introduction

#### 1. Techniques for Tissue Reattachment

Before reviewing the various tissue adhesive technologies, it is worth considering the current practices with which any new tissue bonding adhesive would have to compete. Alternatives are dominated by the traditional approach offered by mechanical devices such as sutures and staples and more recently tissue welding with lasers. Sutures and staples are effective, well established, and widely used wound closure devices. Laser welding can also be used to join tissue defects. The worldwide market in which all of these technologies are to be found is worth in excess of US\$2.5 billion per annum (75).

##### a. Sutures and Staples

For many hundreds of years suturing has been the primary means adopted by surgeons for most wound closure procedures, both postsurgery and posttrauma (Fig. 17). The materials used in the manufacture of sutures have become increasingly more high-tech, and it is now commonplace for these materials to have a predictable and consistent resorption profile to match the requirements of the wound. It

**Figure 26.17** A typical suture line.

therefore comes as no surprise that sutures represent an annual worldwide market worth in excess of US\$1.6 billion (75). Despite the recent search for alternative technologies to replace suturing for difficult procedures involving soft tissues such as liver and kidney, and harder tissues such as bone and cartilage, the market for this simple product continues to expand.

The suture market is dominated by Johnson & Johnson's Ethicon, which retains approximately three-quarters of the U.S. suture market worth US\$550 million per annum (75). The remainder of the market is evenly divided between Sherwood Davis & Geck and U.S. Surgical. Stainless steel staples were first invented in 1969, and although they represent a sizeable market, staples have not replaced sutures.

#### *b. Laser Welding*

Tissue defects can be repaired with the use of lasers (76) in conjunction with minimally invasive surgery (MIS) via a fiber-optic arm. The physical changes in the tissue are dependent on the radiation parameters employed, such as the wavelength, spot size, power, and exposure. The overall efficiency of welding can be considerably enhanced with the use of protein solders such as fibrinogen or albumin-hyaluronic acid to reduce the damage to the irradiated tissue (77,78). Laser welded tissue has the potential to produce watertight closures with less trauma to surrounding tissues and much reduced operating times compared to suturing and stapling. This should also be the case for many of the emerging tissue adhesives.

## 2. Key Requirements of a Tissue Adhesive

Each individual key requirement for a successful tissue adhesive may appear obvious, but each one represents a significant challenge to any scientist working in this field. Only products that satisfy all these criteria can really expect to receive full recognition and widespread acceptance by the surgical community. Table 11 lists the main requirements of any tissue adhesive.

Clearly there is a need for a product that can deliver all these characteristics. Procedures that are inherently com-

**Table 26.11** The Key Requirements of a Tissue Adhesive

---

In use, the adhesive must mimic the mechanical performance of the undamaged tissue.
The adhesive should provide sufficient tack for "primary" fixation with the opportunity for manipulation and realignment prior to setting strongly.
The adhesive must not elicit any toxic response by the surrounding healthy tissue and should facilitate the regrowth of new tissue where possible.
The adhesive should not liberate harmful degradation products. Any exothermic process involved in the curing of the adhesive should not damage the surrounding tissue.
The adhesive should degrade, and as it does so, it should be replaced by new tissue with minimal scarring.
Any biodegradation products should not accumulate in the body but should be eliminated naturally either by excretion or incorporation into the natural biochemical cycle.

---

plicated, such as certain types of fracture repair involving small bone fragments, are difficult to repair using traditional pins, screws, plates, and wiring. Hence there is a need for a new type of adhesive product to be available to surgeons around the world.

## 3. Factors Influencing the Choice of Tissue Adhesives

In selecting the most appropriate wound closure technique, the surgeon has a choice of technologies, which may be used alone or in combination. A surgeon will base the decision on a number of factors, the relative importance of which will vary from one patient or medical procedure to another. These are listed in Table 12. In addition it should be appreciated that the priority placed on delivering these would vary with the surgeon, the patient, and the manufacturer. The aim must therefore be to deliver a product that satisfies all of their needs.

**Table 26.12** Factors Influencing the Use of Tissue Adhesives

---

Cost (in terms of materials and time spent in applying them to a patient)
Availability to the customer
Ease and reliability of the procedure
Properties and local effects of using the material
Applicability to the specific tissue site
Robustness of the treatment
Time to healing

## B. Synthetic Tissue Adhesives

There are two main types of synthetic polymer systems that readily adhere to moist tissue, synthetic and biological adhesives (79). The alkyl-2-cyanoacrylates have been evaluated as tissue adhesives quite widely and probably now lead the field, inasmuch as they attract the most interest from industries looking to enter this market. Other synthetic tissue adhesives, which include gelatin and resorcinol mixtures that are cross-linked by formaldehyde, have also been investigated, but the cross-linking reaction involved is very complex, and this has made investigation into the nature of the adhesion very difficult. Polyurethane prepolymers have received much attention, as this chemistry is well established, and the properties of the adhesive can be varied by choice of the polyol component and the chemical nature of the polyisocyanate. There are also a number of emerging technologies gaining interest from many companies as encouraging results are reported. Each will now be considered in turn.

### 1. Cyanoacrylates

#### a. Development and History of Cyanoacrylates

New developments in cyanoacrylate tissue adhesives are beginning to compete in the wound closure market, which has been traditionally dominated by sutures and staples. For example, Ethicon has a distribution agreement with Closure Medical, whose product, trademarked *Dermabond*, was unanimously recommended for approval by the FDA's General and Plastic Surgery Devices Panel at the beginning of 1998. *Dermabond* is the first synthetic cyanoacrylate adhesive product to join the U.S. market for closure of skin lacerations caused by trauma or small surgical incisions that would normally have been repaired by sutures or staples.

The earliest patents on the preparation of cyanoacrylates were issued in 1949 to Alan Ardis (80,81) and assigned to the B. F. Goodrich Company. These patents refer only to the applications of  $\alpha$ -cyanoacrylates for the production of "hard, clear, glass-like resins," which were simply obtained by heating the monomer. The adhesive properties of  $\alpha$ -cyanoacrylates were discovered by accident during the investigation of a series of 1,1-disubstituted ethylenes in the Eastman Kodak laboratories. In attempting to measure the refractive index of a sample of ethyl- $\alpha$ -cyanoacrylate, a drop of the material was placed between the prisms of an Abbé refractometer with the result that these prisms became firmly bonded together.

Between the years 1955 and 1957, a number of patents were issued to Eastman Kodak including the use of cyanoacrylates as adhesives (82). The material only had speciality uses at first, partly due to its expense, although because

of the tiny amounts of material necessary to form a strong bond, this adhesive was destined not to remain a curiosity for much longer.

#### b. The Role of Cyanoacrylates in the Medical Market

Most people have come across cyanoacrylates because of their widespread availability and common usage around the home as "superglues," but cyanoacrylates also find numerous applications in, among others, the automotive and construction industries. The cyanoacrylate adhesive family is now enjoying increasing popularity as fast-setting "instant" adhesives. The makers of these household superglues have always warned the users that the glue can bond skin in seconds, but today this well-known hazard is being turned into a strong commercial selling point as cyanoacrylates find uses in medicine. The properties of cyanoacrylates that set them apart from nearly all other adhesives are that they are single-component, catalyst-free adhesives capable of bonding at room temperature within just a few seconds. Cyanoacrylates require no external initiation and for the vast majority of applications rely solely on the small amounts of water adsorbed on the surfaces of the substrates for their almost universal adhesion.

Cyanoacrylates were first used for a clinical application in the early 1960s (83,84), and among all the other synthetic polymers that have been considered for medical applications, the cyanoacrylates have received the most attention. Indeed, cyanoacrylates are now commonplace in many accident and emergency departments in hospitals as doctors and patients begin to realize their widespread appeal and clinical advantages. In the early literature, Eastman 910 monomer (methyl-2-cyanoacrylate) was the most noteworthy (the general structure of a cyanoacrylate monomer is shown in Fig. 18). Unlike sutures, which leave behind small openings in the wound (often called dehiscence), cyanoacrylates form a continuous sealing of the wound, along which the load is evenly distributed. This leads to formation of a bacterial barrier and also decreased scarring around the site.

Skin closure is potentially a major application area for cyanoacrylate tissue adhesives, and this has received ex-

(Where R = Me, Et, Bu etc)

Figure 26.18 General structure of cyanoacrylate monomer.

tensive evaluation. Indeed, many of the products marketed are aimed specifically at surface wound closure. There are also literature reports documenting the use of cyanoacrylates to bond bone and cartilage (85–96), nervous tissue (97–100), vascular tissue (97,98,101,102), and intestines (103).

Many other cyanoacrylates have been experimented with surgically. In early applications, methyl cyanoacrylate was used almost exclusively both as the monomer and as a commercial preparation with addition of a plasticizer and a thickener. Later, long chain alkyl cyanoacrylates were also used, especially isobutyl cyanoacrylate. The longer chain cyanoacrylates are generally considered to be less toxic due to their slower degradation when compared to the short side chain versions. The issues of toxicity will be addressed in a subsequent section.

Cyanoacrylates have been available commercially in the U.S. since the 1960s but were removed from the medical market due to concerns over carcinogenicity. However, products such as *Histoacryl* (trademark of B. Braun) have been available on the European market for more than two decades for external medical indications. *Histoacryl*, which is an *n*-butyl-2-cyanoacrylate monomer colored with a blue dye, has been widely used in hospital accident and emergency departments for the treatment of pediatric patients and traumatic skin incisions in adults. *Histoacryl* tissue adhesive has been compared with silk sutures as a means for closing incisions (104). The silk sutures were found to cause a severe inflammatory and giant cell reaction compared to *Histoacryl*, and the healing process was slower with the sutures. The cyanoacrylate caused less scarring and allowed shorter operation times by virtue of its hemostatic properties.

Closure Medical's *Dermabond* contains a different cyanoacrylate monomer, octyl-2-cyanoacrylate, that is less brittle than the butyl derivative and is used as a flexible seal over wound edges. This monomer is slower to polymerize than its butyl counterpart, taking up to 1 minute to polymerize sufficiently for a wound to hold itself together without support. Typically, cyanoacrylates used for these conditions would remain in place for about 7 days and then slowly slough off as the skin cells regenerate themselves and the natural healing process takes over. It is easy to appreciate that the use of cyanoacrylate tissue adhesives in the operating theater offers a much faster procedure when compared to the use of sutures, resulting in a far more acceptable cosmetic effect and, most appealing to younger patients, there is no need to make a second visit to the hospital to have the stitches removed.

Quinn et al. examined the use of *Dermabond* in the treatment of 136 lacerations in humans and recorded excellent results (105). The cyanoacrylate was reported to close

the lacerations in a relatively rapid and painless manner. The authors stressed the importance of ensuring that the wound edges be well apposed to prevent the cyanoacrylate getting between the wound edges and penetrating into the underlying tissues, which may result in foreign body reactions and impaired healing. When used topically, octyl cyanoacrylate can result in fewer foreign body reactions than sutures and can decrease the infection rates in contaminated wounds.

Loctite (UK) has developed a product based on the same chemical monomer, butyl-2-cyanoacrylate, but in a clear formulation that does not tattoo the skin. This product has been granted a CE mark and is sold in Europe under the trademark *Indermil*. The product is sterilizable by gamma irradiation (106) and may be applied through a cannula attached to an electronic peristaltic pump (107) that helps deliver the adhesive in precise doses to the surgical site. The composition comprises a cyanoacrylate and a combination of an anionic stabilizer and a free-radical stabilizer in amounts effective to stabilize the composition during irradiation and to stabilize the sterilized composition during storage prior to use. The glue will form strong bonds almost immediately once the surgeon has applied it to the tissue. In their current formulations, cyanoacrylate monomers are not approved for use inside the body, although resorbable versions are no doubt the target of much research.

Many of the developments in cyanoacrylate technology focus on altering its stability and reactivity with the accurate use of inhibitors and stabilizers. Now researchers and numerous health care companies are turning their attention to developing cyanoacrylates for the medical market. This places additional demands on the cyanoacrylates, and new issues must be addressed that were not pertinent for their more conventional applications, such as toxicity, biodegradation profile, and sterilization issues.

### c. Mechanism of Bonding

Adhesion is achieved through two independent mechanisms, molecular interaction (covalent bonding) and the mechanical interlocking of the poly(cyanoacrylate) with the substrate.

Primary chemical or covalent bonds are obtained when the adhesive undergoes a chemical reaction with the substrate. There are many functional groups present in the tissue substrate, particularly in proteins which are suitable for covalent bonding, most notably amine groups.

Physical or mechanical bonds are formed when the adhesive penetrates the substrate and forms interlocks when the material sets. This can occur very easily with tissue, and low-viscosity fluids such as cyanoacrylate monomers

are particularly suited to this mode of action. The adhesive “enters” the substrate via cracks and channels and quickly becomes locked and held strongly once the polymerization process commences. This results in strong mechanical bonds between closely apposed surfaces. In this case, bond strengths would depend on the surface morphology of the substrates and the mechanical properties of the specific adhesive polymer.

In practice, many of the successful tissue bonds are achieved via a combination of mechanical and chemical bonds. Hence it is a combination of the properties of the adhesive and the substrate that determines the bond strength of the adhesive.

#### d. The Chemistry of Cyanoacrylates

Why are cyanoacrylates unique? The cyanoacrylate monomer is extremely reactive due to the electron withdrawing capacity of the nitrile and the ester groups, which results in the double bond being very polarized in the presence of even very weak nucleophiles. This effect can also be caused by water, which can be responsible for the initiation of the polymerization reaction. The properties of the adhesive can be controlled by varying the length of the alkyl group, by careful use of acidic substances to delay the polymerization, and also by the addition of other polymers to act as thickening agents. These minor components, such as stabilizers, plasticizers, and other additives that improve the viscosity, heat stability, bond strength, and shock resistance, generally account for less than 10% of the total formulation.

Like all acrylates, cyanoacrylates are capable of being polymerized via a free-radical mechanism. However they polymerize preferentially via an anionic mechanism that is catalyzed by bases (including weak nucleophiles such as water) so that the curing process of the single-component monomer is fast on contact with moist tissue. The anionic polymerization reaction is shown simply in Fig. 19.

The  $\alpha$ -cyanoacrylates are prepared by depolymerization of the corresponding polycyanoacrylate formed by the Knoevenagel condensation reaction of an  $\alpha$ -cyanoacetate with formaldehyde. This depolymerization occurs at high temperatures under high vacuum conditions, and pure monomer is distilled from the reaction. Water and bases must be removed or neutralized prior to the depolymerization reaction in order to prevent the polymer reforming during the distillation process. Polymerization inhibitors are usually added immediately to the purified monomer.

Medical-grade cyanoacrylates are far purer than “superglues” used elsewhere but have been formulated to contain specific additives, for example to enable sterilization. Cyanoacrylates would obviously not survive some of

**Figure 26.19** Anionic polymerization mechanism of alkylcyanoacrylate.

the routine sterilization cycles used in the manufacture of many medical products, and care must be taken to choose a suitable procedure that excludes the possibility of unwanted free-radical polymerization.

In the process of polymerization, a bond is created between adjacent tissue surfaces. The poly(cyanoacrylates) are considered to be relatively nonbiodegradable because they break down very slowly both in water and in tissue media. The main degradation products of poly(alkyl cyanoacrylates) are formaldehyde and the corresponding alkyl cyanoacetate. These degradation products, the monomer itself, or other impurities in the monomer may give rise to toxic species. The issues surrounding the toxicity of cyanoacrylates will be discussed in the next section.

The success of the adhesive joint is often judged by how well the tissue is replaced. It is therefore important that the polymeric material is degraded and eliminated from the body leading to the most widely debated area surrounding the use of cyanoacrylates as medical adhesives, namely toxicity.

#### e. Issues of Toxicity in Cyanoacrylates

All cyanoacrylate tissue adhesives are classed as medical devices and are required to be subjected to rigorous safety appraisal to prove that they are safe in use. It is therefore no longer sufficient for a medical adhesive product to rely on its mechanical performance.

Cyanoacrylates are used to bond two nonadherent surfaces and, in the case of external tissue, the adhesive either falls off or can be washed off after a period of time. The polymerization of the monomer at the tissue site can cause localized heat-induced tissue damage, but with only small volumes of adhesive being required, the temperatures reached as a result of the polymerization reaction should

not be sufficient to cause necrosis. The greatest in vivo temperature rises for methyl cyanoacrylate have been reported to be 4°C (108); higher homologues, the hexyl and decyl esters, produce temperature rises of 2°C. It is, however, the chemical breakdown of the adhesive that may result in toxic species.

Cyanoacrylates belong to a class of monomers consisting of the alkyl esters of 2-cyanoacrylic acid. The choice of the alkyl side group greatly affects the properties of the adhesive formed when the monomer polymerizes. The methyl ester is volatile and lachrymatory and polymerizes extremely rapidly to give a rigid polymer. With increasing size of the alkyl group, volatility, polymerization rate, and rate of polymer degradation decrease, whereas the flexibility increases. As examples, methyl (102), ethyl (109), *n*-butyl and isobutyl (103,110–113) and more recently octyl (105) cyanoacrylates have been investigated for surgical use. The study involving the methyl derivative concluded that it caused tissue necrosis and did not spread well on tissues. As a result of this negative finding, much research has focused on the higher homologues, particularly butyl cyanoacrylate. It was believed that increasing the length of the alkyl ester side chain was associated with a decrease in histotoxicity. However, it has been found that the polymers disappear or degrade very slowly and still have too low a flexibility compared with wound tissues and hence are inadequate for use routinely as soft tissue adhesives.

Cyanoacrylates have been used as adhesives in soft tissues (110), arteriovenous malformations (97), ophthalmology, and as drug carriers (114). In practice, few surgeons use cyanoacrylates except in unusual circumstances or in emergency cases. Inflammatory response (113), delayed healing and necrosis (113,115), thrombosis (97,101), and inhibition of bone formation (116) have been noted, whereas other researchers have found relative compatibility of the polymerized cyanoacrylates with the surrounding tissues, resulting in normal healing processes following injury (103,111,117).

It has been proposed that the toxic effects of cyanoacrylate polymers are due to the release of the products of their degradation (118). Cyanoacrylate degradation occurs by the breakdown of the polymer backbone, and it occurs because the methylene hydrogen in the polymer is highly activated inductively by the electron withdrawing neighboring groups. Water associated with the tissue can induce cyanoacrylate hydrolysis by a reverse Knoevenagel reaction liberating formaldehyde and alkyl cyanoacetate.

The degradability of cyanoacrylate polymers has been demonstrated to decrease with an increase in the size of the alkyl side chain, as a result of steric hindrance (119). Degradation also depends upon the molecular weight of

**Figure 26.20** Degradation of cyanoacrylate polymer via a reverse Knoevenagel reaction.

the polymer; lower molecular weight cyanoacrylate polymers exhibit a more rapid release of formaldehyde. The reason for this is that for a fixed mass of polymer, lower molecular weight materials will contain more chain ends resulting in a higher probability of formaldehyde release (Fig. 20).

An alternative degradation mechanism has been proposed whereby the cyanoacrylates degrade by hydrolysis of the ester group to produce cyanoacrylic acid and alcohol. Lenaerts et al. (114) studied degradation of isobutyl cyanoacrylate nanoparticles at pH 7 in phosphate buffer and found that the amount of formaldehyde produced after 1 day was 5% of the theoretical quantity that would have been produced if the polymer had been entirely degraded by this pathway. At pH 12 (in 0.01 N NaOH), this value reached 7%. Conversely, isobutanol production was 85% of the theoretical quantity in the alkaline medium.

This mechanism may occur to some extent in the physiological environment and may be catalyzed by enzymatic processes. Wade and Leonard (120) have shown the poor contribution of the formaldehyde producing pathway to the degradation of methyl cyanoacrylate in vivo and suggested that both hydrolytic chain scission and ester hydrolysis may be involved in the in vivo degradation of cyanoacrylate polymers. This is shown in Fig. 21.

The liberation of formaldehyde inside the body represents a significant issue regarding the acceptance of cyanoacrylates as internal tissue bonding adhesives. This is not a major issue in the use of cyanoacrylates to close external

**Figure 26.21** Ester hydrolysis of cyanoacrylate polymers.

wounds, as care is taken not to use the adhesive inside the wound but only on the surface. Although formaldehyde is a product of the degradation of cyanoacrylate adhesives, it may not be the agent solely responsible for observed histotoxic effects. It is possible that formaldehyde levels released from cyanoacrylates in vivo are low enough to be processed by tissue metabolic systems and/or cleared by the normal flow of physiological fluids over the site, thus preventing buildup. If this is the case, the toxicity is attributable to other mechanisms.

Formaldehyde is a physiological metabolite and vital to the synthesis of essential biochemical substances in man, and it is not toxic at very low concentrations (121). It should be noted, however, that, due to formaldehyde's highly reactive carbonyl group, it undergoes typical aldehyde reactions: it readily reacts with free amino groups in proteins and forms methylol adducts with nucleic acids, histones, proteins, and amino acids. These reactions may be responsible for its toxic effects at higher concentrations. Epidemiological evidence has arisen to suggest that formaldehyde may be a human carcinogen. This has led to its regulation by U.S. federal agencies as a probable human carcinogen (122).

#### f. Future Developments

To date, the use of cyanoacrylates in medicine has been limited because of their physical properties and reports of histotoxicity. The currently available cyanoacrylate tissue bonding adhesives are only approved for external use in most territories, but there are many internal medical procedures that could be revolutionized by this type of product. Any internal procedure involving the use of a biomaterial inevitably relies on the polymer degrading safely inside the body (or not degrading at all and remaining inert), and it is well known that cyanoacrylate polymers are capable of undergoing hydrolytic degradation to produce formaldehyde and the corresponding alkyl cyanoacetate. Internal procedures therefore do not benefit from the adhesive being able to slough off the skin as in the case of an external application.

Clearly the development of a cyanoacrylate adhesive with a somewhat lower acute toxicity and faster degradability than butyl cyanoacrylate would go a long way towards replacing sutures and provide a faster and more efficient method of tissue approximation and wound closure. Further desirable design features would include flexibility of the adhesive polymer, appropriate viscosity (although this can easily be modified by the use of thickeners), and a set time that can be tailored to the needs of the surgeon.

In summary, although the use of cyanoacrylates is becoming more widespread, they are not the ideal tissue ad-

hesive in their current form. Toxicity issues, improvement in their degradation rate, and to a lesser extent flexibility and viscosity will all need to be addressed before the use of these materials becomes commonplace and they gain full regulatory approval for the majority of surgical procedures.

## 2. Other Synthetic Medical Adhesives

### a. Polyurethane Adhesives

A polyurethane is formed by the addition polymerization reaction of a diisocyanate and an oligomeric diol to form a series of urethane bonds. If both ends of the prepolymer that is formed are isocyanate functionalized, then the prepolymer will rapidly undergo gel formation in contact with water or moist tissue. Such a prepolymer may be suitable to act as a tissue adhesive, providing that the gel itself and the products of biodegradation are nontoxic.

Polyurethane prepolymer was first applied to tissue bonding in the late 1950s (123), and polyurethane adhesives were first used for repairing bone fractures (124,125). The adhesive, *Ostamer*, consisted of a prepolymer and an accelerator that were mixed prior to use. Curing occurred in an unacceptable time of 25 to 30 minutes, and maximum strength was not obtained for 1 to 2 days. The mechanisms of adhesion of polyurethane to living tissue have not been fully investigated.

It is possible to synthesize oligomeric diols that are readily biodegradable that can be built into a polyurethane adhesive. As an example, Kobayashi et al. (126) synthesized a copolymer of  $\epsilon$ -caprolactone and D,L-lactide (P(CL-co-LA)) using ethylene glycol or poly(ethylene glycol) as an initiator to obtain hydroxyl terminated biodegradable polyesters. This reaction was carried out at 140°C under  $1 \times 10^{-3}$  mm Hg for six hours. These polyesters were allowed to react with an excess of diisocyanate such as hexamethylene diisocyanate (HMDI), tolylene diisocyanate (TDI), or diphenylmethane diisocyanate (MDI) in order to produce polyesters with terminal isocyanate functionalities. These materials were water curable, and their synthesis is shown in Fig. 22. Various formulations were prepared and evaluated in terms of set time, mechanical properties, and in vitro and in vivo performance (126). The set times were found to be greatly dependent on the composition of the polyesters and the nature of the isocyanate. More hydrophilic systems, such as those containing more polyethylene glycol, tended to cure more rapidly, as did those possessing the more reactive isocyanate groups of MDI. The in vivo degradation rate was almost the same as, or slightly more enhanced than, the in vitro degradation rate, with some adverse tissue responses being observed. In summary, although it was concluded that the incorpora-

**Figure 26.22** Synthesis of biodegradable polyurethanes.

tion of hydrophilic units was essential for high curing and degradation rates, because of the adverse tissue responses observed, further improvements to the prepolymers are necessary if these adhesives are to be used widely in surgery.

*b. Gelatin-Resorcinol-Formaldehyde (GRF) Adhesives*

Certain aqueous polymer solutions are capable of setting through gel formation in a few minutes when a cross-linking agent is added to the solution. Gelatin is an excellent example of such a polymer that is also bioresorbable. The use of cross-linked gelatin as a tissue adhesive was first reported in 1966 (127). A gelatin-resorcinol mixture cross-linked with a combination of formaldehyde (GRF) and also glutaraldehyde (GRFG) was also reported to give satisfactory bond strengths in hepatic and renal tissues (128).

In 1968, Cooper and Falb studied gelatin cross-linked with formaldehyde as a potential tissue adhesive (129).

They also added resorcinol to the gelatin-formaldehyde mixtures in order to improve the bond strengths. Formaldehyde is able to condense with resorcinol to give a three-dimensional cross-linked resin. Possible mechanisms for the curing of gelatin-resorcinol-formaldehyde adhesive are shown in Fig. 23 (130).

This polymerized gelatin chemical glue contains no blood components and, outside the U.S., is a commercially available product. The glue consists of gelatin, resorcinol, and distilled water that is supplied in a sterile tube (usually sterilized by ethylene oxide) that is warmed to 45°C prior to use and applied to the operative site; a small volume of formaldehyde (glutaraldehyde can be substituted for formaldehyde) is then added to polymerize the adhesive.

Gelatin-resorcinol-formaldehyde glue was used to treat aortic dissections for the first time in the late 1970s (131). Although no toxicity problems were observed at the time, because of the presence of formaldehyde, questions have always remained about possible toxic and carcino-

**Figure 26.23** Possible mechanisms for the curing of gelatin–resorcinol–formaldehyde adhesives.

genic effects (132). Even if all the formaldehyde molecules are consumed in the condensation reactions with gelatin and resorcinol, formaldehyde will still be released from the cured adhesive when the gelatin undergoes enzymatic degradation. These concerns have limited its acceptance.

These adhesives bond well even to moist surfaces and have the advantage that they undergo a moderate degradation rate. The curing profile of these adhesives can be altered by careful adjustment of the ratios of the components used. However, the formaldehyde released can be responsible for the considerable inflammatory response, which, for a GRF adhesive, would interfere significantly with the healing process of the surrounding tissues. This echoes the primary concern with cyanoacrylate tissue bonding adhesives, which is their ability to liberate toxic formaldehyde on degradation.

Concerns about carcinogenicity of formaldehyde have prompted the development of gelatin–resorcinol–formaldehyde tissue glues that do not contain the formaldehyde component, this being replaced with both glutaraldehyde and glyoxal (133). These adaptations are not possible for cyanoacrylates.

A modification of GRF glue, so-called GR-DIAL glue has also been developed to reduce the toxicity of GRF by removing the formaldehyde component and replacing it with two less toxic aldehydes, pentane-1,5-dial and ethanedial (134). This type of adhesive is commercially available from Fehling Medical AG under the trademark *Gluetiss*.

### 3. Emerging Technologies

#### a. Bioabsorbable Synthetic Hydrogels as Surgical Sealants

To address the medical need for a biocompatible sealant for use in surgery a bioabsorbable hydrogel has been developed. Hydrogel-based adhesives have several potential advantages over cyanoacrylates such as a faster rate of degradation and the ability to act as space-filling adhesives. One such adhesive system is *FocalSeal* (trademark of Focal Inc.).

The hydrogel is formed by photopolymerization of water-soluble macromers. Poly(ethylene glycol) (PEG) is linked on both ends to hydrolyzable units, trimethylene carbonate (TMC) or lactate (LA) oligomeric segments, and end-capped with polymerizable acrylate groups (AA). In

one embodiment, the hydrogel is polymerized in situ using two parts, a primer and a sealant, as a laminate forming a highly adherent coating of any desired thickness on tissue. The laminate provides both the bonding to the tissue (primer layer) and the desired mechanical properties (the sealant layer).

The materials are applied to the tissue in aqueous solution formulations. The primer solution is first brushed onto the tissue, and then the sealant is mixed with the primer using the brush to provide a transition layer between the primer and sealant layers. The final thicker sealant layer is then flowed over the application area and the laminate is photopolymerized. The primer and sealant macromers are shown in Fig. 24, and the synthesis of these macromers has been described (135) and is shown in Fig. 25.

Typically, photopolymerization is accomplished by formulating the macromers in buffered saline solutions containing triethanolamine and eosin Y as the photoinitiator. Visible light illumination from a xenon arc lamp (470–520 nm) at an intensity of  $100 \text{ mW cm}^{-2}$  is used for 40 seconds to initiate the polymerization (136). The general concern of heat related tissue necrosis is minimized in that the formulation contains a high proportion (>80%) of water.

Once implanted, the hydrogel breaks down by hydrolysis, releasing biocompatible components, as shown in the mechanism, that are metabolized or cleared by the kidneys. Tissue healing has been shown to occur unimpeded in the presence of the sealant.

Burst strengths have been measured for Focal Seal at  $377 \pm 98 \text{ mm Hg}$  and compared to fibrin sealants at  $23 \pm 17 \text{ mm Hg}$ . The degradation of the sealant has been mea-

**Figure 26.24** Primer and sealant macromers used in photopolymerizable adhesive.

**Figure 26.25** Synthesis of poly(ethylene glycol)-co-poly(D,L-lactide) diacrylate photopolymerizable monomer.

sured at various temperatures. At  $67^\circ\text{C}$  there is 100% mass loss after 40 days.

## C. Biological Adhesives

### 1. Fibrin Tissue Adhesives

The majority of biological glues are essentially protein adhesives composed mainly of fibrin generated from fibrinogen activated by thrombin. These glues were first used in cerebral surgery by Grey (137) in 1915, though the hemostatic properties of these materials had already been re-

ported in 1909 (138). Although the biochemical process of fibrin polymerization and cross-linking is well documented, studies in the mechanism of how these biological adhesives actually bond to various tissues are not as widely discussed.

#### a. General Introduction to Fibrin as a Biomaterial

Fibrin glues, or adhesives, have been used extensively in Europe since 1978 for joining tissue in many surgical procedures through products sold under trademarks such as *Tissucol*, *Biocol*, and *Beriplast*. Many of the concerns surrounding fibrin products center on the possibilities of viral transmission. All such products are therefore subjected to rigorous screening procedures, and companies have to go to great lengths to ensure that the risk of viral transmission is minimal. This potential problem is also being addressed by the use of fully recombinant materials that eliminate the use of, for example, pooled human blood products. These issues relating to their safety and efficacy had until recently prevented the U.S. Food and Drug Administration from approving fibrin adhesives (139). However, during 1998 approval was given to a human pooled plasma derived sealant manufactured by Immuno AG and sold under the trademark *Tisseel*. *Tisseel* has now been cleared for use in indications such as to control bleeding during heart bypass surgery, colon surgery, and traumatic spleen surgery, all situations that could involve hemorrhage originating from difficult-to-seal blood vessels. The product is marketed in the U.S. under the trademark *Hemaseel*. These biodegradable and biocompatible materials therefore realize three major clinical goals: reducing hemorrhage, increasing tissue adherence, and allowing the delivery of drugs and biologics, which has resulted in a current worldwide market for fibrin sealants worth in excess of US\$300 million.

#### b. Components of Fibrin Tissue Adhesives and Methods of Manufacture

Fibrin adhesives are made from a number of components produced from pooled human plasma that enable the adhesive to mimic the final stages of blood clotting. The main constituents are fibrinogen, factor XIII, and thrombin, which are typically supplied as two components and then mixed in the presence of calcium ions. Component 1 typically contains concentrates of fibrinogen, factor XIII, and an antifibrinolytic agent, such as aprotinin or in a few cases tranexamic acid, with component 2 containing thrombin and calcium chloride solution. Table 13 outlines a typical formulation of a fibrin sealant product (140).

**Fibrinogen.** Fibrinogen is the polymeric precursor to fibrin monomer with a molecular weight of about 330,000 (141). The main source of fibrinogen is pooled plasma of

**Table 26.13** Typical Components of a Fibrin Sealant

Component	Concentration	Origin
Fibrinogen (clottable)	80–120 g/L	Human plasma
Factor XIII	10–30 IU/mL	Human plasma or human placenta
Fibronectin (antigen)	5–20 g/L	Human plasma
Thrombin (activity)	300–600 NIH-U/mL	Human plasma or bovine plasma
Aprotinin	3000 KIU/mL	Bovine lung
Calcium chloride	40–60 mM	Inorganic

human origin from screened volunteers or plasma from an autologous source. Blood is centrifuged to separate plasma from cellular components and frozen at  $-80^{\circ}\text{C}$  for 24 hours, after which the plasma is thawed and centrifuged. The cryoprecipitate is concentrated in fibrinogen, which may be used immediately or stored under the appropriate conditions (142). Risks associated with possible viral transmission when using large-pool fibrinogen may be overcome using autologous sources (143–145), although this option is not always practical. The strength of fibrin glues is largely determined by the concentration of fibrinogen in component 1 of the adhesive (146).

**Thrombin.** Thrombin is an enzyme that acts to generate fibrin monomer in the initial stages of the clotting process. Until recently, commercial fibrin adhesives used thrombin of bovine origin, but human derived thrombin is now the preferred source, which, if virally inactivated, will prevent possible transmission of infectious agents (140). The concentration of thrombin in the formulation affects the speed of clotting, with increased concentrations giving reduced clotting times (147).

**Factor XIII.** Factor XIII is a cross-linking agent that, when activated by thrombin and calcium ions to factor XIIIa, catalyzes cross-linking of the fibrin polymer. This hardens the clot and thereby increases its mechanical strength and reduces susceptibility to proteolytic degradation by plasmin (148).

**Fibrinolytic Inhibitors.** Most fibrin adhesive compositions contain a fibrinolytic inhibitor that acts to stabilize the fibrin clot against degradation by naturally occurring proteolytic enzymes (140). Typically, an extract from bovine lung called aprotinin is used, although other agents such as tranexamic acid or aminocaproic acid have been used (149). Studies have shown that tranexamic acid decreases early fibrin digestion, while aprotinin is more ef-

**Figure 26.26** Mechanistic cascade of fibrin tissue adhesive clotting and degradation.

fective over longer time periods by increasing fibrin recovery (150).

#### c. Mechanism of Action

Fibrin adhesives mimic the final step of the physiological coagulation cascade (Fig. 26). Thrombin acts proteolytically to cleave fibrinopeptide A and B from fibrinogen to produce fibrin monomer, which then polymerizes by hydrogen bonding and electrostatic reactions to form an unstable, soft clot. Thrombin also activates factor XIII to XIIIa in the presence of calcium ions, which catalyzes the cross-linking of the fibrin through the formation of amide links between glutamine and lysine residues in a variety of proteins (147,148,151). The cross-linking reaction stabilizes the clot as well as increasing clot resistance to proteolytic degradation by plasmin (152). Cross-linking between fibrin and adhesive glycoproteins (collagen, fibronectin, von Willebrand factor) as well as cellular glycoproteins anchors the clot to the site of the injury (140,148).

Clotting time is dependent on the concentration of both fibrinogen and thrombin (153). Figure 27 shows that the gelation rate is inversely proportional to the concentration of thrombin at a fixed level of fibrinogen. The dependency on fibrinogen concentration is more complex, showing a biphasic relationship at constant thrombin concentration (Fig. 28). Studies have also shown the strong influence of ionic strength and pH on clotting time (153).

#### d. Mechanical and Adhesive Properties

Fibrin sealants have typically been used for hemostasis in surgical applications, but their use as tissue joining agents

**Figure 26.27** Clotting time (CT) of 2 mg/mL pure fibrinogen induced by various levels of thrombin or reptilase. (Reprinted from Ref. 153 with permission from Technomic Publishing Co. Inc., copyright 1996.)

**Figure 26.28** Clotting time of various concentrations of fibrinogen induced by 1 U/mL thrombin (with and without 2.5 mM  $\text{Ca}^{2+}$ ). (Reprinted from Ref. 153 with permission from Technomic Publishing Co. Inc., copyright 1996.)

is a relatively new application. Within this area, other techniques, such as staples and soldering, provide alternative solutions. Therefore we must consider both the mechanical and the adhesive properties when characterizing fibrin adhesives.

The tensile strength of fibrin tissue adhesive is increased with increasing thrombin concentration and also

**Table 26.14** Mean Tensile Strength of Wound Closures Using Male Sprague–Dawley Rats

Technique	Tensile strength (g/cm <sup>2</sup> )	
	Day 0	Day 4
Staples	—	530
Fibrin sealant (thrombin activated cryoprecipitate)	99	733
Laser-activated cryoprecipitate	570	779
Laser-activated multicomponent solder	482	668

increases proportionally with fibrinogen concentration (149,154). When compared to other techniques, such as soldering, fibrin glues suffer from low initial mechanical strength, but after several days the strengths are comparable (155) (Table 14). The internal breaking strength of fibrin adhesives has also been shown to increase linearly with fibrinogen concentration at constant thrombin (5 U/ml) and Ca<sup>2+</sup> (10 mM) levels (153) (Fig. 29). In the absence of Ca<sup>2+</sup>, the breaking strengths were reported to be significantly lower, illustrating the importance of Ca ions in factor XIII–induced cross-linking. Trends have been identified between the breaking strength and the pH/ionic strength. The strength of the adhesive increases in relation to both parameters until a plateau is reached at 0.1 M and pH 7.4. This indicates that the fibrin adhesives have their highest strength at physiological pH.

Assessment of restored tissue has shown that cryoprecipitated fibrinogen concentrates compare favorably with suturing (156). Over a period of 90 days, wound closures on Wistar rats using sutures and a fibrin sealant were com-

**Figure 26.29** Breaking strength (g to break a 0.4 cm<sup>2</sup> cross section) of fibrin adhesive at varying fibrinogen concentrations. (Reprinted from Ref. 153 with permission from Technomic Publishing Co. Inc., copyright 1996.)

pared to a nonincised control. The results show that tensile break strength, tensile modulus, and tensile elongation for fibrin healed wounds provided almost 100% restoration of the biomechanical integrity of the control (Table 15).

#### e. Fibrin Adhesives as Delivery Vehicles

Fibrin tissue adhesives also find use as matrixes for the controlled delivery of drugs and biologics. Fibrin acts as an excellent carrier due to its hemostatic properties, natural biocompatibility, and ability to break down as part of the body's healing process.

**Table 26.15** Tensile Data Comparing Fibrin Adhesive, Sutured, and Nonincised Sealing

Sample	Retrieval (days)					
	4	7	14	28	60	90

One of the first delivery matrix applications of fibrin sealants was for antibiotics (157–159). While the fibrin clot forms during bonding, a suitable medium for microbial growth is also formed. Therefore the controlled release of antibiotics from the glue provides a local antimicrobial effect during wound healing (160). Requirements for the delivery of antibiotics must include biodegradability under physiological conditions and ensure that the delivery matrix remains at the site of application. Several examples exist of the successful delivery of antibiotics (160), as either a solution or a solid dispersed within the matrix, including tetracycline (161), ampicillin, carbenicillin, gentamycin, and dibekacin. Some antibiotics, however, were found either to increase the clotting time or to reduce the strength of the resultant fibrin clot (149). Other issues surround the small loadings of antibiotic that may be incorporated into the matrix and also the relatively fast rate at which they are delivered. This rate may be controlled to some degree by the use of insoluble forms of antibiotic.

Fibrin has also been used for the delivery of chemotherapeutic agents (157,162), osteoinducers (163), and various growth factors (157).

#### *f. Clinical Applications of Fibrin Adhesives*

Fibrin adhesives have found use in many surgical applications due to their ability to join tissue, their hemostatic properties, and their ability to act as a barrier to fluid. Delivery of these adhesives to the wound site can be achieved by a dual syringe system, spray technique (164) or endoscopically (165). In reconstructive and aesthetic surgery, fibrin glues have been shown to give high success rates for skin graft take (166). For difficult wound sites, such as on the neck, shoulder, buttocks, and back, the use of fibrin glue to improve early adherence of skin grafts has reduced the amount of postoperative care (149,167–169).

Other indications for fibrin tissue adhesives include otolaryngology (140,170), nerve repair (171), cardiovascular surgery (140,172), thoracic surgery, ophthalmology, dentistry (173), and general traumatology.

## 2. Protein Adhesives

The interest in synthetic adhesives, and the realization of their associated problems, has prompted scientists to look at how nature uses adhesion to perform various functions. For example, in order to develop even better adhesives, chemists have been looking at how common mussels adhere to objects underwater. None of the currently available commercial glues even come close to the incredible sticking power of the natural “glue” used by many molluscs.

There are many other adhesives found in nature, many of which rely on the action of proteins on specific substrates.

### *a. Mussel Adhesive Proteins*

Marine organisms including mussels and barnacles are capable of producing remarkable moisture-resistant adhesives. Since these function in moist environments, often underwater, they are potentially useful as medical adhesives.

The byssus threads of a mussel will hold it strongly to rocks, the hulls of ships, wood, or plant life. The adhesives are even more remarkable in that they function perfectly well over a wide range of temperatures and in fluctuating salinities despite the rigors of waves, tides, and currents in all marine environments.

In order for chemists to mimic the action of naturally occurring adhesives, they must first understand how marine organisms such as the mussel make their bonds. By placing its foot very close to a surface and expelling all the water and creating a partial vacuum it pumps liquid protein into the area through special glands in its foot. This liquid immediately forms a sticky foam and then numerous tiny threads of protein form within the foam. This is very similar to the silk threads formed by spiders and silkworms. It consists of highly insoluble polymeric fibers, much of which is keratin-like (the same protein which makes our fingernails and horses' hooves). Numerous detailed reviews have been published on marine bioadhesives, most notably those of Waite (174,175).

Scientists in laboratories all over the world have had limited success in making adhesives to match the performance and characteristics of the mussel's byssus threads. BioPolymers Inc. markets a glue based on mussel derived proteins under the trademark *Cell-Tak*, which was launched in 1986. This adhesive is used by scientists to attach submerged cells to the surface of tissue culture dishes. Another company, Gentex, has cloned the mussel gene that codes for the preliminary proteins that make byssus. They have been able to insert this gene into yeast cells, which are then able to produce small batches of the protein resin. They hope to make an adhesive that can be used instead of sutures, and that can even reunite severed nerves.

While this substance might make an excellent adhesive for use in wet environments, isolation of the uncured adhesive from mussels for commercial use is not practical since the extraction of 1 kg of the adhesive substance would require the use of 5 to 10 million mussels. A totally synthetic alternative would be a more realistic proposal.

Much of the initial work, however, in this area did con-

concentrate on harvesting the polyphenolic proteins from common mussels, *Mytilus edulis*, and purifying and stabilizing these by isolating the high molecular weight fractions of acid-soluble extracts. These proteins are digested in trypsin to yield a specific decapeptide sequence. These decapeptides are then used as building blocks to make larger polyphenolic molecules possessing the adhesive capabilities of the native bioadhesive protein comprising about 1 to 1000 decapeptide repeating units using amino acid, oligopeptide, or other bifunctional spacers. Methods for purifying this protein and its uses have been published in U.S. patents (176–180).

The natural protein itself is rich in proline/hydroxyproline, serine, threonine, lysine, tyrosine/3,4-dihydroxyphenylalanine (DOPA), and alanine, a composition that suits the protein for interaction with biological surfaces, as shown in Table 16 (181).

The natural adhesive can be mimicked by focusing on the ten-acid sequence. This decapeptide is repeated many times in the long chain polypeptide and is one of the keys to the adhesive characteristics of these materials. In addition to the decapeptide sequence, other significant features identified include the presence of lysine and tyrosine or DOPA residues, which provide the essential cross-linking sites. Furthermore, there is an unusually frequent appearance of proline or hydroxyproline residues and an essentially complete absence of glycine residues, i.e., the decapeptide sequence is not typical of connective tissue proteins such as collagens.

*Mytilus edulis*, which has perhaps received the most attention, is not the only marine organism that has evolved an elaborate mechanism for adhering itself to surfaces. The Atlantic mussel, *Geukensia (Modiolus) demissa*, also possesses an ability to bond in a marine environment. Its proteinaceous adhesive is distinct from that of the common mussel. The Atlantic ribbed mussel adhesive has glycine as one of its most abundant amino acid residues, similar to collagen (though not as plentiful), and one of the novel sequences in this adhesive is based upon a tripeptide frag-

ment that occurs with great frequency in the natural adhesive. Other novel peptide sequences include octapeptide and nonapeptides that contain the characteristic tripeptide “tail.” The tripeptide is GLY-DOP-LYS, where GLY is glycine, DOP is dihydroxyphenylalanine, and LYS is lysine. These specific sequences are covered in a U.S. patent (182).

#### b. Synthetic Analogues of Protein Adhesives

The direct chemical synthesis in the laboratory of a polypeptide identical to those found in mussels represents a huge challenge. Already, analogues of the marine mussel extract have been formed using recombinant technology as disclosed in U.S. patents (183,184).

Synthetic polymers (branch copolymers) have been prepared with a free-amine-rich backbone onto which were grafted variations of the natural decapeptide. These compounds are the subject of a patent by BioPolymers Inc. (185). A formulation based on polyphenolic proteins extracted from the marine mussel has already entered the market under the trademark *Cell-Tak*. *Cell-Tak* has been tested on cartilage surfaces and was found to be of very low adhesive strength (186).

In order to produce large quantities of mussel adhesive proteins for studying mechanisms and developing materials for medical applications, microbial systems have been developed (Genex Corporation) to produce the protein (187). The expression system was based on yeast but contains neither DOPA nor hydroxyproline residues. DOPA residues are unusual in proteins, and it has been suggested that these are crucial for moisture-resistant adhesion to surfaces and for cross-linking to build cohesive strength. Studies with genetically engineered protein support this and show that cross-linking and moisture-resistant adhesion require the presence of the reactive, oxidized form of DOPA, namely quinone. The DOPA adhesive proteins are stable in an acidic solution or as lyophilized powders. The DOPA protein is the preadhesive form of the protein. The adhesive properties are generated when the DOPA residues are oxidized to quinone. In order to achieve moisture-resistant adhesion, there is a need for tyrosine to be hydroxylated. The sequence in Fig. 30 shows the posttranslational modification of tyrosine residues in the *Mytilus edulis* protein (181). This reaction can be catalyzed by tyrosinases derived from mushrooms and bacteria.

Adherence of the engineered mussel protein in an aqueous environment to various substrates including polystyrene, glass, hydrogel, and collagen has been tested. In each case activation to the quinone form of the protein was required for good surface adhesion. The cohesive strength

**Table 26.16** Potential Adhesive Interactions of Frequently Occurring Amino Acids in *Mytilus edulis* Adhesive Protein

Amino acid	Chemical bond
Serine	Hydrogen
Threonine	Hydrogen
Lysine	Ionic
Tyrosine	Hydrogen
Hydroxyproline	Hydrogen
DOPA	Metal complex formation

**Figure 26.30** Posttranslational modifications of tyrosine residues in the *Mytilus edulis* adhesive protein.

of the engineered adhesive protein depends upon intermolecular cross-linking, which requires formation of quinone residues. The nature of the chemical bond involved in the cross-linking has yet to be determined.

It has also been found that the stereochemistry of the decapeptide oligomer is not essential to the adhesive behavior of the protein; the protein need only contain a certain amount of DOPA rather than the entire decapeptide sequence.

A synthetic approach has recently been adopted by Deming and Yu (188), who tested the premise that functionality, and not amino acid sequence, was the only feature necessary for moisture-resistant adhesion. Using the known composition of the natural adhesive proteins, sequentially random copolypeptides through copolymerization of a few select  $\alpha$ -amino acid N-carboxyanhydrides (NCAs) were prepared. NCAs are readily prepared from

amino acids by phosgenation and can be polymerized into high molecular weight polypeptides via successive ring-opening addition reactions that liberate carbon dioxide. The resulting copolymers were oxidized under a variety of conditions, and the effect of the oxidant on both cross-linking and adhesive capabilities was evaluated.

Simple copolypeptides of L-lysine and DOPA containing different compositions of the two monomers were prepared as shown in Fig. 31. L-Lysine was chosen as the other major component since (1) it is present in large quantities in marine adhesive proteins, (2) it is thought to be involved in protein cross-linking reactions, and (3) it should provide good water solubility to the copolymers when the side chain is ionized.

Many factors affect the bond strength in these synthetic systems including copolymer ratio, cure time, temperature, oxidant, and substrate. This system uses inexpensive oxidizing materials, and there is a route defined to produce a supply of adhesive polymers. Through adjustment of the copolymer composition, molecular weight, or curing conditions, the adhesive properties of these synthetic copolypeptides can, it is claimed, be tuned for specific applications (188).

Typical bond strengths for these materials have been measured (188) on steel, aluminum, glass, poly(methyl methacrylate), polystyrene, and poly(ethylene). The tensile strengths range from 2–4 MPa for the steel, aluminum, and glass substrates; the synthetic polymers were considerably less. These results, representing a totally synthetic ap-

proach, compare favorably with natural precursor protein. Natural adhesive precursor protein has been extracted from the blue mussel *Mytilus edulis*, which has the sequence Ala-Lys-Pro/Hyp-Ser-Tyr/DOPA-Hyp-Hyp-Thr-DOPA-Lys. A polydecapeptide having the sequence of the adhesive *Mytilus edulis* (Mw ca. 140,000) was reported to give a tensile strength of 2.75 MPa when cured in water on steel (189).

More recently, Deming has published experimental data showing that the adhesion and cross-linking chemistry of mussel adhesive model polymers is due primarily to the DOPA residues in the materials (190). The studies concluded that the catechol functionality is primarily responsible for moisture-resistant adhesion, and the oxidized *o*-quinone functionality is mainly responsible for cross-linking.

A new generation of biocompatible adhesive materials could soon be developed with the potential to become key components in surgical procedures. Opportunities lie in identifying novel peptide sequences that can be synthetically engineered to produce a strong adhesive. Initial results by key groups indicate that these characteristics are being investigated and optimized.

#### D. Tissue Adhesive Summary

The general properties of currently available tissue adhesives are summarized in Table 17 (130). Each adhesive type has characteristics making it suitable for specific applications. For example, cyanoacrylates give excellent bond strengths (186) (Table 18), and fibrin is rapidly resorbed. These relative benefits and side effects are associated with the use of all tissue adhesives, which are summarized in Table 19 (191).

**Table 26.18** Mean Bond Strengths Between Different Tissue Types for Butt Joints

	Bone strength (MPa)		
	Cartilage	Bone	Skin
<i>n</i> -Butyl-2-cyanoacrylate	1.0	1.4	1.2
GRF	0.15	0.20	0.07
Fibrin	0.0049	0.011	0.019

#### IV. CONCLUSIONS

The increasing understanding of wound management has largely been responsible for the development and formulation of polymers for PSAs that can facilitate the wound healing process. Highly moisture vapor permeable adhesives enable dressings to control wound exudate more effectively, the management of trauma has seen advances made in “smart” PSAs that can change adhesive properties by use of external stimuli, and the controlled delivery of active ingredients using transdermal delivery systems have all required novel PSAs to further this technology.

There are still shortcomings in the currently available tissue adhesives, and their widespread acceptance has been inhibited by the often demanding requirements of many clinical procedures. An ideal tissue adhesive should cure rapidly in situ, form strong bonds to a variety of tissue types, and ultimately be degraded to yield safe, nontoxic by-products. Cyanoacrylates have been used in surgery, but the cured polymers release formaldehyde on biodegradation, which is believed to be responsible for toxicity to-

**Table 26.19** Relative Benefits/Side Effects of Current Tissue Adhesives

Property	Ranking
Adhesive power	Cyanoacrylate > GRF glue > Fibrin sealant
Tensile strength	Cyanoacrylate > GRF glue > Fibrin sealant
Flexibility	Fibrin sealant > GRF glue > Cyanoacrylate
Thrombogenicity	Cyanoacrylate > GRF glue > Fibrin sealant
Resorption rate	Fibrin sealant (10 days) > GRF glue (6 weeks) > Cyanoacrylate (12 months)
Chronic inflammation and stimulation of fibrosis	Cyanoacrylate > GRF glue > Fibrin sealant

wards tissue. Butyl-2-cyanoacrylate is now being used as a safe cyanoacrylate for skin closure, although it is always stressed that the monomer should not be allowed to penetrate below the level of the skin. Fibrin has been more widely used in surgery than cyanoacrylates, not only as an adhesive but also as a hemostatic agent and surgical sealant, although fibrin only produces very weak adhesive bonds.

Significant developments have therefore been made in the area of medical adhesives over the last 20 years. Although PSA technology is well established, there have been many advances that have expanded their potential beyond a simple method of fixation. Research into tissue adhesives, however, has yet to identify the ideal surgical adhesive, although several candidate materials show promise and are currently under development.

## Glucose-Sensitive Hydrogel Membranes

Jin Ho Lee, Jung Ju Kim, and Kinam Park  
*Purdue University, West Lafayette, Indiana*

### I. INTRODUCTION

#### A. Hydrogels

Hydrogels are three-dimensional networks of hydrophilic polymers that can absorb large amounts of water (usually more than 20% of the total weight) but remain insoluble (1–7). Three-dimensional networks are usually formed by chemical or physical cross-linking of hydrophilic polymer chains. In chemical gels, polymer chains are connected by covalent bonds, and thus it is difficult to change the shape of chemical gels. On the other hand, polymer chains of physical gels are connected through noncovalent bonds, such as van der Waals interactions, ionic interactions, hydrogen bonding, hydrophobic interactions, traces of crystallinity, and multiple helices. Since these bonds are reversible, physical gels possess sol–gel reversibility. The key characteristic property of hydrogels is the reversible swelling/deswelling in aqueous solution. The hydrogels swell in aqueous solution because hydrophilic polymer chains of the cross-linked network try to dissolve in water. Upon absorption of water (or swelling), the glassy polymer network becomes elastic. The extent of swelling is determined by the nature of polymer chains and cross-linking density. The extent of swelling is quantified by the ratio of the volume (or weight) of the swollen hydrogel ( $V_s$ ) to the volume (or weight) of the dried hydrogel ( $V_d$ ). Thus the swelling ratio ( $Q$ ) is defined as  $V_s/V_d$ .

#### B. Environment-Sensitive Hydrogels

All hydrogels have the same fundamental property of swelling in the presence of water and deswelling (or shrinking) in the absence of water. Some hydrogels have additional properties, such as swelling or shrinking, in response to changes in environmental conditions. The presence of thermodynamically active functional groups on polymer chains makes the hydrogels sensitive to certain stimulants, or environmental factors (8). These hydrogels with additional functions are collectively called “environment-sensitive” hydrogels or “stimuli-responsive” hydrogels. Compared with ordinary hydrogels without such additional properties, environment-sensitive hydrogels are more advanced, and for this reason they are also called “smart” or “intelligent” hydrogels. One of the unique properties of these types of hydrogels is that they change their swelling ratio rather abruptly upon small changes in environmental factors. This abrupt volume change is known as volume transition. If the volume transition occurs to make the volume smaller, it is called “volume collapse.” The volume transition of smart hydrogels can occur by only a small change in environmental conditions, such as pH, temperature, ionic strength, electric field, magnetic field, ultrasound, solvents, electrolytes, external stress, light, pressure, specific molecules, or enzymes (8–12). It is this unique property of smart hydrogels that

makes them useful in various areas, such as pharmaceutical, biomedical, and biotechnological applications.

### 1. pH-Sensitive Hydrogels

Of the many smart hydrogels, pH-sensitive hydrogels have been most frequently used in glucose-sensitive insulin release devices. pH-sensitive hydrogels are cross-linked polyelectrolytes (i.e., polymers with a large number of ionizable groups) that display big differences in swelling properties depending on the pH of the environment. When a polymer becomes charged, its hydrogel swells substantially more than at the neutral state. Figure 1 shows examples of pH-sensitive polymers. Hydrogels made of polyanions, such as poly(acrylic acid) (PAA), swell less as pH becomes lower due to the loss of charges. On the other hand, polycations, such as poly(*N,N'*-diethylaminoethyl methacrylate) (PDAEM) swell substantially more at lower pH due to the generation of charges on the polymer chains. Both types of polyelectrolyte hydrogels have been used for preparing glucose-sensitive hydrogels.

### 2. Glucose-Sensitive Hydrogels

Some of the environment-sensitive hydrogels are glucose-sensitive hydrogels that can be used for glucose sensing and modulated (or self-regulating) insulin delivery. The glucose-sensitive hydrogels undergo changes in the swelling ratio or changes in physical states (i.e., sol and gel) in response to small changes in the glucose concentration in the environment (13). Development of glucose-sensitive hydrogels is critical in the development of self-regulating

insulin delivery systems. Unlike other controlled release drug delivery systems, the insulin delivery systems require monitoring of glucose levels and the release of insulin just enough to reduce the elevated blood glucose level. Since the amount of insulin to be delivered will be different each time and depend on the glucose level, this type of self-regulating insulin delivery system presents the ultimate challenge in controlled drug delivery technologies. This chapter reviews various glucose-sensitive hydrogels that have been developed for glucose sensing and self-regulated insulin delivery.

## II. GLUCOSE-SENSITIVE HYDROGELS FOR SELF-REGULATED INSULIN DELIVERY

Conventional methods of controlled drug delivery are mainly based on diffusion at a certain rate through polymer membranes or matrices. This mode of drug delivery results in relatively constant drug levels in blood, but it may not be suitable for insulin delivery. For management of diabetes, the level of insulin delivery has to be adjusted depending on the blood glucose level. Daily injections of insulin are known to be inadequate for maintaining normal blood glucose levels and preventing long-term complications of diabetes, and this increases demands for self-regulated insulin delivery systems. Since insulin release has to be in harmony with increase in the blood glucose level, the most desirable insulin delivery system requires a glucose-sensing ability and an ability to trigger release of the necessary amount of insulin (14). The methods that have been used for development of glucose-sensitive insulin delivery systems can be divided into biological and bioengineering approaches. In the biological approach, cultured, living pancreatic  $\beta$ -cells are used after encapsulation in polymeric membranes. Improvement has to be made for the long-term survival of encapsulated cells for this approach to be practical. In the bioengineering approach, mechanical glucose sensor and insulin delivery pumps are used. This approach has to overcome substantial hurdles in terms of reliability and convenience.

Recently, many researchers have focused on an alternative approach utilizing glucose-sensitive hydrogels. For the hydrogels to possess glucose sensitivity, they have to contain molecules that specifically interact with glucose molecules. Currently used glucose-sensitive molecules are concanavalin A (Con A), phenylboronic acid, glucose oxidase, and glucose dehydrogenase. These molecules have been incorporated into hydrogels for glucose sensing and modulated insulin delivery.

**Figure 27.1** pH-dependent ionization of polyelectrolytes. Poly(acrylic acid) becomes ionized at high pH, while poly(*N,N'*-diethylaminoethyl methacrylate) becomes ionized at low pH. Ionized hydrogels swell more due to the presence of charges.

## A. Con A as a Glucose Responsive Unit

### 1. Complexes of Con A and Glycosylated Insulin

#### a. Initial Concept

This approach, which was first introduced by Brownlee and Cerami (15,16), is based on competitive binding between glucose and glycosylated insulin for carbohydrate specific binding sites on Con A. Con A is a globular lectin that is composed of 237 amino acid residues and four polypeptide subunits. Each subunit has a molecular weight of 26,000 daltons and a dimension of  $44 \times 40 \times 39 \text{ \AA}^3$  (17,18). The glycosylated insulin molecules can be bound to each subunit of Con A and reversibly displaced from Con A by glucose in direct proportion to the concentration of external glucose. In this approach, the Con A/glycosylated insulin complex is enclosed in a polymer membrane that is permeable to glucose and glycosylated insulin, but not to Con A or antibodies. It is important to prevent release of Con A from the membrane of the device, because Con A is known to be immunotoxic (19–22). When the blood glucose level rises, glucose enters the reservoir and competitively displaces glycosylated insulin from Con A (23). The glycosylated insulin is then released by diffusion through the membrane into the body as shown in Fig. 2.

While the idea behind this approach is strikingly elegant and serves as a role model for other approaches, it has a few inherent limitations. First, each insulin molecule has to be modified with glucose, and this creates a new chemical entity. The glycosylated insulin is not the same as native insulin, and it has to go through the approval process as a new chemical entity. Second, Con A is a relatively large molecule but has only four glucose binding sites. This creates a problem of small reservoir capacity that is not suitable for long-term delivery. The binding constant of the glycosylated insulin to Con A needs to be higher than that of glucose to prevent easy displacement of glycosylated insulin with consequent danger of hypoglycemia.

**Figure 27.2** Schematic representation of self-regulated insulin delivery system.

### b. Various Insulin Formulations

The glycosylated insulin approach has been further investigated by Kim and his coworkers (23–29). Various insulin derivatives having variable binding constants to Con A were synthesized and examined for their stability and biological activity. As shown in Fig. 2, the complexes of Con A and insulin derivatives are enclosed in a porous polymer membrane. Initially, poly(hydroxyl methacrylate) (poly-HEMA) membrane was used, but it was replaced later with cellulose acetate tubing or thin nylon membrane due to its weak mechanical strength.

The main drawbacks of the encapsulation system were leakage of potentially immunogenic Con A through the polymer membrane and the slow onset of insulin release when the device was challenged by high glucose concentration. To avoid the leakage, Con A was immobilized to Sepharose beads, which were then enclosed in a macroporous membrane (30). This device still suffered in performance due to the settling of the beads by gravity and the bulk size of the beads. A cross-linked Con A gel was also synthesized to further prevent Con A leakage through the membrane (30). The long unwanted lag phase for the onset of glycosylated insulin release was partly the result of the limited solubility of Con A/glycosylated insulin complex (31). The limited solubility was due to the tetrameric nature of Con A and the formation of dimers or hexamers by glycosylated insulin derivatives (32,33). In an effort to prevent dimerization or hexamerization of insulin derivatives, insulin was derivatized with glycosyl polyethylene glycol (PEG) for improved solubility and solution stability at physiological pH (34). To reduce the response time, the surface area was also increased by applying microcapsules and microspheres (30,35,36). A series of improvements made in this system is shown in Table 1.

### 2. Complexes of Con A and Glucose-Containing Polymers

A Con A-loaded hydrogel system was shown to undergo swelling and deswelling in response to different saccharides (38). The gel consisted of a covalently cross-linked network of poly(N-isopropyl acrylamide) and physically entrapped Con A associated with dextran sulfate. Since the hydrogel swelled due to ionic osmotic pressure induced by the anionic inclusion, it shrank when the dextran sulfate was displaced from the Con A binding site by uncharged saccharides.

Con A also reacts with glucose-containing polymers to form precipitates (39,40) or hydrogels (41). The hydrogels made of Con A and poly(2-glucosyloxyethyl methacrylate) swelled in the presence of glucose due to the dissociation

**Table 27.1** Self-Regulated Insulin Delivery Systems Using Con A as a Glucose Sensing Unit

	Binding substrate	Insulin derivative	Membrane	Comments
I	Soluble Con A tetramer	SAPG-insulin SAPM-insulin	PolyHEMA, cellulose acetate.	Con A leakage. Decreased permeability of glucose and G-insulin resulting in long lag times.
II	Con A immobilized onto Sepharose beads	SAPG-insulin SAPM-insulin	Cellulose acetate, Nucleopore membranes.	Con A leakage. Settling of Con A beads. Poor response by glucose increase.
III	Con A hydrogel	SAPG-insulin	Durapore membrane fabricated into a pouch	No Con A leakage. Increased permeability of glucose and G-insulin. Heat sealable membrane for easy fabrication.
IV	Con A microcapsules	SAPG-insulin	Durapore membrane fabricated into a pouch	Microcapsules (30–250 $\mu\text{m}$ containing Con A/SAPG-insulin resulted in short response time.
V	Soluble Con A oligomer	SAPG-insulin	Hollow fiber recirculation system	Con A oligomers were not permeable to hollow fiber membrane. Short lag time. Refillable system.

of the Con A–polymer complex by competitive binding of free glucose. The hydrogels made of Con A and polysucrose complexes were used as rate-determining membranes for release of a solute in the reservoir as a function of the glucose concentration (42–44). The solute release through the membrane was controlled by the viscosity change resulting from the gel-to-sol transition of Con A/polysucrose complexes.

### 3. Sol–Gel Phase-Reversible Hydrogels

Con A and glucose-containing polymers were used to form stable hydrogels undergoing phase transition between sol and gel (14,45–48). To prepare phase-reversible glucose-sensitive hydrogels, Con A was used as a physical cross-linking agent for glucose-containing polymers, such as

poly(allyl glucose-co-acrylamide) (poly(AG-co-AM)), poly(allyl glucose-co-vinylpyrrolidone) (poly(AG-co-VP)), and poly(allyl glucose-co-3-sulfopropylacrylate potassium) (poly(AG-co-SPAK)). The gel–sol phase transition of this system is schematically described in Fig. 3 (46). In the absence of free glucose, Con A interacts with polymer-bound glucose to form a hydrogel. The increase in free glucose, however, results in detachment of polymer-bound glucose from Con A and thus transition to a sol. Upon removal of free glucose, the sol becomes a gel again, and this process can be repeated. In the sol state, the increased mobility of polymer chains allows solute molecules to diffuse more easily. Indeed, the release of insulin was shown to be faster in the sol state of the glucose-sensitive hydrogel membrane (14). The free glucose concentration necessary to induce phase transition of the hydrogels can

**Figure 27.3** A gel–sol phase-reversible hydrogel system sensitive to glucose. (From Ref. 46.)

**Figure 27.4** Insulin release profiles from glucose-sensitive hydrogel matrices. The matrices were prepared by MPEG5–Con A conjugate (14 w/v%) and different glucose-containing polymers.  $\Delta$ , poly(AG-co-AM) (2 w/v%);  $\square$ , poly(AG-co-VP2) (2 w/v%);  $\circ$ , poly(AG-co-SPAK3) (3 w/v%). (From Ref. 49.)

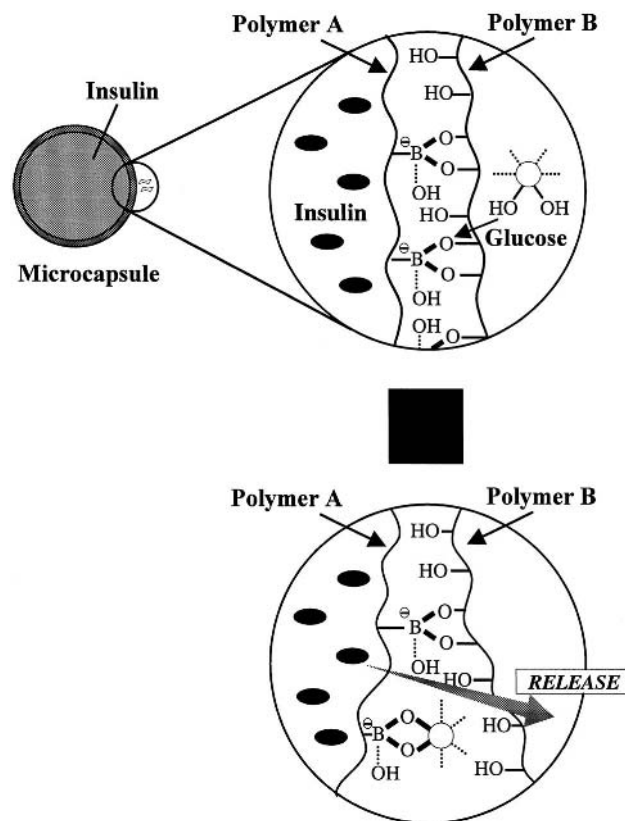

be made within the physiological range (which is 1 ~ 4 mg/mL) by adjusting the molar ratio of Con A to glucose-containing polymer.

One of the difficulties in preparation of Con A-based glucose-sensitive hydrogels is the poor water solubility of Con A. To alleviate this problem, Con A was conjugated with monomethoxy poly(ethylene glycol) (MPEG) (49). The MPEG–Con A conjugate showed increased solubility and stability in aqueous solution. The hydrogels made of MPEG–Con A showed pulsatile release of insulin in response to the changes in glucose concentration between 1 mg/mL and 4 mg/mL as shown in Fig. 4 (49). The insulin release at the glucose concentration of 4 mg/mL, representing the hyperglycemic level, was several times higher than that at 1 mg/mL of glucose, representing the normal blood glucose level. Such pulsatile release of insulin can be continued as long as the membrane remains intact.

**B. Phenylboronic Acid as a Glucose-Responsive Unit**

In addition to Con A, phenylboronic acid (PBA) was used as a glucose-responsive unit. PBA is known to have a reversible binding property to dihydroxyl compounds when the two hydroxyl groups are in a coplanar configuration (50–53). Since most carbohydrates, including glucose,

possess a cis-diol moiety in the structure, they can form a relatively strong complex with borate. A polymer having pendant PBA groups can form a gel with a polyol, such as polyvinyl alcohol (PVA), through the complex formation. When glucose is added to this complex gel, the gel swells and dissolves due to a decrease in the cross-linking density caused by the substitution reaction of glucose with the pendant hydroxyl groups of the polymer. This swelling results in increased release of loaded insulin. Reduction in free glucose concentration leads to reformation of borate–polyol cross-linking in the complex gel with subsequent reduction in insulin release. This concept was used to prepare glucose-sensitive insulin delivery formulations based on a reservoir system (54–57). An example of the reservoir system is schematically shown in Fig. 5. Poly(vinylpyrrolidone-co-*m*-acrylamidophenylboronic acid) is commonly used as a PBA-containing polymer. One of the problems of this system is that the complex gel is sensitive to glucose only under alkaline conditions (pH > ~9.0). This problem was partly overcome by incorporating amino groups into the PBA polymer (57).

**Figure 27.5** Concept of polymer capsule type glucose-sensitive insulin delivery system using PVA/poly(VP-co-PBA) complex. Polymer A, poly(VP-co-PBA); polymer B, PVA. (From Ref. 55.)

The borate–polyol cross-linked gel was also used as a glucose-sensitive erodible matrix system (58). In this erodible system, a gel is formed between *m*-aminophenylboronic acid-substituted polyacrylamide (poly(PBA-co-AM)) and diglucosyl hexanediamine (DGHDA). In the presence of free glucose, the gel matrix is disrupted by replacement of DGHDA with glucose through competitive binding to PBA, and this results in solubilization of the matrix and a significant increase in the insulin release rate. One of the advantages of using PBA is that it is a synthetic molecule that may not be immunotoxic as Con A is. For this system to be practical, however, the glucose-specificity of the PBA moiety has to be improved.

### C. Glucose Oxidase as a Glucose Responsive Unit

pH-sensitive hydrogels (such as those shown in Fig. 1) can be used to prepare glucose-sensitive insulin delivery systems. In this approach, pH-sensitive hydrogels usually contain immobilized glucose oxidase (GOD), which converts glucose to gluconic acid in the presence of oxygen:

The formation of acid results in lowering of the pH of the medium, and pH-sensitive hydrogels change their swelling

ratio, i.e., the pore sizes inside the hydrogels change to affect the diffusion of solutes such as insulin molecules. Since the mechanism of insulin release depends on the type of polyelectrolyte used, this approach can be further classified based on the charge type used.

#### 1. Hydrogels Made of Cationic Polyelectrolytes

Commonly used cationic polyelectrolytes are polymers made of cationic monomers, such as N,N-dimethylaminoethyl methacrylate (DMAEM) and N,N-diethylaminoethyl methacrylate (DEAEM) (59–66). Hydrogels made of these polymers undergo swelling as the pH is lowered as a result of formation of gluconic acid (Fig. 6). The increased swelling, in turn, results in more release of insulin. One of the problems of this system is the leveling off of the response as the glucose concentration is increased above 0.5 mg/mL, while the glucose concentration in the body can be as high as 10 mg/ml (65). This limited glucose sensitivity is due to the fact that GOD is a flavoprotein. GOD requires an electron acceptor, such as oxygen, to reoxidize the flavin adenine dinucleotide that is reduced as glucose is consumed (65). Thus the sensitivity of this system depends on the presence of oxygen in the medium. The same mechanism has been used to prepare variations of glucose-sensitive insulin delivery systems. Both matrix type (67) and reservoir type (68–71) devices have been prepared.

**Figure 27.6** Schematic representation of mechanism of action of glucose-sensitive membrane. A, in the absence of glucose, at physiologic pH, few of the amine groups are protonated; B, in the presence of glucose (G), glucose oxidase (GOD) produces gluconic acid; C, gluconic acid can protonate the amine groups. The fixed positive charge on the polymeric network leads to electrostatic repulsion and membrane swelling. (From Ref. 59.)

2. Hydrogels Made of Anionic Polyelectrolytes

a. "Squeezing" Hydrogels.

Glucose-sensitive polyanionic hydrogels were prepared using poly(methacrylic acid-g-ethylene glycol) (poly(MAA-g-EG)) (10). Methacrylic acid and PEG monomethacrylate were copolymerized in the presence of GOD. At low pH, interpolymer complexes are formed in these hydrogels due to hydrogen bonding between the hydrogen atoms of the methacrylic acid units and the oxygen atoms on the ether groups of the PEG chains. Such hydrogen bonding results in the collapse of the gel due to increased hydrophobicity in the polymer network. As the carboxylic groups become ionized at high pH, the polymer chains in complexes become separated and the gel swells. If GOD is incorporated into the hydrogels at high pH, lowering of pH in the presence of free glucose results in "squeezing" of the hydrogels. If the glucose level decreases, less gluconic acid is produced, resulting in slow increase in pH of the environment. The squeezed hydrogel would then swell, and this cycle can be repeated.

b. "Chemical Gate" Hydrogel Layers

Poly(acrylic acid) and GOD were grafted to porous films, such as porous cellulose and poly(vinylidene fluoride) membranes (72,73). At neutral pH, negatively charged poly(acrylic acid) chains are fully extended to close up the pores of the membrane for poor diffusion of insulin. As pH decreases below 5 as a result of GOD action on glucose, poly(acrylic acid) chains become protonated and the chains collapse into coils on the pore walls, leading to the opening of the pores for the free diffusion of insulin (Fig. 7). The

**Figure 27.7** Principle of controlled release system of insulin. (Left) In the absence of glucose, the chains of poly(acrylic acid) grafts are rodlike, lowering the porosity of the membrane and suppressing insulin permeation. (Right) In the presence of glucose, gluconic acid produced by GOD protonates the poly(acrylic acid), making the graft chains coil-like and opening the pores to enhance insulin permeation. (From Ref. 72.)

insulin diffusion through the open gate, however, was only a few times higher than the diffusion in the closed state. Poly(acrylic acid) was grafted onto the cellulose membrane by either plasma polymerization or ceric ion-induced radical polymerization, and GOD was immobilized by coupling with 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide.

3. Hydrogels Made of pH/Temperature-Sensitive Polymers

pH/temperature-sensitive polymers were used to prepare glucose-sensitive insulin delivery systems (74,75). GOD was incorporated into the poly(N,N-dimethylaminoethyl methacrylate-co-ethylacrylamide) (poly(DMAEM-co-EAM)) matrix. Hydrogels made of poly(DMAEM-co-EAM) have different temperature-responsive swelling properties at different pH values, e.g., pH 4.0 and 7.4. The lower critical solution temperature (LCST) of the copolymer at pH 4.0 is higher than the LCST at pH 7.4 due to the increased electrostatic repulsion of DMAEM groups at pH 4.0. This means that at a given temperature the copolymer does not dissolve at pH 7.4 but becomes dissolved at pH 4.0. As shown in Fig. 8, the generation of gluconic acid from free glucose results in a lowering of the pH, and thus an increase in the LCST. The ultimate outcome is the dissolution of the copolymer and the subsequent release of the incorporated insulin.

**Figure 27.8** Schematic representation of glucose-responsive insulin delivery system using poly(DMA-co-EMA). (From Ref. 75.)

#### 4. Erodible Polymers Surrounded by GOD-Containing Hydrogels

The pH-dependent erodible poly(ortho esters) were used to develop glucose-sensitive insulin delivery systems (76–80). The erosion rate of the poly(ortho esters) increases as the pH decreases. Insulin is physically dispersed in the poly(ortho esters) matrix, which is surrounded by a hydrogel containing immobilized GOD (80). When external glucose diffuses into the hydrogel to be oxidized by GOD to gluconic acid, the pH within the hydrogel drops and the erosion of the polymer matrix accelerates. When the concentration of external glucose drops, production of gluconic acid ceases, and the pH within the hydrogel rises again as gluconic acid diffuses from the hydrogel. This process leads to modulated insulin release from the device. One problem related with this device is that the amount of insulin released may not be proportional to the decrease in pH, and the on-and-off process of insulin release is not fast enough (80).

#### D. Glucose Dehydrogenase as a Glucose Responsive Unit

In addition to GOD, glucose dehydrogenase (GDH) was also used as a glucose-responsive unit (72,81). The reason for using GDH was to provide better glucose sensitivity than GOD does (81). For higher and faster glucose-sensitive insulin release, insulin molecules are grafted to the substrate surface through a disulfide bond. When glucose molecules are present in solution, GDH oxidizes the glucose molecules to generate electrons that reduce the disulfide bonds for release of the grafted insulin (Fig. 9). This process requires enzyme cofactors, nicotinamide adenine dinucleotide (NAD), and flavin adenine dinucleotide (FAD), which act as electron mediators. The glucose sensi-

tivity was increased as NAD and FAD were immobilized to the surface and further enhanced by coimmobilization of GDH (Fig. 9). While this type of system can provide improved sensitivity to glucose and faster release of the immobilized insulin, the system has a major drawback in the limited amount of insulin that can be grafted onto the surface.

### III. GLUCOSE-SENSITIVE HYDROGELS AS GLUCOSE SENSORS

The detection and quantification of glucose in blood plays a vital role in the diagnosis and management of diabetes. Glucose levels are dynamically changing throughout the day depending on food intake, insulin availability, exercise, stress, and illness (82). Measurement of the accurate blood glucose levels and timely delivery of exact amounts of insulin are critical to the maintenance of normal life for diabetic patients. Currently, diabetic patients determine their blood glucose levels by obtaining a small amount of blood with a finger stick, followed by external analysis of the blood sample for the glucose content. This method, although accurate, is painful, inconvenient, and discontinuous, and it has a risk of infection (83). Devising a reliable noninvasive technique for continuous monitoring of glucose levels in the blood has important medical implications. The desired characteristics of *in vivo* glucose sensors are safety, clinical accuracy and reliability, feasibility of *in vivo* recalibration, long-term stability, small size, ease of insertion and removal, and a sufficiently fast response to allow timely intervention (84).

Several attempts have been made to prepare noninvasive glucose sensing devices. One of the most desirable noninvasive methods is near-infrared spectroscopy, which, unlike electrochemical sensors, responds directly to the glucose molecule (85–91). The main practical limitation of this system is that the glucose signal is very weak in the midst of much larger signals from proteins, lipids, and scattered light (92). Table 2 summarizes the blood glucose measurement techniques currently under evaluation (82). Regardless of the approaches, the lack of proper calibration in each system remains as the main limitation.

More realistic approaches in continuous glucose sensing may involve implanting glucose-sensitive devices. Two types of implantable glucose sensors have been reported, fully implantable and percutaneous (worn through the skin) (93). The fully implantable devices, which include electronics and a battery, are designed for longevity and intended to be implanted by a physician either subcutaneously or in a blood vessel. Glucose-sensitive hydrogels, e.g., sol–gel phase-reversible hydrogels, can be implanted,

and the glucose concentration-dependent changes of the hydrogels can be monitored using external spectroscopic devices (94). The percutaneous sensors are needlelike or inserted through a needle and are designed to operate for a few days and be replaced by the patient. Those implantable glucose sensors are mostly amperometric enzymatic sensors (95–98). GOD has been most widely used as a glucose sensing unit in amperometric glucose sensors because GOD transfers electrons to diffusing and nondiffusing mediators, withstands chemical immobilization techniques, and has a high turnover rate ( $\sim 10^3 \text{ s}^{-1}$ ) at ambient temperatures (99). However, conventional GOD-based glucose sensors have some disadvantages. Variations in the level of dissolved oxygen may cause fluctuations in the electrode response, and the dynamic range of glucose detection can be limited by lack of dissolved oxygen (100,101). Diffusion mediators for electron transport such as quinones and ferrocenes have been used in enzyme electrodes to overcome oxygen dependence. However, in vivo leaching of the mediator has been a serious problem. To eliminate me-

**Table 27.3** Glucose-Sensitive Hydrogels Used for Glucose Sensing

Glucose sensing unit	Hydrogel system	Detection method	References
GOD	Poly(HEMA)	H <sub>2</sub> O <sub>2</sub>	103, 104
	Poly(VP) or poly(VP-VI)/OS derivative/PEG redox hydrogels	Current	84, 99, 101, 105–109
	Poly(allylamine)/OS derivative	Current	110

	Gelatin	Photoacoustic wave	117
	Poly(carbamoyl sulphonate)	Chemiluminescence	118
	Polyacrylamide-based colloidal crystal hydrogel	Optical intensity	119, 120
	Con A	FITC-dextran	Fluorescence
Poly(GEMA)		Optical intensity	40
PBA	Poly(IPPm-co-PBA-co-DMA-PAA)	Optical intensity	122
GDH	Poly(ether amine quinone)	Current	123
	Poly(VI)/Os derivative/PEG redox hydrogel	Current	124

APEG: 8-armed, amine-terminated PEG. FITC-dextran: fluorescein-labeled dextran. Os: osmium. PAzSt: poly(m-azidostyrene). PC: polycarbonate. PDMAA: poly(dimethyl acrylamide-co-2-cinnamoyl ethyl methacrylate). Poly(DMAA/AzSt/VFe): poly(dimethylacrylamide-co-azidostyrene-co-vinylferrocene). Poly(GEMA): poly(glycosyl-ethyl methacrylate). Poly(HEMA): poly(hydroxyethyl methacrylate). Poly(IPPm-co-PBA-co-DMA-PAA): poly(N-isopropylacrylamide-co-3-acrylamido-phenylboronic acid-co-N-(3-dimethylaminopropyl)acrylamide). Poly(VP): poly(vinylpyrrolidone). Poly(VP-VI): poly(vinylpyrrolidone-co-1-vinylimidazole). PTFE: polytetrafluoroethylene. SPA: di-succinimidyl ester of PEG  $\alpha$ ,  $\omega$ -dipropionic acid.

diator leaching, the mediator has been immobilized in different hydrogels. Sensors for in vivo monitoring of glucose also require biocompatible interfaces with the tissue in which they have been implanted (102). The interface material must be permeable to glucose and the product of its oxidation, gluconolactone. It also must not be fouled by proteins, cellular attachment, or fibrous encapsulation. Fast inactivation of the implanted sensors has been attributed to protein adsorption and cell adhesion. Hydrogels are known to have excellent biocompatibility due to large water contents and the ability to prevent protein adsorption and cell adhesion. Thus coating the surface of implantable glucose sensors with hydrogel layers would be a good approach for extending the lifetime of the sensors. Table 3 briefly summarizes the approaches used for glucose sensing using glucose-sensitive hydrogels. Glucose-sensitive hydrogel systems are those described in the previous section of this chapter.

#### IV. PROPERTIES TO IMPROVE FOR PRACTICAL APPLICATIONS

There are many hurdles to overcome to develop clinically useful self-regulated insulin delivery systems based on glucose-sensitive hydrogels. Those systems that work very well in the laboratory rarely work as well when applied in vivo. A number of improvements need to be made for practical applications. First, to be clinically useful, self-regulated insulin delivery devices should react fast to changes in the blood glucose concentration and release the necessary amount of insulin. The fast on-and-off function is critical for adequate control of the dynamically changing glucose levels in the blood. The response time of hydrogels depends on the time for diffusion of glucose molecules, and the hydrogel thickness has a big impact on the response time. Second, more biocompatible glucose-sensitive molecules need to be developed. Currently used glucose sensing moieties are proteins, such as Con A, GOD, and GDH. To minimize any side effects resulting from long-term use, glucose sensing moieties based on nonproteinaceous molecules are preferred. Implantable glucose sensing moieties should be biocompatible, nontoxic, cost-effective, and independent of environmental factors such as pH, ionic strength, or the presence of divalent cations (125). Third, the implantable devices, if used for the long term, tend to be isolated from the body by tissue remodeling around the implants. The formation of new tissues around the implant significantly retards the diffusion of glucose, which in turn delays the response time and sensitivity. This necessitates frequent recalibration of the implanted devices, since there is no clear understanding of

the relationship between glucose levels in the blood and in the tissue (93). Continued research on these hurdles will undoubtedly present answers in the future. For now, however, biodegradable glucose-sensitive hydrogels can be developed so that they can be used to develop short-term glucose sensing as well as self-regulated insulin delivery.

### I. INTRODUCTION

The fate of a drug after administration *in vivo* is determined by a combination of several processes: distribution and elimination when given intravenously; absorption, distribution, and elimination when an extravascular route is used. Regardless of the mechanisms involved, each of these processes depends mainly on the physicochemical properties of the drug and therefore, for the most part, on its chemical structure.

During the last few decades, research workers have been trying to develop delivery systems that would allow them to control the fate of drugs within the patient. Using dosage forms known as controlled release systems, pharmacists have succeeded, at least in part, in governing the first process, *i.e.*, drug absorption. The aim of current research is to control the second process, drug distribution within the organism, by the use of carriers (Fig. 1).

As shown in Table 1, the carriers available at present can be divided into three main groups: first-, second-, and third-generation carriers.

The so-called first-generation carriers are systems capable of delivering the active substance specifically to the intended target but are not true carriers. Indeed, in order to do this, they have to be implanted as closely as possible to the site of action. Microcapsules and microspheres for chemoembolization belong to this group, as do similar systems used for the controlled release of proteins and pep-

tides. Recently, much interest has been directed towards the use of small (10  $\mu\text{m}$  or less) microparticles by the oral route, because of their selective uptake by Peyer's patches, which gives them great potential as carriers for oral vaccines.

In contrast, the carriers known as second-generation are true carriers (usually of colloidal size). Indeed they are capable not only of releasing an active product at the intended target but also of carrying it there after administration by a general route. This group includes so-called passive carriers such as liposomes, nanocapsules and nanospheres, and certain active carriers such as temperature-sensitive liposomes and magnetic nanospheres. It should be noted, however, that after intravenous administration, most colloidal carriers are rapidly removed from the circulation by phagocytic cells in the liver and spleen. This lim-

**Figure 1** Illustration of the drug carrier concept.

**Table 1** Definition of Different Carrier Systems

Generation	Size	Definition	Examples
First	>1 $\mu\text{m}$	Systems able to release a drug at the target site but necessitating a particular type of administration	Microspheres and microcapsules for chemoembolization and for controlled release of proteins and peptides
Second	<1 $\mu\text{m}$	Carriers that can be given by a general route able to transport a drug to the target site	<i>Passive carriers:</i> Erythrocytes, liposomes, nanoparticles, sterically stabilized liposomes, and nanoparticles <i>Active carriers:</i> Temperature or pH-sensitive liposomes, magnetic nanoparticles
Third	<1 $\mu\text{m}$	Carriers able to recognize the target specifically	Monoclonal antibodies, second-generation carriers, usually sterically stabilized, targeted with monoclonal antibodies or other ligands

its their targeting potential. Over the last ten years, system surface properties have been modified to avoid the deposition of plasma proteins and thus avoid recognition by phagocytes. These are known as sterically stabilized carriers and may remain in the blood compartment for a considerable time. Although such colloidal particles cannot cross normal continuous capillary endothelium, they have been shown to extravasate into sites where the endothelium is more permeable, such as solid tumors or regions of inflammation and infection.

The carriers referred to as third-generation are also true carriers and are capable of specific recognition of the target. For example, monoclonal antibodies belong to this group, as do certain second-generation carriers (liposomes, nanocapsules, nanospheres) piloted by monoclonal antibodies or other ligands. Of course, targeted colloidal carriers will be much more effective if they are also sterically stabilized.

This chapter, dealing with polymeric micro- and nanoparticles as drug carriers, is mainly based on the work carried out in our laboratory. Rather than giving a catalogue of our research we will concentrate on some of the most important areas. The chapter is divided into two main sections. The first deals with microparticles (microspheres and microcapsules) for the encapsulation of peptides and proteins, including vaccines. The second focuses on nanoparticles (nanospheres and nanocapsules). After a review of the general properties and therapeutic potential of these two different systems, we make special mention of nanoparticles with bioadhesive properties for drug delivery at mucosal surfaces and sterically stabilized nanoparticles that avoid phagocytosis, as described above.

As a preliminary remark, we would like to mention that the term “nanoparticle” is considered in this chapter as a submicron drug carrier system of polymeric nature. Thus

this term is somewhat general, since it does not take into account the morphological and structural organization of the polymer. In this respect “nanosphere” is used to identify a nanoparticle system with a matrix character and constituted by a solid core with a dense polymeric network (Fig. 2). In contrast, “nanocapsules” are formed by a thin polymeric envelope surrounding an oil-filled cavity. Nanocapsules may thus be considered as a “reservoir” system (Fig. 2). Despite these definitions, in practice the term nanoparticles is also used (instead of nanospheres) to designate polymeric colloidal systems with a matrix structure. Most of the work described in this chapter is of a multidisciplinary nature and was carried out in collaboration with a large number of other groups both within and outside France, especially insofar as the biological evaluation of these systems is concerned. They are too many to mention individually but their names will be found in the reference list.

## II. CONTROLLED DELIVERY OF PEPTIDES AND VACCINES BY PLGA MICROSPHERES

During the last years, the design of preparation methods able to encapsulate hydrophilic drugs in biodegradable microparticles has allowed the development of several lines of research on the delivery of peptides and vaccines. This has led to the market several drugs mainly for the delivery of LHRH agonist peptides, and many research teams have approached the development of single-shot vaccines. Recent studies have focused on the delivery of neuropeptides and mucosal vaccines.

### A. Delivery of Cholecystokinin (CCK) Analogs

One example of the delivery of neuropeptides is given by cholecystokinin (CCK) analogs. Peptide cholecystokinin, which is widely distributed in the central nervous system and in the gastrointestinal tract, plays a critical role as a neuromodulator in the central nervous system and seems to control emotional and adaptation processes through specific binding sites located in various brain regions. Cholecystokinin octapeptide (CCK-8), the predominant form in the brain, fulfills the criteria of a neurotransmitter or a neuromodulator (7). Numerous studies suggest that CCK is involved in satiety (8), motivated behavior (9), memory (10,11), nociception (12,13) and anxiety (14,15). Moreover, in humans, I.V. injection of CCK-4, the C-terminal fragment of CCK-8, was shown to induce panic attacks, which were suppressed by selective CCK-B antagonists (16). However, the site and the mechanism of action of CCK-4 remain unclear. To study the long-term effect of CCK agonist, a CCK-8 analog, pBC 264 (Boc-Tyr(SO<sub>3</sub>H)-gNle-mGly-Trp-Nle-Asp-Phe-NH<sub>2</sub>), which is a very potent and selective agonist for CCK-B receptors, was developed (17). This compound has been shown to give responses at low doses in behavioral and electrophysiological tests following local administration (18–20). However, chronic local stimulation of CCK-B receptors is hindered by the rapid elimination of pBC 264 from the brain after central administration (21). In order to study the long-term effects resulting from local stimulation of CCK-B receptors, the possibility of slowly delivering pBC 264 into a particular brain structure for a long period of time has been considered by its encapsulation into poly(lactide-co-glycolide) (PLGA) microspheres.

pBC 264 was encapsulated into microspheres sized between 1 and 10 μm. Using the basic multiple emulsion solvent evaporation procedure, the encapsulation efficiency of pBC 264 in microspheres was very low. However, when introducing in the inner aqueous phase a stabilizing agent such as ovalbumin (OVA) at a concentration of 2%, the encapsulation efficiency was significantly improved (22). An additional and dramatic improvement of the encapsulation rate was also observed when the pH of the internal aqueous phase was basic (pH 8 corresponding to the optimal solubility of pBC 264) and when the pH of the external aqueous phase was acid (pH 2.5 corresponding to a lower solubility of pBC 264) (23). In this case, the internal aqueous phase was playing the role of a real “trap” for the peptide. Therefore the simultaneous stabilizing effect of the OVA and the adjustment of the pH allowed an optimal entrapment to be obtained. OVA was believed to prevent the destruction of the internal globules during the process of preparation, therefore avoiding leakage of the peptide into the outer aqueous phase. The inner emulsion should also be stabilized due to the rigid structure formation (hydrophobic barrier) surrounding the drug cores following interaction between basic compounds and dissociated polymers. This improved stability resulted in a better entrapment of pBC 264.

Release kinetic experiments were performed in phosphate buffer solution (pH 7.4). pBC 264 was rapidly released from microspheres exhibiting a dramatic burst effect (22). Thus the microspheres obtained did not exhibit a typical controlled release profile. The presence of OVA as a stabilizer was shown to be responsible for the observed burst effect. Electron microscopy observations clearly showed that OVA induced the formation of pores at the surface of the microspheres (22). Actually, as OVA is totally insoluble in methylene chloride, it did not interact with the polymer as suggested by DSC measurements (22). The protein was assumed to be located at the interface between the first and second emulsion. Therefore OVA might have formed aggregates on the surface of the microspheres. The elution of the OVA aggregates from the surface during the microsphere washing process is probably responsible for the formation of pores. These pores could constitute a pathway for the observed fast release of pBC 264.

To reduce the porosity of the microspheres, other surfactants were used as stabilizers of the internal aqueous phase (PVA or Pluronic® F68) (23). The influence of the surfactant on the stability of the first emulsion as well as the encapsulation efficiency and the release of pBC 264 were examined. The encapsulation efficiency was very low for the formulation containing PVA. Pluronic® F68-containing microspheres displayed a lower encapsulation efficiency as compared to OVA-stabilized microspheres

(23). The most important factor for the successful encapsulation of hydrophilic compounds in microspheres prepared by the W/O/W solvent evaporation method is the stability of the first inner emulsion. From the stability studies, it was shown that when PVA was used as a stabilizer, the internal emulsion was unstable and the droplets coalesced. Thus it was assumed that in these conditions the peptide leaked out to the external aqueous phase. A similar phenomenon occurred with Pluronic® F68 but to a lesser extent, since the stability of the emulsion was improved. Pluronic® F68 and PVA are hydrophilic surfactants that are not suitable for stabilizing W/O emulsions. On the contrary, proteins have a tendency to localize at the interfaces, increasing the stability of emulsions, therefore reducing the leakage of the peptide to the external aqueous phase.

Release of pBC 264 from microspheres prepared with Pluronic® F68 was compared to the release obtained from OVA-stabilized microspheres. The burst observed was much smaller when the microspheres were prepared in the presence of Pluronic® F68 (23). The release profile and the extent of the initial peptide burst was significantly influenced by the structure of the microspheres. As mentioned above, the microspheres prepared with OVA had a porous structure and thus provide a fast release profile with a large peptide burst. In contrast, microspheres prepared in the presence of Pluronic® F68 did not have pores and were characterized by a smooth surface (23). With Pluronic® F68 it may be hypothesized that the inner drug cores were more finely dispersed throughout the polymer matrix without any aqueous channels. Therefore the differences in the initial burst from the tested formulations seemed to result from morphological differences.

For *in vivo* studies, microspheres were implanted into the rat brain in the anterior part of the Nucleus Accumbens (N. Acc.). After the administration of fluorescently labeled microspheres, observations of histological coronal sections confirmed that the microspheres were effectively localized in the anterior part of the N. Acc., and one hour after implantation the microspheres remained located around the injection site (24). The behavioral testing was carried out by placing rats in the open field (24). The behavioral effect was quantified by recording for 6 min: (a) the latency (or time)(s) to move out from the corner where the animal was placed and to cross two squares; (b) locomotion scores of the total number of squares crossed; (c) total number of rears; (d) number of defecation boli left on the field; and (e) number of grooming bouts. No behavioral change was observed 24 hours or 8 days after administration of unloaded microspheres as compared to the control group, whatever the parameters measured in the open field test were (24). Finally, implanted microspheres were well tolerated and minimally reactive, since only a localized

inflammatory reaction was observed. This reaction was similar to the one induced by the administration of carboxymethylcellulose (24). Two different kinds of microspheres differing only by the stabilizing agent added to the inner aqueous phase (OVA or Pluronic® F68) were implanted into the rat brain. The *in vivo* studies showed that pBC 264 was almost completely released from the microspheres prepared with OVA within the first hour, whereas only 35% of peptide was released after 8 days when microspheres prepared with Pluronic® F68 as the stabilizing agent were administered (24). This was in agreement with the *in vitro* results (22,23). Intact pBC 218 was found to be released from PLGA microspheres containing Pluronic® F68 both *in vitro* and *in vivo* (23,24). In addition, the brain diffusion of pBC 218 was very limited, and its presence in the blood could not be detected. The peptide was essentially found concentrated near the site of administration in the N. Acc., showing that chronic behavioral studies using pBC 218 microspheres were made possible using the right formulation (24).

## B. Delivery of Vaccines

One recent application of microspheres is the mucosal delivery of vaccines. For this application, the antigen delivery systems consisting of biodegradable microspheres are designed to increase antigen uptake by the M cells if the diameter of the particles is smaller than 10  $\mu\text{m}$  (25), to enhance the mucosal immune response (26), and to induce long and slow antigen release (27). This approach was validated by showing that oral immunization of mice with phosphorylcholine (PC) could induce a mucosal secretion of specific anti-PC IgA. PC was chosen as an antigen because it is a ubiquitous hapten present on different pathogenic microorganisms that colonize or invade host mucosa at different epithelial sites (28–30). Since it has been demonstrated that an immune response disseminated to several effector mucosal sites can be obtained after stimulation of a unique mucosal inductor, one can now hope for unique mucosal vaccines with several potentialities. This is of interest because mucosal vaccines have a number of obvious advantages over invasive vaccines, particularly with respect to simplicity, safety, and cost effectiveness.

PC was conjugated to thyroglobulin (PC-Thyr) and entrapped in PLGA microspheres (31). The preparation used contained 97% of the microspheres with a diameter lower than 10  $\mu\text{m}$ . The encapsulation efficiency of the conjugate was as high as 80% when the initial protein-to-polymer ratio was 1:8, the total protein load being approximately 9% w/w of the microspheres. It was also shown that only about 30% of the PC-Thyr entrapped in the microspheres was released within 30 minutes under acidic gastriclike

conditions, and that the preparation was stable thereafter (31). Also, a major drawback of microencapsulation by the solvent evaporation method of antigens for vaccine development is the potential degradation of the antigen during the preparation process. However, this risk was lowered in the multiple emulsion solvent evaporation method used in the present study, because the contact between the compound and the organic solvent was limited. Indeed, the absorbance spectrum of PC-Thyr was not modified by the microencapsulation process, nor was its PC-immunologic reactivity, as judged in an ELISA using a monoclonal anti-phosphorylcholine antibody (31). This strongly suggested that only minor, if any, modifications of PC integrity occurred.

Oral administration of PC-Thyr, entrapped in PLGA microspheres, induced in mice a specific IgA response in intestinal, pulmonary, and vaginal secretions in addition to a strong specific systemic immune response. When mice were challenged with an oral infection induced by *Salmonella typhimurium*, only the animals that were vaccinated with microspheres containing the PC-Thyr conjugate were protected (32). However, only nasal administration, and not oral, was able to protect mice against the pulmonary infection by *Streptococcus pneumoniae* (33,34).

Very recently, a milk protein,  $\beta$ -lactoglobulin (BLG), was entrapped in PLGA microparticles sized around 7  $\mu\text{m}$  (35,36). These particles were able to induce after oral administration an immunological oral tolerance against BLG. In addition, the amount of protein necessary to reduce the IgE response was 10,000 times lower when the BLG was entrapped into microspheres as compared with the native BLG (37). These results allow us to broaden the field of application of biodegradable microparticles to their use in the reduction of oral allergies.

### III. POLYMERIC NANOPARTICLES AS DRUG CARRIERS

#### A. Nanospheres

##### 1. Preparation and Characterization of Nanospheres

Submicronic macromolecular particles can be obtained following an emulsion or micellar polymerization of polymerizable monomers dispersed in an aqueous phase, or from preformed—natural and synthetic—macromolecules such as polymers, proteins, and polysaccharides. For drug-delivery purposes, the colloidal material needs to meet physicochemical and biological requirements adapted and optimized for these specific applications. Among these requirements, biocompatibility, safety, and biodegradability to nontoxic metabolites are of crucial importance, thus

limiting the number of materials available. Methods for nanosphere production have been reviewed in Ref. 38.

##### a. Nanosphere Preparation by Polymerization of Monomers

In our laboratory, we have concentrated on poly(alkylcyanoacrylate) nanospheres. The most significant advantage of alkylcyanoacrylate is that, in contrast to other acrylic derivatives that require an energy input for the polymerization step, which could affect the stability of the adsorbed drug, alkylcyanoacrylates can be polymerized easily without such a contribution (39). These nanospheres are prepared by an emulsion polymerization process, in which droplets of water-insoluble monomers are emulsified in an aqueous phase (40). Anionic polymerization takes place in micelles after diffusion of monomer molecules through the water phase and is initiated by the water itself. The pH of the medium determines both the polymerization rate and the adsorption of the drug when the latter is ionizable (31). Drugs can be combined with nanospheres after dissolution in the polymerization medium either before the introduction of the monomer or after its polymerization. Since only nontoxic additives are used, no further purification is needed, and freshly prepared nanospheres may be freeze-dried with their drug content.

This preparation method is easily reproducible regarding size and drug adsorption rate, even after preparation at a semi-industrial level. Moreover, when prepared under sterile conditions in an aseptic room under laminar flow, poly(alkylcyanoacrylic) nanospheres met the usual requirements needed for intravenous administration such as sterility and lack of bacterial endotoxins (42).

Scanning electron microscopy of nanospheres generally shows spherical particles with a diameter of approximately 150 nm. Freeze-fracture studies revealed that the internal structure of the poly(alkylcyanoacrylic) nanospheres consisted of a matrix made up of a dense polymeric network (43). Molecular weight determinations made by gel permeation chromatography (GPC) suggested that nanospheres are built up from an entanglement of numerous small oligomeric subunits rather than from the rolling-up of one or a few long polymer chains (44). The low molecular weight of oligomeric subunits is consistent with observations concerning metabolism and elimination of nanospheres after the *in vivo* administration discussed below. The density of poly(isobutyl-cyanoacrylate) and poly(ethyl-butyl-cyanoacrylate) have been determined by isopycnic centrifugation in sucrose gradients and found to be 1.14 and 1.10  $\text{g}/\text{cm}^3$ , respectively (45).

As far as drug association is concerned, it was found that nanospheres can entrap drug according to a Langmuir

adsorption mechanism, due to their large specific surface area (46). The drug can either be incorporated into nanospheres during the polymerization process or be adsorbed onto the surface of preformed particles. In the former case, the drug–polymer interaction may result in the covalent linkage of the drug with the polymer. This was observed with vidarabine, an antiviral agent, whose nucleophilic N in position 3 and 7 may play the role of initiator for the anionic polymerization mechanism of the cyanoacrylic monomer (47). A similar interaction was observed, to a lower extent when a peptide, growth hormone releasing factor (GRF), was associated with nanospheres (48). In contrast, other drugs such as ampicillin are simply adsorbed. Based on the surface potential and surface pressure experiments, models of poly(isobutylcyanoacrylate)–ampicillin arrangements in the interfacial region have been proposed for low and high polymer surface densities (49).

Both the nature and the quantity of monomer influence the adsorption capacity of the carrier. Generally, the longer the alkyl chain length, the higher the affinity of the drug; the capacity for drug adsorption is related to the hydrophobicity of the polymer and to the specific surface area of the carrier. Moreover, the percentage of drug adsorption generally decreases with the quantity of drug dissolved in the polymerization medium, according to the Langmuir isotherm (50).

Poly(alkylcyanoacrylate) particles are degraded by surface erosion process (51), through enzymatic hydrolysis of the ester side chains of the polymer (52). Thus the polymeric backbone remains intact but gradually becomes more and more hydrophilic until it is water soluble. The rate of degradation is dependent on the length of their alkyl chain (53). Therefore it is possible to choose a monomer whose polymerized form has a biodegradability corresponding to the required profile for drug release (54). Indeed, by using a double radiolabel technique ( $^{14}\text{C}$ -labeled nanospheres loaded with  $^3\text{H}$ -actinomycin), it was found that drug was released from nanospheres as a direct consequence of polymer bioerosion (52). This was confirmed using the peptide GRF (48).

Biodegradable nanospheres suitable for pharmaceutical applications can also be prepared from another monomer, poly(methylidene malonate 2.1.2), using a similar emulsion polymerization technique (55).

#### *b. Preparation of Nanospheres from Preformed Polymers*

In order to avoid some of the limitations associated with polymerization of a monomer, in particular the possibility of residual monomer and the risk of drug interaction and inactivation, methods of obtaining colloidal drug-delivery

systems from preformed, well-defined macromolecular materials with known physicochemical and biological properties have been developed. These methods were initially adapted from industrial techniques available for the preparation of the artificial latexes used in surface-coating applications: paints, adhesives, textile sizing, paper coating. Original methods based on nanoprecipitation have been developed in our group, capable of yielding nanospheres from both preformed synthetic polymers and from natural macromolecules such as proteins or polysaccharides.

Among many other water-insoluble synthetic polymers, polyesters such as poly(lactide), poly(glycolide), and their copolymers meet the biological requirements of safety and biodegradability to nontoxic metabolites. The methods initially developed for the preparation of nanospheres from these polymers were derived from solution-emulsification techniques. Gurny et al. (56) and Krause et al. (57) prepared poly(lactide) nanospheres according to the solution-emulsification technique. A polyester is dissolved in an organic volatile solvent immiscible with water, such as chloroform, and the organic solution is dispersed in an aqueous phase to form an O/W emulsion. Continuous emulsification under mixing prevents coalescence of organic droplets and allows the spontaneous evaporation of the solvent at room temperature and the formation of the colloidal particles. Residual organic solvent is removed under reduced pressure. The emulsifiers can, if necessary, be removed by dialysis of the suspension, or by washing following the separation of nanospheres by ultracentrifugation.

One major limitation of the method is the size and the homogeneity of the droplets containing the macromolecular material. An ultrafine emulsification is necessary to obtain particles smaller than one micron, and it is very difficult to obtain a monodisperse population of nanospheres. More recently, microfluidization has been used in this step, for example, to prepare poly(lactic acid) nanoparticles coated with human serum albumin (58). As an alternative to the solution-emulsification technique, methods based on the desolvation of macromolecules have been developed.

Desolvation is a well-known method for isolating macromolecules from liquid media. Thus polymers can be precipitated from organic solutions following the addition of a third component, or of a nonsolvent miscible with the organic solvent. The same effect is obtained with an aqueous solution of proteins when neutral salts, i.e., sodium or ammonium sulfate, or alcohol are added. However, the process leads to a bulk precipitate of polymeric or protein material, but not to colloidal particles.

Fessi et al. (59) were the first to propose a new and simple method yielding polymeric nanospheres without

the use of preliminary solution-emulsification or the use of autoemulsifying polymeric material. Briefly, an organic solution of the polymer is prepared and added to a nonsolvent. Both solvent and nonsolvent must have low viscosity and high mixing capacity in all proportions. As an example, acetone and water meet these conditions. The only complementary operation following the mixing of the two phases is thus to remove the volatile solvent by vaporization under reduced pressure. Further concentrations of the aqueous suspension can be carried out under the same conditions or by freeze-drying. This method has been successfully applied to various polymeric materials such as poly(lactic acid) and poly(lactic acid)-co(glycolic acid), poly( $\epsilon$ -caprolactone), ethylcellulose and cellulose acetophosphate, poly(alkylcyanoacrylate), poly(vinyl chloride-coacetate), poly(styrene), and poly(acrylic acid). The mean diameter of the particles obtained was about 200 nm with low polydispersity.

Small amounts of surfactants, either lipophilic or hydrophilic, can be added to the solvent and/or to the nonsolvent. The presence of a surfactant was not necessary to obtain the colloidal dispersion, which forms spontaneously, but only to stabilize it and to facilitate its redispersion following sedimentation. It was observed that the size of particles was mainly related to the polymer used and less to the experimental conditions. It was also noteworthy that the sense and the rate of mixing of the two phases had no influence; the organic solution of the polymer could be slowly or rapidly added to the nonsolvent or vice-versa, with or without the aid of additional stirring. In fact, the most critical conditions for obtaining the spontaneous formation of colloidal particles alone, avoiding any bulk precipitation of the material, were the concentration of the polymer in the organic phase and the ratio of solvent to nonsolvent. Depending on its physicochemical nature, the drug of interest can be added either to the solvent or to the nonsolvent. In the first case, it can be incorporated into the polymeric matrix, and its release will be determined by its rate of diffusion with this matrix and by the rate of degradation of the polymer. On the other hand, drug present in the nonsolvent will be adsorbed on the particle surface, and its release will be the result of partitioning. Zeta potential measurements can be a useful tool to determine the location of the drug in nanoparticulate systems (60).

Chang et al. (61) and Bodmeier et al. (62) have described a similar method to prepare nanospheres without any surfactant, using acrylic copolymers bearing quaternary ammonium groups. These autoemulsifying polymers are sensitive to the pH of the dispersing phase and may become soluble, thus limiting both the applications and the choice of the starting material. By using carboxylated polymers, i.e., acrylic Eudragit S, Fessi et al. (59) were able

to prepare colloidal particles by simple addition of an aqueous alkaline solution of the macromolecular material to an acidic medium. However, subsequent neutralization of the suspension to physiological pH led to a clear colloidal solution.

Allemann et al. (63) have described a method of nanosphere preparation by reverse salting out. An organic solution of the polymer is included in a O/W emulsion by using an aqueous phase with a high salt concentration, with which the organic solvent is not miscible. Addition of pure water to the system reduces the ionic strength and leads to mixing of the two solvents and deposition of the polymer as nanoparticles. However, the resulting suspension is very dilute and requires subsequent concentration by removal of large amounts of water.

The method of Fessi et al. (59) can be adapted to prepare nanospheres from natural macromolecules. Thus Stainmesse et al. (64) developed a technique to prepare protein nanospheres in a single step by pouring an aqueous solution of the protein (e.g., albumin) into a nonsolvent. In particular, the nonsolvent can be boiling water, thus leading to heat-denaturation of albumin and formation of colloidal particles as small as 80 nm. Further strengthening of the albumin nanospheres can be obtained either by heat-sterilization (121°C) or by chemical cross-linking. It is noteworthy that no surfactant was necessary to obtain a stable dispersion of albumin nanospheres, due to the small and monodisperse size of the particles, even under the conditions of heat-sterilization. More recently, the nanoprecipitation technique has also been applied to amphiphilic cyclodextrins (65). An advantage of using these cyclic glucose oligomers would be that it provides a third possibility for drug association; as well as entrapment within the matrix and adsorption on the surface, suitable molecules could be included within the hydrophobic core of the cyclodextrin.

## 2. Therapeutic Applications of Nanospheres

Nanospheres have been designed mainly for administration by the intravenous route. In this case, particles whose surface has not been modified to avoid opsonisation will be limited in their applications by their distribution, which is mainly characterized by a rapid uptake into phagocytic cells of the liver, spleen, and bone marrow. These can be summarized as follows: concentrating drugs in accessible sites, rerouting drugs away from sites of toxicity, and increasing the circulation time of labile or rapidly eliminated drugs. Within these limits, nanospheres can not only change the distribution of the drug at the organ or tissue level, but also at the cellular level, by increasing uptake or modifying the intracellular localization of the drug. These

properties will be illustrated by work done in our laboratory with three different classes of molecules: antibiotics, anticancer drugs (in particular doxorubicin), and oligodeoxynucleotides (ODN).

*a. Application to the Treatment of Intracellular Infections*

The need for intracellular chemotherapy has been recognized for many years, since a variety of bacterial diseases originate from so-called obligate or facultative intracellular parasites, which are often located within macrophages, often within the lysosomes (66). These infections are often resistant to commonly used antibiotics because of low intracellular uptake or reduced activity at the acidic pH of lysosomes. An alternative strategy to the development of new antibiotics would be the use of drug-delivery systems to obtain controlled release or targeting to specific sites, thereby improving the efficiency of existing drugs. In particular, the need for antibiotics with intracellular efficacy led to the association of antibiotics with colloidal systems: liposomes or nanoparticles, which can be endocytosed by the infected cells (reviewed in Ref. 67). In particular, our laboratory has developed antibiotics bound to poly(alkylcyanoacrylate) nanospheres.

It has been shown that linkage of ampicillin to poly(isohexylcyanoacrylate) (PIHCA) nanospheres increased its efficacy in treating *Salmonella typhimurium* infection in C57BL/6 mice by a factor of 120. A single injection of 0.8 mg of nanosphere-bound ampicillin was just as efficient as 3 doses of free drug in suppressing all mortality. The bacterial counts of the liver and spleen were 10 to 10,000 times lower in the mice given free ampicillin mixed with, or bound to, nanospheres than in control mice. None of the treatments tested was, however, able to sterilize the organs of the mice, since living bacteria were found in the livers and spleens of all mice still alive 60 days after bacterial inoculation, although the use of the nanosphere-bound form greatly increased the ampicillin concentration in these organs (68).

This high efficacy of nanosphere-bound ampicillin observed in the treatment of acute murine experimental salmonellosis is probably attributable to the combined effect of two types of targeting: first, the linkage of ampicillin to nanospheres led to the concentration of the drug in the liver and spleen; second, the uptake of ampicillin by infected macrophages was higher when the drug was bound to nanospheres than when it was in the free form (69). Transmission electron microscopy showed nanospheres colocalized with intracellular bacteria (70), and ultrastructural autoradiography showed that ampicillin itself could reach

the bacterial cell walls, both by direct contact with nanospheres and by diffusion through the cell (71).

Ampicillin bound to PIHCA nanospheres was also effective against experimental listeriosis in athymic nude mice, a model involving a chronic infection of both liver and spleen macrophages (72). The nanosphere-bound form of ampicillin was capable of ensuring liver sterilization after two injections of 0.8 mg of nanosphere-bound drug, whereas no such sterilization was ever observed with any of the other regimens tested (free ampicillin or free ampicillin + unloaded nanospheres). On the other hand, spleen bacterial counts were less affected by the treatments (free or bound ampicillin). This was consistent with the *in vivo* distribution profile of nanospheres after intravenous administration. Autoradiographic studies performed with PIHCA nanospheres have shown that most of these particles were present in the liver 5 min after intravenous administration. Later, they also concentrated in the spleen, but to a lesser extent (73). The distribution profile of [<sup>14</sup>C]-PIHCA nanospheres in mice showed that 60–80% of the polymer concentrated in the liver, whereas only 2–6% was in the spleen (74). This probably explains the fact that the spleen bacterial counts were less affected than the liver ones by ampicillin targeted by means of nanospheres.

In an attempt to kill both dividing and nondividing bacteria, a fluoroquinolone antibiotic, ciprofloxacin, has been associated with poly(isobutylcyanoacrylate) (PIBCA) and PIHCA nanospheres. In an animal model of persisting salmonella infection, although an effect on the early phase of the infection was observed, neither free nor nanoparticle-bound ciprofloxacin was able to eradicate truly persisting bacteria (75).

*b. Application to the Treatment of Cancer*

Intravenously administered anticancer drugs are distributed throughout the body as a function of the physicochemical properties of the molecule. A pharmacologically active concentration is reached in the tumor tissue at the expense of massive contamination of the rest of the body. For cytostatic compounds, this poor specificity raises a toxicological problem that presents a serious obstacle to effective therapy. The use of colloidal drug carriers could represent a more rational approach to specific cancer therapy. This section focuses on the increase of the therapeutic index of doxorubicin when attached to poly(alkylcyanoacrylate) nanospheres. The possibility that multidrug resistance might be overcome by using doxorubicin-loaded nanospheres will also be considered.

The antitumor efficacy of doxorubicin-loaded nanospheres was first tested using the lymphoid leukemia L-

1210 as a tumor model. In this study, one intravenous injection of doxorubicin-loaded PIBCA nanospheres was found to be more effective against L1210 leukemia than when the drug was administered in its free form following the same dosing schedule (76). Although the increased life span (ILS%) of mice injected with doxorubicin-loaded PIBCA nanospheres was twice as high as the ILS% for free doxorubicin, there were no long-term survivors.

The effectiveness of doxorubicin-loaded poly(isohexylcyanoacrylate) (PIHCA) nanospheres against L1210 leukemia was even more pronounced than that of doxorubicin loaded onto PIBCA nanospheres. The drug toxicity was markedly decreased when it was bound to this sort of nanosphere, so that impressive results were obtained with this formulation at doses for which the therapeutic efficiency of free doxorubicin was completely masked by the overpowering toxicity of the drug (76). Furthermore, preliminary experiments suggested that one I.V. bolus injection of doxorubicin-loaded nanospheres was more active, in L1210-bearing mice, than perfusion of the free drug for 24 h.

The superiority of doxorubicin targeted with the aid of poly(alkylcyanoacrylate) nanospheres was later confirmed in a murine hepatic metastases model (M5076 reticulosarcoma) (77). Irrespective of the dose and the administration schedule, the reduction in the number of metastases was much greater with doxorubicin-loaded nanospheres than with free doxorubicin, particularly if treatment was given only when the metastases were well established. The improved efficacy of the targeted drug was clearly confirmed by histological examinations showing that both the number and the size of the tumor nodules were lower when doxorubicin was administered in its nanoparticulate form (77). Furthermore, liver biopsies of animals treated with the nanosphere-targeted drug showed a lower cancer cell density inside tumor tissue. Necrosis was often less widespread with the nanosphere-associated drug than in the control group and the group treated with free doxorubicin.

Studies performed on total homogenates of livers from both healthy and metastases-bearing mice showed extensive capture of nanoparticulate doxorubicin by the liver; no difference in hepatic concentrations was noted between healthy and tumor-bearing animals (77). In order to elucidate the mechanism behind the enhanced efficiency of doxorubicin-loaded nanospheres, doxorubicin measurements were made in both metastatic nodules and neighboring healthy hepatic tissue. This provided quantitative information concerning the drug distribution within these tissues (78). During the first 6 h after administration the exposure of the liver to doxorubicin was 18 times greater for nanosphere-associated doxorubicin. However, no special affinity for the tumor tissue was detected, and the nano-

spheres were seen by electron microscopy to be located within Küpffer cells (macrophages). However, at later time points, the amount of drug in the tumor tissue increased in nanosphere-treated animals to 2.5 times the level found in animals given free doxorubicin. Since uptake of nanospheres by neoplastic tissue is unlikely, this increase in the doxorubicin concentration in tumor tissue probably resulted from doxorubicin released from healthy tissue, in particular Küpffer cells. Hepatic tissue could play the role of drug reservoir from which prolonged diffusion of the free drug (from nanospheres entrapped in Küpffer cell lysosomes) toward the neighboring malignant cells occurs. Similar results were obtained with doxorubicin-containing liposomes (79).

This hypothesis raises the question of the long-term effect of an 18-fold increase of doxorubicin concentration in the liver. Although toxicological data have shown that doxorubicin-loaded nanospheres were not significantly or unexpectedly toxic to the liver in terms of survival rate at high doses, body weight loss, and histological appearance (80), this possibility should be borne in mind, especially since a temporary depletion in the number of Küpffer cells, and hence the ability to clear bacteria, was observed in rats treated with doxorubicin-loaded liposomes (81). A systematic study using unloaded poly(alkylcyanoacrylate) nanoparticles confirmed a reversible decline in the phagocytic capacity of the liver after repeated dosing, as well as a slight inflammatory response (82,83). Nanoparticle-associated doxorubicin also accumulated in bone marrow, leading to myelosuppression (84). However, this tropism of carriers might be useful to deliver myelostimulating compounds such as granulocyte colony stimulating factor to reverse the suppressive effects of intense chemotherapy (85). Nanospheres are also captured by splenic macrophages (86). In this study, the spleen architecture was shown to play a role in the localization of the nanospheres: in the mouse, uptake was mainly in metallophilic macrophages of the marginal zone, whereas in the rat, which has a sinusoidal spleen similar to that of the human, particles were found in the red pulp macrophages.

On the other hand, alteration of the drug distribution profile by linkage to nanospheres can in some cases considerably reduce the toxicity of a drug because of reduced accumulation in organs where the most acute toxic effects are exerted. This concept was indeed illustrated with doxorubicin, which displays severe acute and chronic cardiomyopathy. After intravenous administration to mice, plasma levels of doxorubicin were higher when the drug was adsorbed onto nanospheres, and at the same time the cardiac concentration of the drug was dramatically reduced (87). In accordance with the observed distribution profile,

doxorubicin associated with nanospheres was found to be less toxic than free doxorubicin (80).

The ability of tumor cells to develop simultaneous resistance to multiple lipophilic compounds represents a major problem in cancer chemotherapy. Cellular resistance to anthracyclines has been attributed to an active drug efflux from resistant cells linked to the presence of transmembrane P-glycoprotein, which was not detectable in the parental drug-sensitive cell line. Drugs, such as doxorubicin, appear to enter the cell by passive diffusion through the lipid bilayer. Upon entering the cell, these drugs bind to P-glycoprotein, which forms transmembrane channels and uses energy from ATP hydrolysis to pump these compounds out of the cell (88). To solve this problem, many authors have proposed the use of competitive P-glycoprotein inhibitors, such as the calcium channel blocker verapamil, which are able to bind to P-glycoprotein and to overcome pleiotropic resistance. However, since the adverse effects of verapamil are serious, its clinical use to overcome multidrug resistance is limited.

During the past few years, many studies have been devoted to evaluating the antitumor potential of carrier-drug complexes (89). We have evaluated the effect of nanospheres loaded with doxorubicin, resistance to which is known to be related to the presence of P-glycoprotein. We compared the cytotoxicity of free-Dox, Dox-loaded PIHCA nanospheres (NP-Dox) (mean diameter 300 nm), and nanospheres without drug (NP) against sensitive (MCF7) and multidrug-resistant (Dox R MCF7) human breast cancer cell lines (90). MCF7 cells were more sensitive to free-Dox than Dox R MCF7 cells with a 150-fold difference in the  $IC_{50}$ . No significant difference was observed in the survival rate of MCF7 treated with free-Dox or NP-Dox. In contrast, for Dox R MCF7, the  $IC_{50}$  for Dox was 130-fold lower when NP-Dox was used instead of free-Dox (90). These results indicated that nanospheres provided an effective carrier for introducing a cytotoxic dose of doxorubicin into the pleiotropic resistant human cancer cell line Dox R MCF7.

Complementary experiments, conducted with other sensitive and resistant cell lines, have confirmed this efficacy of nanospheres (91,92). Doxorubicin resistance was circumvented in the majority of the cell lines tested, and some encouraging results were obtained *in vivo* in a P388 model growing as ascites (91). Further studies were undertaken to elucidate the mechanism of action of poly(alkylcyanoacrylate) nanospheres. The incubation time and number of particles per cell were important factors (93), and, when PIBCA nanospheres were used, doxorubicin accumulation within P388/ADR resistant leukemic cells was increased compared with free drug, although no endocytosis of nanospheres occurred (94). On the other hand, when the less

rapidly degradable PIHCA nanospheres were used, reversion was observed in the absence of increased intracellular drug (95). The degradation products of poly(alkylcyanoacrylate) nanospheres [mainly poly(cyanoacrylic acid)] were also able to increase both accumulation and cytotoxicity of doxorubicin, although they were soluble in the culture medium. Hence the reversion of resistance seems to be due both to the adsorption of nanospheres on the cell surface and to the formation of a doxorubicin-poly(cyanoacrylic acid) ion pair that facilitates the transport of the drug across the cell membrane (95).

In the light of the results obtained with doxorubicin-loaded nanospheres in the liver metastases model described above (78), the role of macrophages as a reservoir for doxorubicin was tested in a two-compartment coculture system *in vitro* with both resistant and sensitive P388 cells (96). Even after prior uptake by macrophages, doxorubicin-loaded PIBCA nanospheres were able to overcome resistance. However, this reversion was only partial. It was decided to take advantage of the particulate drug carrier offers to associate an anticancer drug and a compound capable of inhibiting the P-gp. This approach was tested with doxorubicin and cyclosporin A bound to the same nanospheres and was found to be extremely effective in reversing P388 resistance (96). The association of cyclosporin A with nanospheres would ensure that it reaches the same sites as the anticancer drug at the same time and would also reduce its toxic side effects.

### *c. Nanospheres for Oligonucleotide Delivery*

Oligodeoxynucleotides are potentially powerful new drugs because of their selectivity for particular gene products in both sense and antisense strategies. However, they pose a challenge to pharmaceutical technology because of their susceptibility to enzymatic degradation and their poor penetration across biological membranes. Liposomal systems have been shown to protect oligonucleotides from nucleases and to improve their efficacy *in vitro* (97,98). Nanoparticulate preparations might be an interesting alternative because of better stability in the presence of biological fluids. In the case of nanospheres, since oligonucleotides have no affinity for the polymeric matrix, association with nanoparticles has been achieved by ion pairing with a cationic surfactant, cetyl trimethyl ammonium bromide (CTAB) adsorbed onto the nanoparticle surface. Oligonucleotides bound to poly(alkylcyanoacrylate) nanospheres in this way were protected from nucleases *in vitro* (99), and their intracellular uptake was increased (100). Antisense oligonucleotides formulated in this way were able specifically to inhibit mutated Ha-*ras*-mediated cell proliferation and tumorigenicity in nude mice (101).

This approach has recently been applied to the association of a phosphodiester antisense oligonucleotide directed against the 3' nontranslated region of the PKC $\alpha$  gene with nanoparticles prepared from poly(isobutylcyanoacrylate). These nanospheres were able to inhibit PKC $\alpha$  neoexpression in cultured Hep G6 cells (102).

Nanospheres containing oligonucleotides have also been formulated from a naturally occurring polysaccharide, alginate, which forms a gel in the presence of calcium ions. In this case, the oligonucleotides penetrate into the gel matrix by reptation, thus providing a high loading yield and good protection against nucleases (103).

## B. Nanocapsules

### 1. Preparation and Characterization of Nanocapsules

As explained in the introduction, nanocapsules are characterized by an oily core surrounded by a thin polymeric wall (Fig. 2).

#### a. Preparation of Nanocapsules

A wide range of oils are suitable for the preparation of nanocapsules, including vegetal or mineral oils as well as pure compounds such as ethyl oleate and benzyl benzoate. The criteria of selection for oils are the absence of toxicity, the absence of risk of degradation of the polymer, and a high capacity to dissolve the drug in question.

Polymers, generally used at 0.2–2% (w/w), can be of different origins: natural (arabic gum, gelatine), hemisynthetic (ethylcellulose, hydroxypropylmethylcellulose phthalate, diacyl  $\beta$  cyclodextrins), or, more commonly, synthetic [poly(D,L-lactide), poly( $\epsilon$ -caprolactone), poly(alkylcyanoacrylate)].

Both lipophilic and hydrophilic surfactants are used in the preparation of nanocapsules, usually at 0.2–2% (w/w). Generally the lipophilic surfactant is a natural lecithin of relatively low phosphatidylcholine content, while the hydrophilic one is synthetic: anionic (lauryl sulfate), cationic (quaternary ammonium), or, more commonly, nonionic (poly(oxyethylene)-poly(oxypropylene) glycol).

Two main techniques for the preparation of nanocapsules have been described: interfacial deposition processes and an emulsification diffusion technique.

The interfacial deposition processes may begin with either a preformed polymer (104,105) or a monomer (usually alkylcyanoacrylate) that polymerizes at the oil–water interface (106). In both cases, the procedure generally consists of mixing a water-miscible organic phase such as an alcohol or a ketone containing oil (with or without lipophilic surfactant) with an aqueous phase containing a hy-

drophilic surfactant. In the first case a preformed synthetic, hemisynthetic, or natural polymer is solubilized in the organic phase (or in a phase in which the polymer is soluble). After addition of the organic phase to the aqueous phase, the polymer diffuses with the organic solvent and is stranded at the interface between oil and water. In the second case, monomers of alkylcyanoacrylates are solubilized in ethanol and oil and then dispersed in water containing surfactants. Anionic polymerization of the cyanoacrylate in the oily phase is initiated at the interface by nucleophiles such as hydroxyl ions in the aqueous phase, leading to the formation of nanocapsules.

Gallardo et al. (107) reported that the most important factor that leads to the structure of nanocapsules is the diffusion of the organic solvent, with a complete miscibility of the organic phase in the aqueous phase and an insolubility of the polymer in both the oily phase and the aqueous phase. On the other hand, the stirring and the temperature of the aqueous phase do not seem to influence the characteristics of the nanoparticles formed.

Although the preparation of nanocapsules by interfacial deposition of preformed polymer is a simple, reproducible, easily scaled-up technique, applicable to many polymers, the interfacial polymerization process could also be interesting. In fact, in some cases (depending on the drug to be encapsulated) polymerization can lead to covalent reactions that could improve its encapsulation and retard its release (47).

The emulsification diffusion technique described by Quintanar et al. (108) is based on the initial formation of an O/W emulsion containing an oil, a polymer, and a drug in the organic solvent, in an aqueous solution of a stabilizing agent. Finally, the organic solvent is displaced into the external phase by addition of excess water. This alternative technique to prepare biodegradable nanocapsules, also starting from preformed polymers, is an interesting method of preparation that has several advantages: large choice and small quantities of solvents, simplicity, control of the size of the nanocapsules obtained (from 80 to 900 nm), control of the thickness of the polymeric wall by increased concentrations of the polymer (109), and the possibility of preparing nanocapsules with an inner aqueous core (110); however, a large amount of water has to be removed by evaporation if the organic solvent is highly miscible with water.

#### b. Characterization of Nanocapsules

The size of nanocapsules is usually found to be between 100 and 500 nm and depends on several factors: the nature and the concentration of the polymer and encapsulated drug, the amount of surfactants, the ratio of organic solvent to water, the concentration of oil in the organic solution

(111) or the speed of diffusion of the organic phase in the aqueous phase. This size evaluation is most frequently made by quasi elastic-light scattering. Scanning and transmission electron microscopy and scanning electron microscopy without or after freeze fracture have also been used to check their size and evaluate the structure of nanocapsules (105,108,112–114). Rollot et al. (112) estimated the thickness of polymeric wall of the particles prepared by interfacial deposition process as about 5 nm based on freeze-fracture microscopy. This agrees with theoretical calculations based on the relative volumes of oil and polymer in the formulations. Freeze-fracture microscopy also allowed visualization of different possible organizations of lipophilic surfactant, which can form vesicles, micelles, bilayers, or monolayers depending on the concentration (105). Quintanar et al. (108) have recently confirmed the spherical shape of these nanocapsules, which also appeared as smooth spheres by atomic force microscopy.

Measurement of the zeta potential is the technique most frequently used to characterize the surface of nanocapsules (60). The zeta potential reflects the electrical surface potential of particules, which is influenced by the charge of the different components of the nanocapsules located at the interface with the dispersing medium. High zeta potential values, above 30 mV (positive or negative value), lead to more stable nanocapsule suspensions, because repulsion between particles prevents their aggregation. Lecithins, poloxamer, and polymer are the major components that can affect this potential; while the polymers, especially the  $\alpha$ -hydroxyacids such as poly(D,L-lactide) and lecithins impart a negative charge to the interface; poloxamer, a nonionic surfactant, tends to reduce the absolute value of the zeta potential (116). Chouinard et al. (117) showed that the molecular weight of poly(alkylcyanoacrylate) polymers influenced the surface charge of nanocapsules. Higher zeta potential values were observed with lower molecular weight polymers, presumably because the number of charged end groups was greater. As described by Benita and Levy (118) for emulsions, it is possible to modulate the negative charge by the choice of the lecithins and their purity, since the negative charge is due to phospholipids other than phosphatidylcholine in the lecithin. Monolayer studies carried out with mixed surfactant monolayers by Santos-Magalhaes et al. (119) have shown that the adsorption of the poloxamer surfactant is enhanced by the presence of phospholipids. Recently Calvo et al. (120) proposed alternative nanocapsules coated with positively charged hydrophilic polymer based on polysaccharide chitosan. Their surface charge depends mainly on the viscosity of the chitosan used.

Atomic force microscopy also allowed the surface of nanocapsules prepared by the emulsification diffusion technique to be observed (109). These surfaces are smooth

with contrasting shiny regions, as compared with images of nanospheres, that could be due to free oil or to resonance frequencies during the scanning process.

Gallardo et al. (107) showed that ultracentrifugation of nanocapsules prepared from IBCA and Miglyol 812 yielded both a floating layer (nanocapsules) and a small pellet (nanospheres). This could be explained by the postulated mechanism of formation of nanoparticles at the interface of the rapidly diffusing organic solvent and water, which fragments to produce nanocapsules and nanospheres, depending on whether oil is entrapped or not.

Centrifugation in a density gradient is an accurate method to confirm the existence of nanocapsules by comparison with colloidal carriers prepared without polymer or without oil. Chouinard et al. (117) and Quintanar et al. (109) have reported isopycnic centrifugation in a density gradient of Percoll with respectively poly(alkylcyanoacrylate)/Miglyol and PLA/Miglyol nanocapsules. The density of nanocapsules was found to be intermediate between that of nanospheres and that of emulsions. They also demonstrated that the density of nanocapsules and the band thickness increased when the quantity of polymer increased.

One of the advantage of nanocapsules over nanospheres is their low polymer content and a high loading capacity for lipophilic drugs. The percentage of encapsulation is generally related to the solubility of the drug in the oily inner core, as demonstrated by Fresta et al. (114) with different antiepileptic drugs.

The conservation of nanocapsules can be also improved by freeze-drying (121,122). However, these carriers need large amounts of cryoprotectors such as trehalose to prevent the capsules from disintegrating and to avoid aggregation on their rehydration. Recently Calvo et al. (120) showed that chitosan coated nanocapsules can be freeze-dried with lower amounts of cryoprotective agents than uncoated negatively charged nanocapsules.

Release of encapsulated drugs from nanocapsules appears only to be by the partition coefficient of the drug between oily core and the aqueous external medium and the relative volumes of these two phases. The rate of diffusion of the drug through the thin polymeric barrier does not seem to be a limiting factor, nor does the nature of polymeric wall. On the other hand, the nature of the external aqueous phase is of prime importance. For example, Ammoury et al. (115,123) showed variations in the release profile of indomethacin as a function of the medium: drug release was faster and more complete in the presence of albumin, which acts as an acceptor in the aqueous phase. Similarly, release of halofantrine, a highly lipophilic anti-malarial drug, was only observed in the presence of serum, since the drug has a high affinity for lipoproteins (124).

However, the nature of the nanocapsule surface can modulate the release rate in some cases. For example, the presence of excess lecithin at the interface could decrease the rate of release of indomethacin (123). Release of halofantrine from surface-modified nanocapsules bearing poly(ethylene glycol) chains (see Section III. D) was reduced compared with conventional nanocapsules (124).

## 2. Therapeutic Applications of Nanocapsules

The potential of nanocapsules as carriers for liposoluble drugs will be discussed with respect to the route of administration: oral, parenteral, or ocular.

### a. Oral Route

The oral route was the first route of administration of nanocapsules loaded with indomethacin and insulin in the mid-1980s with the aim of avoiding local side effects and/or improving the biological response. Several *in vitro* studies have evaluated the release rate of drugs encapsulated in nanocapsules prepared from polyester and poly(alkylcyanoacrylate) polymers in media mimicking pH of the gut (125–127). The results seemed to indicate that the kinetics were more sensitive to changes in drug partitioning related to the change of pH than the nature of polymers as suggested by Magalhaes et al. (113). Although acidification may catalyze hydrolysis of the ester linkages of the polymer, the release of drugs is not dependent on the destruction of the nanocapsules. In order better to understand the behavior of nanocapsules after oral administration, Marchais et al. (126), Kedzierewicz et al. (127), and Lowe and Temple (128) also analysed the interactions of nanocapsules with digestive enzymes. Drug release from nanocapsules was accelerated in the presence of proteases and esterases. In the latter case, this was correlated with a decrease in polymer molecular weight.

Damgé et al. (129) studied the fate of nanocapsules after oral administration *in vivo* using an iodized oil (Lipiodol), a contrast agent for tomography, as a marker. This showed that encapsulation increased the plasma concentration of the marker, which remained at a high level for a few hours. This improved absorption was attributed to the prolongation of the contact between the encapsulated iodized oil and mucosa, or to a transfer of the drug still associated with nanocapsules through the intestinal mucosa by a paracellular pathway. Evidence of the latter pathway was given by the observation of nanocapsules in the intestinal capillaries by electron microscopy coupled with atomic absorption spectroscopy, but this technique did not allow the extent of passage to the blood to be quantified.

*Mucosal protection.* Two major nonsteroidal antiinflammatory agents have been encapsulated in this carrier

in order to reduce their side effects on the gastric mucosa. The pharmaceutical activity of diclofenac (130) and indomethacin (131) after oral administration does not seem to be influenced by the encapsulation of the drug in nanocapsules. In fact, nanocapsules containing these two drugs exhibited drug concentration–time profiles in the plasma of rats similar to those obtained with the corresponding aqueous solutions. These observations seemed to be independent of the nature of the polymer coating (132). In contrast, the side effects of both drugs were completely modified and reduced by encapsulation in nanocapsules. In fact, nanocapsules induced a marked protective effect on the gastrointestinal mucosa as compared with the ulcerative effect observed with the drug solutions. Fawaz et al. (133) also observed a reduced rectal irritability of indomethacin after administration of nanocapsules by the rectal route. These results suggested that mucosal side effects after oral administration were of local rather than systemic origin, since intravenous administration of nanocapsules did not reduce the gastrointestinal side effects. This protection could be attributed to a slow release of the drugs in the acidic gastric environment or to the reduced toxicity of the acidic form of diclofenac or indomethacin encapsulated in nanocapsules compared with the sodium salt in the aqueous solution (130).

*Improvement of biological response.* Poly(isobutylcyanoacrylate) nanocapsules were shown 10 years ago to be able to encapsulate insulin and to increase its activity as assessed by a reduction of glycemia (134). Several aspects of this phenomenon are surprising: encapsulation of a hydrophilic drug in the oily core of nanocapsules; reduction of glycemia was only obtained with diabetic animals; hypoglycemia appeared two days after administration and was maintained for up to 20 days depending on the insulin doses, although the amplitude of the pharmacological effect (minimum level of blood glucose) did not depend on the insulin dose. Damgé et al. (135) and Lowe and Temple (128) suggested that nanocapsules could protect insulin from proteolytic degradation in intestinal fluids, based on the protection of encapsulated insulin, observed in the presence of different enzymes *in vitro*. Later studies showed that insulin did not react with the alkylcyanoacrylate monomer during the formation of nanocapsules and was located within the oily core rather than adsorbed on their surface (136,137).

The capacity of insulin nanocapsules to reduce glycemia could be explained by their translocation through the intestinal barrier, as suggested by Damgé et al. (135), for example by paracellular pathway or via M cells in Peyer's patches (138). Recently, the use of Texas Red<sup>®</sup>-labelled insulin allowed this translocation to be visualized more

readily (139). One hour after oral administration, nanocapsules reached the ileum. The presence of fluorescent areas within the mucosa and even in the lamina propria suggested that insulin-loaded nanocapsules could cross the intestinal epithelium. Although this passage is certainly an important factor, it does not explain the duration of the hypoglycemia. This prolonged action could be due to the retention of a part of the colloidal system in the gastrointestinal tract.

Interestingly, a prolonged hypoglycemic effect was also observed with insulin entrapped in poly(alkyl cyanoacrylate) nanospheres when these were dispersed in an oily phase containing surfactant (140). This suggests that some components of nanocapsules could act as promoters of absorption.

Recently, Damgé et al. (141) showed that the incorporation of octreotide, a somatostatin analogue, in poly(alkylcyanoacrylate) nanocapsules also improved and prolonged the therapeutic effect of this peptide, after administration by the oral route.

Another application by the oral route concerns anti-infectious agents such as atovaquone and rifabutine, two compounds active against *Toxoplasma gondii*, an opportunistic parasite whose antiparasitic activity is limited by their poor bioavailability due to their insolubility in water. Encapsulation of atovaquone resulted in an increase of both the survival of mice infected by the parasite and of its activity after an intragastric administration (142). This improvement of activity translated as a decrease in the brain parasitic burden, which was more pronounced in mice treated with loaded nanocapsules than in those treated with free drug.

#### b. Parenteral Route

As far as the parenteral route is concerned, nanocapsules are useful for formulating poorly soluble drugs for injection and for modulating the distribution of a drug after injection according to the properties of the carrier.

*Encapsulation of poorly soluble drugs.* Two poorly water-soluble nonsteroidal anti-inflammatory agents that showed different behavior after I.V. administration have been studied: indomethacin and diclofenac. Diclofenac in solution or in nanocapsules showed similar plasma concentration profiles, whereas encapsulated indomethacin showed lower plasma concentrations than free drug, due to enhanced hepatic uptake of loaded nanocapsules (143). In contrast to the oral route, the similar pharmacokinetic parameters obtained after I.V. administration were accompanied by similar deleterious effects at the level of the intestinal mucosa. Subcutaneous injection did not lead to a slow release of the drug either. One possible explanation about the lack of modification of the pharmacokinetics of

anti-inflammatory agents could be the rapid rate of release of these drugs into the circulation in the presence of plasma proteins. Nevertheless, after I.M. administration, nanocapsules of diclofenac showed significantly reduced inflammation at the site of injection as compared with the free drug in solution (144). Similar observations were made by Hubert et al. (145) with nanocapsules of darodipine, a poorly soluble antihypertensive.

*Passive targeting to macrophages.* As early as 1986, Al Khouri et al. (106) observed that, like other colloidal carriers, nanocapsules, administered by the I.V. route in rabbits, were taken up rapidly by organs of the mononuclear phagocyte system.

As well as changing the distribution of a drug, nanocapsules may also affect its elimination. Since encapsulated drug is concentrated in the Kupffer cells of the liver, the proximity to the hepatic parenchymal cells may increase its secretion into bile. This was found to be the case in rabbits, when indomethacin-loaded PLA nanocapsules were administered intravenously (143). Both the biliary excretion and the enterohepatic circulation were increased with the nanocapsule form.

One application that takes advantage of this uptake concerns nanocapsules of MTP-Chol (Muramyl tripeptide cholesterol) developed in our laboratory. This immunostimulating agent is able to activate macrophages and induce toxicity towards tumor cells and would therefore be a useful agent to treat metastatic cancer. The mechanisms by which activated macrophages arrest tumor proliferation include production of nitric oxide and TNF- $\alpha$ . We showed in *in vitro* models of rat alveolar macrophages and RAW 264.7 mouse monocyte macrophage line that nanocapsules based on poly(D,L-lactide) containing MTP-Chol are more efficient activators than the free drug (146,147). This action could be due to an intracellular delivery of the immunomodulator encapsulated in nanocapsules after phagocytosis and to an intermediate transfer of the drug to serum proteins (148). This system has also demonstrated its efficiency *in vivo*; in fact Barratt et al. (149) reported antimetastatic effects of nanocapsules containing MTP-Chol in a model of liver metastases. Some antimetastatic activity was also seen after oral administration.

#### c. Ocular Delivery

Tear turnover, lachrymal drainage, and the hydrophobic structure of the corneal epithelium combine to reduce greatly the ocular bioavailability of drugs formulated as eye drops. First studies carried out with nanocapsules, as ocular drug carriers, attempted to increase the penetration of lipophilic drugs into the eye by prolonging the precorneal residence time, as observed with other colloidal systems, liposomes, and nanospheres. These studies, which

concerned antiglaucomatous agents such as betaxolol, carteolol, and metipranolol encapsulated in nanocapsules, only showed a reduction of the noncorneal absorption (systemic circulation) leading to reduced side effects as compared with the free drug (150–152). These systemic side effects are due to a poor ocular retention of drugs, which are directly absorbed into the systemic circulation by conjunctival and nasal blood vessels. In two cases (carteolol and betaxolol), encapsulation in nanocapsules produced a better pharmacological effect (reduction of intraocular pressure) than free drug and nanospheres (although the penetration of nanocapsules was not tested) and reduced cardiovascular systemic side effects (150,151). Metipranolol showed the same activity alone and associated with nanocapsules but, as in the case of carteolol and betaxolol, its side effects were reduced. When betaxolol was used, the nature of the polymer making up the nanocapsule wall was found to be important, and poly( $\epsilon$ -caprolactone) was more efficient than poly(isobutylcyanoacrylate) or poly(lactic-co-glycolic acid) (151).

Calvo et al. (153) explored the mechanisms of interaction of nanocapsules with ocular tissues the better to understand the pharmacological responses obtained with antiglaucomatous agents. By confocal microscopy, they showed that poly( $\epsilon$ -caprolactone) nanocapsules could specifically penetrate the corneal epithelium by an endocytic process without causing any damage to the cells, in contrast with poly(isobutylcyanoacrylate) nanoparticles, the uptake of which was associated with cellular lysis (154). These results explained the improved therapeutic effect and the reduction of systemic side effects as a result of drug loss through the conjunctiva provided by poly( $\epsilon$ -caprolactone) nanocapsules by increasing corneal epithelium penetration of lipophilic drugs. Calvo et al. (155) also excluded the influence of the oily inner structure in the activity of the nanocapsules, in the light of the absence of differences in penetration between nanospheres and nanocapsules, in contrast with Marchal-Heussler et al. (150), who observed a better therapeutic effect with nanocapsules than with nanospheres. Moreover, Calvo et al. (155) demonstrated with indomethacin-loaded nanocapsules that the colloidal nature of the carrier was the main factor influencing its ocular bioavailability. The same authors were also interested in the influence of the nature and the charge of the surface of the nanocapsules on their physical stability and on their ocular bioavailability (156,157). They found that coating the negatively charged surface of poly  $\epsilon$ -caprolactone nanocapsules with cationic polymers could prevent their degradation caused by the adsorption of lysozyme, a positively charged enzyme found in tear fluid (156). Moreover, they noticed that a cationic polymer, chitosan, adsorbed on the surface of nanocapsules, was able to provide the best corneal drug penetration without any local intoler-

ance as compared to another positively charged polymer. This was achieved by a combination of effects: penetration of particles into the corneal epithelial cells, mucoadhesion of positively charged particles onto negatively charged membranes, and a specific effect on the tight junctions (157).

This effect of improvement of ocular absorption was also reported by Calvo et al. (158) with the immunosuppressive peptide cyclosporin A. The corneal level of the drug was increased fivefold as compared with an oily solution of the drug owing to a highly loaded nanocapsule preparation, also containing poly( $\epsilon$ -caprolactone). The efficacy of this topical formulation has also been observed on a penetrating keratoplasty rejection model in the rat (159). Le Bourlais et al. (160) also proposed an alternative preparation of cyclosporin nanocapsules based on poly(alkylcyanoacrylate) dispersed in poly(acrylic acid) gel able to reduce drastically the toxicity of poly(alkylcyanoacrylates) on the cornea and to promote absorption of the drug.

### C. Bioadhesive Interactions of Nanoparticles with Intestinal Mucosae

Controlled drug delivery not only consists in the release of drugs in a time-controlled manner but also often necessitates an adequate and finely tuned localization of the delivery system in the body. In this respect, nanoparticles are of considerable interest, since their physicochemical properties can be modulated for increasing their interactions with specific tissues or cells. In the last decade, the bioadhesive potential of nanoparticles in contact with intestinal mucosae has been thoroughly explored, for improving the delivery of poorly absorbed drugs.

Different targets can be considered in the gastrointestinal tract for immobilizing nano- or microparticles in close contact with the intestinal mucosa, including (1) epithelial cells, (2) specialized immunocompetent cells organized in Peyer's patches and (3) the mucus layer covering the mucosa with a continuous adherent blanket. Interactions can be mediated by nonspecific forces, which are driven by the surface properties of the particles and the intestine, or specific interactions can occur when a ligand attached to the particle is used for the recognition and attachment to a specific site at the mucosal surface.

#### 1. Nonspecific Bioadhesive Interactions of Nanoparticles

##### a. *In Vitro Experiments*

Nonspecific adhesion of nanoparticles have been reported *in vitro* and *in vivo*. Adsorption experiments have been conducted under flow (161,162) or static conditions (163–166) by placing suspensions of nanospheres made of vari-

ous polymers in contact with excised gut fragments. Interaction equilibria are generally reached rapidly [e.g., 10 min for 230 nm poly(styrene) nanospheres], and it has been shown that it was controlled by the kinetics of diffusion of the particles in the suspension medium (163).

Interactions of poly(styrene) latex (163–165) and poly(isobutyl cyanoacrylate) nanoparticle suspensions (167, 168) with rat intestinal mucosa have been described by using adsorption models. The shape of adsorption isotherms of poly(styrene) latexes were dependent on a particle size threshold (163,164). For nanoparticles up to 670 nm, the isotherm consisted in a linear increase in adsorbed amounts up to a plateau that was reached suddenly for particle concentrations in the bulk particle suspension of about 2.5 g/L, indicating a sudden saturation of the mucus layer by the particles. The saturation values, expressed as the mass of polymer per unit of apparent mucosal surface, ranged typically between 0.5 and 1.0 g/m<sup>2</sup> depending on the type of particles, which corresponded to multilayers of particles. In contrast, the adsorption of 2- $\mu$ m polystyrene particles increased progressively, and saturation could be obtained for polymer concentrations in the bulk particle suspension higher than 10 g/L. The saturation values were in the range of 2 g/m<sup>2</sup> but, due to the larger size of the particles, it could be calculated that it corresponded approximately only to a single layer of particles on the mucosal surface. Adsorption isotherm of poly(isobutylcyanoacrylate) nanoparticles showed a linear increase in particle adsorption at least up to a bulk concentration of 20 g/L in the particle suspension (168). For poly(isobutylcyanoacrylate) nanoparticles, the slope of the linear segments of the isotherms is lower than the slope for poly(styrene) latex, suggesting a lower affinity of poly(isobutylcyanoacrylate) nanoparticles for the rat intestinal mucosa compared to poly(styrene) particles in the same size range (i.e., 200 nm).

The characteristics of adsorbing species (e.g., concentration, size, surface properties) and adsorbent (e.g., number of sites available for adsorption, geometry) determine the shape of adsorption isotherms. Giles et al. (169) has proposed a general classification of isotherms based on the shape of the isotherms. Nanoparticle adsorption isotherms have been analyzed in this framework (164). Isotherms of 200 nm poly(isobutylcyanoacrylate) nanoparticles and 230 and 670 nm poly(styrene) latexes had the characteristic isotherm shape of adsorbates that penetrate into a porous adsorbent. In this situation, the linear increase of the isotherm corresponds to the creation of new adsorption sites when the bulk particle concentration is increased. These sites are available for further adsorption up to the isotherm plateau, which corresponds to a saturation of the available sites. The porous nature of the hydrogel mucus layer for undermicron particles is likely. The possibility of a diffu-

sion of particles into the mucus layer has been demonstrated by diffusion studies for polystyrene nanoparticles in gastrointestinal mucus (170). Confocal microscopy studies by Scherrer et al. (171) have shown that fluorescently labeled poly(isobutylcyanoacrylate) particles (211 nm in diameter) could penetrate at least 60  $\mu$ m deep into the mucus layer of rat intestine mucosal fragments. Alternatively, scanning electron microscopic photographs made by Damgé et al. (135) showed 200-nm nanocapsules in close contact with the mucous network a short time after oral administration to rats.

In the case of larger particles, such as 2- $\mu$ m poly(styrene) particles, Langmuir-type isotherms are observed. The adsorbate adsorbs in a monolayer on the adsorbent surface, which behaves like a smooth surface.

### *b. In Vivo Considerations*

After oral administration, nanoparticles can transit directly and/or adhere to the mucosa before fecal elimination. However, oral absorption (translocation) can also occur (172–175), and nanoparticles are likely to cross the gastrointestinal barrier to deliver their drug content in the blood, lymph, or even target organ. A direct contact and/or adhesion of the particles to the mucosal surface is a prerequisite for the translocation process. Obviously, the capture of nanoparticles by M cells in the Peyer's patches and further translocation of the particles is rate limited and quantitatively secondary.

After peroral administration of radiolabeled poly(hexylcyanoacrylate) nanoparticles to mice, whole-body autoradiography showed that thirty minutes after administration the particles were exclusively localized in the stomach (174,176). After 4 h, a large quantity of radioactivity was found in the intestine in the form of clusters without macroradiographic evidence of accumulation at specific intestinal sites. On the contrary, a persistent film of nanoparticles adhering to the stomach wall was observed. In this study, very little of the radioactivity was found to be absorbed. In a similar study, microautoradiographs confirmed the presence of radioactivity throughout the whole gut (174,177). The amount of radioactivity dropped to 30–40% of the 90-min value within 4 to 8 h and to 5%, 24 h after dosing. Histological investigation showed radioactivity adjacent to the brush border, incorporated into the underlying cell layers, and in goblet cells up to 6 days after administration.

After intragastric administration of <sup>14</sup>C-labeled poly(lactide) micron-range microspheres a dynamic description of the intestinal transit of a suspension of colloidal particles has been proposed (178). Firstly, the suspension of particles immediately enters in contact with a portion of

the oral mucosa (step 1). From this moment, the concentrated suspension acts as a reservoir of particles, and very rapidly an adsorption process takes place, leading to the adsorption of a fraction of the available particles (step 2). Adsorption occurs with the mucus layer and is an irreversible process. The luminal particle suspension transits through the intestine, sweeping progressively the whole mucosa. The simultaneous adsorption process results in a progressive covering of the intestinal mucosa by adherent particles (step 3). Finally, due to mucus turnover, detachment of the particles from the mucosa begins to occur in the proximal region and is progressively extended to the distal region (step 4). Nonadherent particles from the lumen pool and detached particles from the mucoadherent pool are finally eliminated in the feces. Quantitatively, in this description, particle translocation through the intestinal mucosa remains a marginal phenomenon.

## 2. Specific Bioadhesive Interactions of Nanoparticles

In order to increase the adhesivity of the nanoparticles as well as their site specificity, modifying nanoparticles for exploiting receptor-mediated interactions within the gastrointestinal tract has been suggested. For this purpose, nanoparticles have been conjugated to different ligands which show an affinity for a receptor located into the gastrointestinal cavity. The attachment is generally obtained by grafting onto the polymer making up the particles. Different targets within the gastrointestinal tract can be foreseen, including (1) mucus glycoproteins (mucins), (2) epithelial cell membranes, (3) M-cell membranes, Peyer's patches, or gut-associated lymphoid tissue (GALT), and (4) abnormal glycoproteins secreted by cancerous cells (local tumors). Different ligands have been suggested, including plant, viral, and bacterial lectins, invasins, antibodies (179–182), and vitamin B12 (183).

Lectins are proteins that bind with considerable specificity to carbohydrate moieties expressed by large molecules, such as glycoproteins. So far, the capacities and limits of tomato lectin (TL) conjugates have been extensively studied.

According to Kilpatrick and coworkers (184), the tomato lectin resists digestion and binds to rat intestinal mucosa without any obvious deleterious effects. Furthermore, it is recognized as a natural component of our diet. The potential of this lectin as an oral drug delivery agent was first shown by Naisbett and Woodley (185) who reported that this lectin bound avidly to the small intestine epithelial surface and that this interaction was mediated through N-acetylglucosamine-containing glycoconjugates. The use of fluorescently labeled polystyrene latex coated by adsorp-

tion with TL revealed that these conjugates avidly adhered to isolated fixed pig enterocytes in vitro, while the albumin coated control conjugates did not (186). Later, adhesion experiments were carried out by placing a suspension of conjugated microspheres in contact with isolated rat intestinal segments (187,188). Two sets of intestinal mucosa were assayed, with or without Peyer's patches (PP). For intestinal samples without PP, the extent of interaction of TL conjugates decreased from duodenum to ileum, which was attributed to a progressive decrease in the mucin concentration along the gastrointestinal tract, although interactions could also take place with enterocytes after diffusion of the particle conjugates through the mucus layer. About 1.5 g of TL conjugate per m<sup>2</sup> of apparent surface of intestine were adhered to the mucosa, which was significantly higher than the 0.3 g/m<sup>2</sup> observed for control BSA conjugates. Nevertheless, the interaction of TL conjugates with mucosa samples having PP was dramatically decreased. Fluorescence microscopy gave clear evidence of the absence of surface interactions between TL conjugates and PP regions (188).

Recently, some in vivo experiments have been performed in rats. On the one hand, fluorescently labeled TL-latex conjugates were intraduodenally administered to study the transit time of the conjugates. After killing the animals 4 h after a single dose administration, no significant difference was found in the distribution of TL conjugates and controls (189). On the other hand, after multiple dosing, TL-latex conjugates showed unusual absorption. Simple dosing produced no evidence of uptake, whereas 5 or 10 days daily dosing caused uptake of 18% of the dose, not due to tissue damage but perhaps to the induction of receptor expression by the lectin (172). Therefore TL conjugates induced a marked increase in systemic uptake (a 10-fold increase in absorption over plain latex after 5 days daily dosing), which could only be accounted for by induction of uptake through enterocytes as well as lymphoid tissue (190). Analysis of tissue samples revealed that significant amounts of TL conjugates remained bound to the mucosa for several hours in spite of peristalsism and mucus turnover (191). By microscopy, these authors have demonstrated the accumulation of conjugates within the mucus layer, their penetration through the gel layer, and their passage along the serosa layer indicative of the absorption. In contrast with controls, low uptake of TL conjugates by the PP was found (187). Further, TL conjugates showed high circulating levels in the blood, suggesting the low ability of the reticuloendothelial system to sequester them (192).

Finally, the specificity of asparagus pea (*Lotus tetragonolus*) lectin (AL) conjugates to various structures of the intestinal mucosa ex vivo was tested. It appears that

these conjugates, which are specific for L-fucose residues, moderately interacted with regular intestinal segments (188). By using intestinal segments containing PP, a 25% increase in the interaction was observed when compared with segments without PP. This last result is in agreement with the reported presence of L-fucose residues on PP regions, especially in M cells (193) and may be of interest for oral vaccination.

### 3. Increased Oral Bioavailability after Drug Delivery by Nanoparticles

Immobilization of drug carrying particles at the mucosal surface would result in (1) a prolonged residence time at the site of drug action or absorption, (2) a localization of the delivery system at a given target site, (3) an increase in the drug concentration gradient due to intense contact of the particles with the mucosal surface, and (4) a direct contact with intestinal cells, which is the first step before particle absorption. Therefore association to nanoparticles may be of benefit for poorly absorbed or unstable drugs.

The pharmacokinetics of several drugs after oral administration have been improved by means of nanoparticles (128,129,131,135,141,194–197). Most of these studies were carried out with conventional formulations, which means that the carriers were generally not specifically designed for improving the bioadhesion performances of the particles. Some results obtained with nanocapsules by the oral route have been discussed in Section III.B.2.a; these concern mainly peptides such as insulin, calcitonin, and somatostatin. Cyclosporin loaded into poly(isohexylcyanoacrylate) nanocapsules had an increased bioavailability when compared to emulsions (194).

The bioavailability of vincamine was about 25% when administered as an aqueous solution to rabbits, whereas after oral administration adsorbed on poly(hexylcyanoacrylate) nanoparticles, its bioavailability reached 40%, probably due to a prolonged period of contact of the drug delivery system with the mucosa (195). The bioavailability of avarol was also improved by association with poly(alkylcyanoacrylate) nanoparticles (196). The anti-inflammatory effect of hydrocortisone was also increased when the drug was incorporated into microspheres (197), while less significant results were obtained for interferon (198). Interesting results have also been obtained for human growth hormone and heparin by using proteinoid microspheres in the micron range (199). Microparticles made of a copolymer of fumaric acid and sebacic acid (FA:SA) and specifically designed with bioadhesive properties were shown to be efficient in transfecting epithelial cells in vivo by a model plasmid DNA pCMV/ $\beta$ gal, coding for the  $\beta$  galactosidase (200).

These pharmacological observations suggest a high potential for nanoparticles as a peroral drug delivery system. However, most of those studies make no attempt to relate the pharmacological modifications to the fate of the particles in the GI tract, which is generally not characterized. In these examples, it can be estimated that bioadhesion is likely to occur to some extent (as demonstrated in vitro and in vivo for model particles), but the exact incidence of the extent and duration of the adhesion on drug absorption remains unknown. This point should be determined in detail in the future, since it will be crucial for evaluating the interest of the concept of bioadhesive particulate systems for oral delivery.

### D. Nanoparticles Avoiding Uptake by Phagocytic Cells

Despite the promising results with some first-generation drug carrier systems, their usefulness is limited by their distribution and in particular by their recognition by the mononuclear phagocyte system. Recently, a great deal of work has been devoted to developing so-called Stealth<sup>TM</sup> particles, which are invisible to macrophages (Stealth<sup>TM</sup> is a registered trademark of Liposome Technology Inc.). A major breakthrough in the liposome field consisted in the use of phospholipids substituted with poly(ethylene glycol) (PEG) chains of molecular weight from 1 to 5 kDa (201). This provides a cloud of hydrophilic chains at the particle surface that repels plasma proteins, as discussed theoretically by Jeon et al. (202). These “sterically stabilized” liposomes have circulating half-lives of up to 45 h, as opposed to a few hours or even minutes for conventional liposomes. They have been shown to function as reservoir systems and can penetrate into sites such as solid tumors (203,204). A similar strategy has been applied to nanoparticles. PEG can be introduced at the surface in two ways, either by adsorption of surfactants or by the use of block or branched copolymers, usually with poly(lactide) (PLA).

As far as the adsorption of hydrophilic surfactants onto the particle surface is concerned, Illum et al. (205) studied the use of surfactants with polyoxyethylene blocks, such as the poloxamer and poloxamine series onto polystyrene latex surfaces. In particular, they found that coating with poloxamer 407 avoided uptake by Küppfer cells but promoted uptake by the bone marrow (206). Moghimi and coworkers (207) found that poloxamine 908 reduced liver uptake of polystyrene particles, which they interpreted as being due to reduced adsorption of opsonins and increased adsorption of dysopsonins. However, this surfactant, even when not associated with particles, also activated phagocytic cells so that a second dose some days later was

cleared rapidly by the liver. The group of Müller (208,209) confirmed reduced plasma protein deposition and uptake by phagocytes of particles coated with these two surfactants, for polystyrene and for biodegradable poly(ester) particles. However, with the more hydrophilic biodegradable polymeric surfaces, reversible adsorption *in vivo* was observed (210). On the other hand, biodegradable nanospheres prepared from PLGA coated with PLA-PEG diblock copolymers showed a significant increase in blood circulation time and reduced liver uptake in a rat model, as compared to naked PLGA nanospheres (211).

Polysorbate 80 coated nanospheres (212) have been shown to accumulate in the brain, and to allow the delivery of analgesics that do not normally penetrate the blood-brain barrier, but this may be due to the toxicity of the surfactant.

The same approach has been applied to nanocapsules. Lenaerts et al. (213) encapsulated phthalocyanines, important agents in photodynamic tumor therapy, and modified the surface of nanocapsules by adsorption of different poloxamers with various lengths of their POE and POP domains. Their results indicated that some poloxamers, such as poloxamer 407, decreased the uptake of nanocapsules by organs rich in phagocytic cells and increased accumulation of phthalocyanines in primary tumors. Concentration of photosensitizers in the tumor were maximal 12 h after injection of loaded nanocapsules. These carriers allowed an accumulation 200-fold higher in the tumor compared with blood.

Despite these results, the use of copolymers in which PEG is covalently attached to a hydrophobic block would seem to be the better choice, since it avoids the possibility of desorption. Nanospheres prepared from copolymers of PLA, PLGA, or poly( $\epsilon$ -caprolactone) (PCL) with one or more PEG chains of molecular weight 2–20 kDa have been extensively studied in order to optimize their surface characteristics (length and density of PEG chains) for minimizing their interactions with plasma proteins and maximizing their circulating half-life (214–216). It was found that the average calculated distance between two terminally attached PEG 2 kDa chains had to be 2.2 nm or less for repulsion of complement proteins (217). Steric repulsion was also sufficient to avoid strong interactions with the plasma factors of the coagulation system and formation of aggregates between particles and calcium ions in the presence of sodium cholate (218). Recently, nanospheres have been prepared from a series of PEG-PLA copolymers in which the Mw of both the PLA and PEG blocks were varied (219,220). Moreover, the use of blends of PLA and PEG-PLA allowed nanospheres to be prepared coated with a PEG “brush” of varying thickness (related to the PEG Mw) and density (related to the content of PEG in

the nanospheres). It was thus possible to study the effect of these coatings on competitive plasma protein adsorption, surface charge, and interaction with phagocytic cells.

Although PEG of 5 kDa was more effective than PEG of 2 kDa in terms of reduction of the total amount of plasma protein adsorption, increasing the chain length further, up to 20 kDa, gave no additional advantage (219). The major plasma proteins adsorbed onto these nanospheres were albumin, immunoglobulin G, immunoglobulin light chains, and the apolipoproteins apoA-I and apoE. It was shown further that at optimal PEG chain length (5 kDa) a PEG surface density corresponding to a distance of less than 1.5 nm between two terminally attached PEG chains is required to minimize the total amount of plasma protein adsorbed. A study of phagocytosis by polymorphonuclear (PMN) cells as measured by chemiluminescence and zeta potential carried on with these particles agreed well with these findings: the same PEG surface density threshold (1.5 nm) was found both to ensure efficient steric stabilization and to avoid the uptake by PMN cells. Finally, at optimal coating conditions, it was shown that the nature of the core material (PLA, PLGA, or PCL) played a major role in determining the nature and the amount of the plasma proteins adsorbed (220). On the other hand, a better avoidance of uptake by THP-1 monocytes was provided by 5 kDa PEG chains than by 2 kDa PEG chains at a distance of 1.2–1.4 nm (215).

Lidocaine was used as a model lipophilic drug in an attempt to establish the main factors that determine the encapsulation efficiencies and the release kinetics (221). Human serum albumin (HSA), as a model protein, was also encapsulated in PLA-PEG nanospheres (222,223). HSA loading as high as 7 wt% was thus obtained with 200 nm nanospheres, and controlled release over several days was observed. Surface analysis techniques established that HSA was mainly entrapped deep inside the cores and not adsorbed on their surface (222). As well as their potential as circulating microreservoirs, such systems might be useful for controlled release of antigens. Tetanus toxoid (TT) could also be entrapped in nanospheres of about 150 nm, with high efficiency. When gelatin was included as a stabilizer, active antigen could be released for at least 28 days (224). The transport of radiolabeled TT through the rat nasal mucosa was highly dependent on the surface properties of the nanospheres: the PEG coated ones led to a much higher penetration of TT into the blood circulation and the lymph nodes than the uncoated PLA ones.

PEG chains have also been attached covalently to poly(alkylcyanoacrylate) polymers by two different chemical strategies. In the first, PEG was added during the emulsion-polymerization of alkylcyanoacrylate monomers (225). When PEG blocked at one terminal (MePEG) was used, a

brushlike configuration would be expected, whereas when unblocked PEG was added, both ends could be linked to the poly(alkylcyanoacrylate), yielding a loop structure. Studies of complement consumption suggested that this latter structure was the most effective in repelling proteins from the particle surface. The second strategy consisted in the synthesis of a cyanoacrylate monomer substituted with PEG and its copolymerization with hexadecylcyanoacrylate in a 1:4 ratio (226). Both types of particle have shown long-circulating properties in vivo (225,226).

Recently, we have prepared nanocapsules from PLA-PEG copolymers, with the aim of creating circulating reservoirs with a high capacity for lipophilic drugs. In this case, both PEG chain length and density were found to be important in reducing interactions with phagocytic cells in vitro and prolonging circulation time in vivo (227). We compared systems containing PLA-PEG with those stabilized by poloxamer F68. The latter showed some Stealth™ properties in vitro at low dilution, but these were lost at higher dilution and in vivo. The nanocapsules containing PLA-PEG of 5 kDa, with a spacing of 4.3 nm, avoided capture by the liver better and remained longer in the circulation than those containing PLA-PEG of 20 kDa (spacing 7.8 nm), and both were better than nanocapsules with adsorbed poloxamer F68. When a denser coverage of PLA-PEG 20 kDa was used, better Stealth™ properties were obtained than with PLA-PEG 5 kDa at the same spacing (228). These nanocapsules have been used to encapsulate an antimalarial drug, halofantrine (124), in order to prepare a well tolerated, injectable form for the treatment of severe disease.

Another strategy for preparing long-circulating colloidal systems can be considered as biomimetic in that it seeks to imitate cells or pathogens that avoid phagocytosis by reducing or inhibiting complement activation. One example is the development of liposomes with a membrane composition similar to that of erythrocytes, e.g., liposomes containing GM<sub>1</sub>, (229) and those coated with poly(sialic acid) (230). These systems may show circulating half-lives as long as liposomes bearing PEG. Attempts to introduce sialic acid onto the surface of nanospheres, either by adsorption of glycoproteins (231) or by synthesis of a PLA-poly(sialic acid) copolymer (232), were not successful, in the first case because of desorption in the presence of plasma proteins and in the second because of either the water-solubility of the polymer or an inappropriate conformation of the polysaccharide.

Another biomimetic approach, which has yielded more promising results, is the use of heparin, the anionic polysaccharidic anticoagulant, also known to inhibit several steps of the complement cascade, as the hydrophilic part of amphiphilic diblock copolymers capable of forming

nanospheres (233). The hydrophobic segment was poly(methylmethacrylate) (PMMA), a nonbiodegradable polymer, which was however suitable for validating the concept. These systems were indeed able to avoid complement activation, as shown by two-dimensional immunoelectrophoresis of C3 (234). Using a fluorescent marker randomly copolymerized in the PMMA segment, it was possible to demonstrate reduced uptake by macrophages in vitro (235), and an increased half-life in vivo (5 h or more depending on the injected dose, compared with a few minutes for PMMA nanospheres) for the heparin-bearing systems (236). It is interesting to note that nanospheres prepared from a diblock copolymer with dextran, intended as controls, had only low complement-activating potential, in contrast to cross-linked dextran, i.e. Sephadex®, and also showed long-circulating properties; thus a steric hindrance effect caused by a brushlike arrangement of end-attached polysaccharide chains may also contribute to the long-circulating properties of these nanospheres.

### I. INTRODUCTION

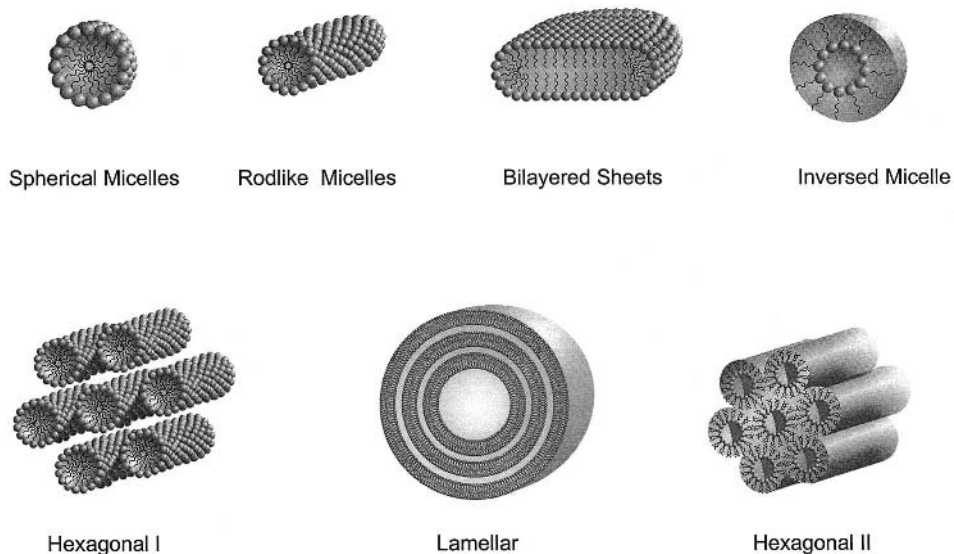

Liposomes or (phospho)lipid vesicles are self-assembled colloidal particles that occur in nature or can be prepared artificially. In the beginning, liposomes were used to study biological membranes, while several practical applications, most notably in drug delivery, emerged in the 1970s. After three decades of research, several products are commercially available. They rely on liposome colloidal, microencapsulating, and surface properties. Products range from drug dosage forms (antifungals, anticancer agents, and vaccines) and cosmetic formulations (skin care products, shampoos) to diagnostics and food industry products. However, at present, it seems that drug delivery applications are now the most widely investigated area of their practical applications.

#### A. Properties of Amphiphiles, Bilayers, and Liposomes

Amphiphiles are a class of organic molecules that contain both polar (or in most cases charged) and nonpolar segments and are therefore simultaneously hydrophobic and hydrophilic. Typical examples of these molecules are detergents and phospholipids. Due to hydrophobic and hydrophilic interactions, these molecules orient and self-organize in polar and nonpolar solvents. Aqueous systems of amphiphiles exhibit a very rich phase behavior, and

some of the structures formed are schematically shown in Fig. 1. The most common structures that most phospholipids adopt spontaneously are the concentric bilayer vesicles in excess water (see Fig. 2). In the bilayer structure the lipid hydrophilic head groups orient toward the aqueous phase, and the nonpolar hydrocarbons are associated at the center, away from water molecules. In comparison most detergents and lysophospholipids form micelles that vary in size and shape depending on the type of detergents. Certain amphiphiles, such as long-chain phosphatidylethanolamine (PE), do not form bilayers but adopt a structure known as the inverted hexagonal ( $H_{II}$ ) phase (see Figs. 1 and 2). Various types of cubic phases have also been discovered (42). In drug delivery, the dispersed, self-closed lamellar phase—the liposomes—is most important and used for most applications. In other applications, such as gene transfer and regional drug delivery applications, other structures such as the dispersed  $H_{II}$  and cubic phases, and the micelles, may be also important.

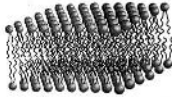

The ability of lipids to adopt structures other than the bilayers upon hydration is known as lipid polymorphism. A generalized concept of geometric shape properties can be ascribed to various amphiphilic molecules that reflect the phase structure they prefer under given conditions, as illustrated in Fig. 3. Molecules, such as lipids, that prefer the bilayer structure, have cylindrical shapes, i.e., similar areas of polar heads and the cross sections of nonpolar

**Figure 29.1** Common types of structures (phases) formed by amphiphiles in aqueous solution. Most detergents and lysophospholipids form various types of micelles. Most phospholipids form spontaneously into concentric bilayer vesicles. Certain amphiphiles, such as long-chain phosphatidylethanolamines (PE), can form inverted hexagonal ( $H_{II}$ ) phase. Micellar and liquid-crystalline phases are stable thermodynamic phases, while lamellar colloidal suspension liposomes is a kinetically trapped state.

Amphiphiles	Shape	Organization	Phase
Soaps Detergents Lysophospholipids	 $P < 1/3 - 2/3$	 Micelle	Isotropic hexagonal I
PC PS PI Short-chain PE Sphingomyelin Dicetylphosphate Some cationic lipids	 $P \sim 1$	 Bilayer	Lamellar
Long-chain PE PA Cardiolipin Phospholipids Lipid A	 $P > 1$	 Hexagonal II	Reverse micelles Hexagonal II
Mixture of Lyso- PC + PE or PEG-lipid + PE	 $P \sim 1$	 Bilayer	Lamellar

**Figure 29.3** The concept of molecular geometry and structure of the amphiphilic phases as determined by packing of surfactant molecules (steric effects) (From Ref. 43.)

chains. In the case of a larger polar head with respect to a smaller nonpolar tail, the molecules tend to pack into structures with high radii of curvature, such as micelles. A structural parameter  $P$  is defined as

$$P = \frac{v}{al}$$

Where  $v$  is the volume of the amphiphile,  $a$  the cross-sectional area of the polar head, and  $l$  the length of the nonpolar tail. For values of  $P$  below  $1/3$ , spherical micelles are favored structures; for values between  $0.8$  and  $1.1$ , preferably around  $1$ , bilayers are the most stable structure, while for values of  $P > 1$  to  $1.1$ , inverse structures form. In the case of ideal mixing within the bilayer, one can define an average  $P$  as the sum of the mole fractions of individual values of  $P$  of individual lipids:

$$\langle P \rangle = \sum_i x_i P_i$$

where fractions are taken for lipid  $i$  with structural parameter  $P_i$ . We shall use this concept later to explain liposomes with built-in instability.

Liposomes are simply lipid vesicles in which an aqueous volume is entirely enclosed by a membrane composed of lipid molecules. Liposomes were first discovered by Alec D. Bangham in the early 1960s when investigating the role of phospholipids in the clotting cascade (10). The bilayer structure of the liposomes is in principle identical to the lipid portion of natural cell membranes—the “sea of phospholipids” in the Singer and Nicholson mosaic model. Since then, liposomes have been used as models of biological membranes because liposomes can be prepared from natural constituents and membrane proteins can be reconstituted.

**Figure 29.4** Chemical structures of neutral and anionic phospholipids commonly used in liposomes for drug delivery.

With respect to the size and number of membranes (lamellarity) we distinguish large multilamellar vesicles (LMV or MLV) and unilamellar vesicles (UV), which can be small (SUV), large (LUV), or giant (GUV), as shown in Fig. 2. MLVs are normally formed when dry lipid is hydrated in aqueous solution. Small liposomes are normally defined as the ones where curvature effects are important for their properties. This curvature depends on the lipid composition and can vary from 50 nm for soft bilayers to 80 to 100 nm for mechanically very cohesive bilayers. Giant vesicles are normally those with diameters above 1  $\mu\text{m}$ . The thickness of the bilayer depends on the type of lipids, the hydrocarbon chain length, and the temperature, and is around 4 nm.

## B. Chemical Structures of Lipids

### 1. Zwitterionic and Anionic Lipids

Lipids used for lipid vesicles are extracted from natural sources or chemically synthesized. The most common natural lipids are lecithins (phosphatidylcholines, PC), sphingomyelins, and phosphatidylethanolamines (PE), which are zwitterionic at physiological pH (see Fig. 4 for structures). The common sources for these lipids are egg yolks, soya beans, and (ox) brains.

Anionic natural lipids include phosphatidylserine (PS), phosphatidylglycerols (PG), and phosphatidylinositols (PI). One serious drawback of the natural lipids is that they contain a mixture of acyl chains. Natural lipids are less

commonly used for liposome/vesicle preparations for several reasons. First, membranes prepared from natural lipids tend to be leakier to solutes, due to the low main phase transition temperatures (see below), and therefore they are not suitable for drug delivery when drug retention and carrier stability are emphasized. Second, for basic biophysics researches involving artificial lipid membranes, synthetic lipids are preferred, since in most cases one would like to be able to control the physical properties of the membranes and be able better to interpret the experimental results. The last problem for using natural lipids particularly as drug carriers for human use concerns the possible contamination from the source, especially if it is animal in origin.

The stability of natural lipids can be increased by hydrogenation (reduction of double bounds). The degree of hydrogenation is described by the iodine value (*I.V.*), where  $I.V. = 1$  for fully saturated chains. A typical high *I.V.* number is 65 of EPC. Commercially, *I.V.* values of 1, 10, 20, 30, and 40 are normally available.

In contrast, chemical synthesis can produce lipids with well-defined acyl chains (number of carbons on the chains and degree of saturation) attached to the same polar heads. The most commonly used acyl chains are dimyristoyl (C14:0), dipalmitoyl (C16:0), distearoyl (C18:0), dioleoyl (C18:1), and palmitoyl-oleoyl (C16:0-C18:1). The structures of some common phospholipids are shown in Fig. 4. Cholesterol is a very important component in lipid vesicles for improving the mechanical stability of the lipid bilayers and therefore increasing the retention of the encapsulated agents.

## 2. Cationic Lipids

Cationic lipids, with the exception of sphingosine and some lipids in primary life forms, practically do not exist in nature. The first lipid that was used to complex DNA (80) and transfect DNA in cell culture (30) was DOTMA (dioleoxypropyltrimethylammonium chloride). Many more cationic lipids have been synthesized to improve the transfection capability and to decrease the toxicity (see Fig. 5 for structures). The best-known monocationic lipids include DOTAP, DMRIE, DODAP, DDAB, and DODAC, and all these are efficacious for DNA transfection. Natural cations, such as spermine<sup>4+</sup> and spermidine<sup>3+</sup>, can also be coupled to fatty acyl chains. In DC-CHOL the positive charge is associated on the sterol backbone (33). The chemical structures of the most frequently used cationic lipids for DNA delivery are given in Fig. 5. DOPC, DOPE, and cholesterol are the most often used neutral lipids and are often called helper lipids. mPEG-PE and mPEG-ceramides have often been used to increase circulation and to prevent aggregation. The ma-

jority of positive charges of cationic lipids are based on (poly)amines and quaternary ammonium salts. The  $pK_a$  values for most cationic lipids are currently unknown. Quaternary ammonium salts are very strong bases, and  $pK_a$  values are above 12. For simple alkyl amines,  $pK_a$  values are typically above 10 for primary and secondary amines and above 9 for tertiary.

## C. Thermodynamic Properties of Lipids

### 1. Thermodynamic Properties of Pure Lipids

Liposome characteristics are determined by surface and membrane properties, including surface charge, steric interaction, and membrane rigidity. The most common lipids used for preparing liposomes for drug delivery are neutral or zwitterionic lipids, such as PCs and PEs. Therefore the characteristics of these types of liposomes are determined by the thermodynamic properties of these lipids. One of the most important thermodynamic parameters of chemically pure lipids is the phase transition temperature ( $T_m$ ) and the associated enthalpy ( $\Delta H$ ). The low temperature phase for PC and PE is commonly referred to as the gel phase, where the acyl chains are packed tightly and lateral movement of lipid molecules is restricted (Fig. 6). For this reason, solute transport through lipid bilayers in the gel phase is limited. The high-temperature phase is called the liquid-crystalline, or fluid, phase, where the acyl chains become mobile and disordered, although the lipids are still arranged in a smooth bilayer structure. This phase transition between the ordered gel phase and the fluid phase is most commonly referred to as the main phase transition ( $T_m$ ). Lipid phase transitions are cooperative events and can occur over a very narrow temperature range of less than one degree (58,59,61).

Factors affecting the phase transition properties are the type of polar head groups, the length of the acyl chains, and the degree of saturation of the acyl chains. For the same polar head groups  $T_m$  increases with increasing acyl chain length (58,61,100). Lipids with unsaturated acyl chains have much lower  $T_m$  values, due to the introduced disorder of the double bond. PEs usually have higher values of  $T_m$  than the corresponding PCs with identical acyl chains, because of the stronger interactions (intermolecular H-bonding) between PE head groups. The presence of charge on the polar heads (i.e., cationic and anionic lipids) tends to decrease the value of  $T_m$ , due to the repulsive interactions between molecules. It should be noted that some anionic lipids, such as phosphatidic acid (PA) and PS, are known to exhibit strong intermolecular hydrogen bonding and therefore may have higher values of  $T_m$  (15,16). There are relatively few studies on the phase properties of the cationic lipids commonly used for genome formation.

Figure 29.5 Structures of cationic lipids used in gene transfection.

**Figure 29.6** Illustration of phase transition for phospholipids in a lipid bilayer when fully hydrated. Crystalline phase ( $L'_\beta$ ) transforms into a gel phase ( $P'_\beta$ ) at temperature  $T_p$ . The  $P'_\beta$  transforms into liquid-crystalline phase ( $L_\alpha$ ) at  $T_m$ . In the  $L'_\beta$  phase, lipid molecules are packed tightly with hydrocarbon chains tilted to a certain degree. In the  $P'_\beta$  phase, the hydrocarbon chains also packed closely, but the bilayer surface becomes rippled. In the  $L_\alpha$  phase, the lipid chains become mobile and disordered, and in addition lipid molecules can move freely within the bilayer. A transition from lamellar phase to reversed hexagonal phase ( $L_\alpha$  to  $H_{II}$ ) can occur for some lipids having small head groups and bulky hydrocarbon chains, such as DOPE. The phase temperatures and enthalpies can be conveniently monitored by differential scanning calorimetry (upper curve).

## 2. Thermodynamic Properties of Binary Lipid Mixtures

In most cases, liposomal formulations designed for drug delivery contain more than one type of lipid. An essential parameter to consider for formulation stability is the miscibility of the lipid matrix. Lipid mixtures that are poorly miscible will eventually fail in stability tests, due to lipid phase separation. For lipids with the same head groups, the degree of miscibility is mostly determined by the mismatch of the acyl chains as well as the degree of saturation of the acyl chain. PC, for instance, with an acyl chain length differing by two carbons, has high miscibility, while a four-carbon difference results in poor miscibility. In contrast, di-18:1 $\Delta^9$  PC has better miscibility with di-14:0 PC than with di-18:0PC (82). The binary phase behavior of PC with other types of lipids is rather complicated (60,61). PC and PE have medium or low miscibility unless the two have the same acyl chain length. It is interesting to note that PC and PG can be ideally miscible when the two have

the same acyl chain length, because the thermodynamic properties of PG are very similar to their corresponding PCs.

Cholesterol as one of the most useful liposome components can be readily incorporated into PC bilayers to a maximum of 50 mol%. Cholesterol itself does not exhibit a phase transition, but it does broaden significantly the main phase transition of the lipid bilayer into which cholesterol is incorporated. The primary purpose of using cholesterol is to increase the membrane rigidity, and it therefore improves mechanical properties of liposomes, which leads to better drug retention and longer liposome circulation.

## II. TECHNIQUES OF LIPOSOME PREPARATION

Unlike other polymer-based drug delivery systems, the emphasis in making liposomes is not towards assembling the membrane, since lipid bilayers form spontaneously

upon hydration, but towards getting the swollen membranes to form vesicles/liposomes of the desired size and structure, and to achieve high solute trapping efficiency and good pharmacological properties of the liposomal delivery system.

The common procedures for generating various types of lipid vesicles are summarized in Table 1 and will be described in detail below. Two of these involve the initial solubilization of lipids in organic solvents or detergents that have to be removed subsequently. The third procedure does not require solubilizing agents. But first it is useful to introduce two primary parameters that have been used extensively by liposomologists to describe liposomes for their attributes as drug carriers. The first parameter is the trapping efficiency, which is defined as the percentage of aqueous solute that is entrapped within the liposomes. The second parameter is the trapped (or the captured) volume, which is defined as the internal aqueous volume enclosed by a given amount of lipids and is often expressed as L/mol lipid. We will describe first the generation of different

types of vesicles (i.e., MLV, LUV, and SUV) and then the most common preparation procedures.

### A. Mechanical Dispersion by Direct Hydration (MLVs)

The conventional procedure for generating MLVs is very simple and straightforward. Lipids are dissolved in organic solvent, such as chloroform, or a chloroform/methanol mixture (2/1 to 3/1 vol/vol) and then dried by rotary evaporation to form a thin film on the glass wall of a round-bottom flask. The residual amount of solvent is then removed by vacuum (< millitorr) for several hours. Aqueous medium is then added to hydrate the lipids at temperatures 5–10°C above the  $T_m$  for the lipid (or the  $T_m$  for the lipid with the highest  $T_m$  value, in case of mixed lipids). Often, agitation, such as shaking, vortexing, or even the use of glass beads, is required to remove all lipids from the glass wall and to generate homogeneous lipid suspensions. At this stage, vesicle formation lipids are said to “swell” and

**Table 29.1** Common Methods for the Generation of Multilamellar and Unilamellar Vesicles

Technique	Type of vesicles	Trapped vol. (L/mol lipid)	Advantages	Disadvantages
Direct hydration (hand-shaking) (36,64)	MLV	0.5	Fast	Low trapped volume; low trapping efficiency; unequal distribution of solute
Direct hydration plus freeze-thaw (36,63)	MLV	5–10	Fast, high trapped volume; high trapping efficiency	Solute dependent
Extrusion of MLV (40)	LUV	1–2	Fast, high trapping efficiency, uniform size	Relatively low trapped volume
Sonication	SUV	0.2–0.5	Fast, small size, most suitable for small volume preparation	Low trapped volume, size less uniform than extruded LUVS, small scale
Ethanol injection (25)	LUV/SUV	5–10	Convenient	Limited lipid-solubility in ethanol, low trapping efficiency, low lipid concentration, ethanol needs to be removed
Ether injection (25)	MLV/LUV	5–10	High lipid concentration, high trapping efficiency	Small scale, heterogeneous size
Reverse-phase by sonication/rotary evaporation (84)	LUV/MLV	10	High trapping efficiency	Small scale, heterogeneous size, safety concern
Reverse-phase by sonication/N <sub>2</sub> evaporation (36)	MLV (SPLV)	10–20	Even distribution of solute	Low trapping efficiency (< 30%), heterogeneous size, safety concern
Detergent dialysis (27,44)	SUV/LUV	0.5–5	Reconstitution of proteins, high trapped volume	Slow process, detergents difficult to remove completely, size difficult to control, low trapping efficiency

Source: Ref. 23.

peel off the glass support in sheets and form vesicles. MLVs have been very useful as model membranes for fundamental research, such as studies on the thermodynamic and structural properties of lipids and lipid interactions with drugs, peptides, or proteins (72,85,96–98,100,101). They have very limited use as drug carriers, particularly for systemic delivery of water-soluble agents, because MLVs produced by the above method give rise to very low trapping volume (36,64). In addition, they have a very wide size distribution. However, lipid-soluble agents can be entrapped inside the lipid bilayers of MLVs to very high efficiency, provided that they are not presented in quantities oversaturating the structural capacity of the lipid bilayers. The trapping efficiencies and trapped volumes of MLVs produced by this direct hydration method can be dramatically increased by a procedure called freeze-and-thaw, in which the lipid suspension is subjected to cycles of freezing and thawing between subzero temperatures (i.e., freezing in liquid nitrogen or dry ice) and temperatures above the  $T_m$  of the lipid (see Fig. 2) (36,64).

For preparations that will be used in humans, the use of chloroform or methylene chloride is not recommended, although that it can be pumped off below 1 ppm relatively quickly. Thus an alternative method of generating homogeneous MLVs is to freeze-dry the lipids dissolved in a suitable organic solvent. Tertiary butanol is considered the most suitable solvent. Aqueous medium is added to the dry lipid, which is in an expanded foamlike form (cake), and MLVs are then produced by rapid mixing above the  $T_m$  of the lipids (3).

### B. Extrusion/Homogenization (LUVs)

The majority of applications, however, require smaller and better-defined liposomes. For systemic delivery of drug, liposomes with sizes in the range of 100–150 nm are desired, while for genosomes, SUVs smaller than 50 nm are often preferred. LUVs can be conveniently produced by an extrusion technique, where MLVs produced as described above or by other methods are forced through polycarbonate filters at temperatures above the  $T_m$  (77). It was later improved by employing a purposely built high-pressure extruder that allowed rapid extrusion under high pressure up to 5.5 mpa from a nitrogen tank (40,63). LUVs with sizes ranging from 50 to 200 nm can be generated by the extrusion procedure using appropriate filters (see Fig. 2). The extruded liposomes have well-defined size distribution and thus have been widely used both in research laboratories and in industries. Further, high lipid concentrations (up to 400 mg/mL) can be employed, which is critical for achieving high trapping efficiencies for hydrophilic agents.

Homogenization and microfluidization (or microemulsification) are the easiest ways for the scale-up. In homogenization, MLV solution is forced at high pressure through a small hole; it collides into a wall, a small ceramic ball, or the tip of the pyramid in an interaction chamber. Microfluidization devices split the suspension of MLVs into two parts, which are collided head on at pressures up to 20,000 psi. This technique offers such advantages as simplicity, large capacity, and speed (depending on the size of the homogenizer one can prepare 10 mL to hundreds of liters in 1 hour). Some of the disadvantages are possible lipid degradation and wider size distributions compared with liposomes produced by the extrusion method.

Another device, called the French press, originally designed for disrupting plant and bacterial cells (SLM-Amino Inc. Urbana, Illinois), can also be used for producing homogeneous liposomes in the mid size range (30–80 nm) (11,51). In this procedure, the MLV suspension is enclosed in a pressure chamber (20,000–40,000 psi), and the suspension is forced through an outlet orifice. As in other homogenization processes, the vesicles are disrupted into lipid fragments by the large shear force generated by the high pressure, and small liposomes are thus formed. The size and the homogeneity of the liposomes for a given lipid are inversely proportional to the flow rate through the orifice. For different lipid matrixes the size of the liposomes produced by the French press procedure depends on variables like lipid composition, temperature, and pressure. Consequently, this method can only be used when high reproducibility is not necessary. In addition to the high initial cost of the device, the French press has not been as popular as some other methods described above.

### C. Sonication (SUVs)

Sonication has long been used as a convenient method for producing SUVs with the smallest size possible in small scale (41). In recent years it has been the most often used method for generating cationic liposomes for gene delivery studies (see Fig. 9C) (28,29,35,51,73). Both bath and probe ultrasonic disintegrators can be used, and each has advantages and disadvantages. For larger volume and dilute samples, bath sonication is more suitable. Normally 5 to 10 min sonication above the  $T_m$  of lipids is sufficient for producing SUVs of 50 nm or even smaller. The advantages of bath sonication include a controllable operating temperature, freedom from contamination, and no loss of lipid material. Probe sonication, on the other hand, dissipates more energy into the sample and therefore is often used for achieving the smallest size possible and for concentrated samples or suspension in more viscous aqueous solutions. Different size probes are available for different volumes

of samples. One problem with the probe sonication is the heating of the sample solution, which can cause lipid degradation. This situation can be overcome by placing the sample vessel in a circulating water bath and under a nitrogen blanket. Another problem with probe sonication is contamination from the titanium particles from the probe tip, which must be removed by centrifugation or filtering. The size of liposomes produced depends on lipid concentration and composition, temperature, sonication time and power, volume of sample, as well as tuning; i.e., by carefully adjusting the position of the tip, one can achieve better energy dissipation. Consequently this process is not very reproducible in some circumstances. One should also be aware that the vesicle size may start to increase after a minimum size has been achieved, due to vesicle fusion resulting from colliding of vesicles in the process.

#### D. Solvent Injection

Several methods for liposome preparation involve the solubilization of lipids in organic solvent, which is then brought into contact with the aqueous solution containing the materials to be entrapped within the liposomes. Liposomes are formed almost instantly when the solvent is diluted or evaporated. Ethanol and ether are the two most often used solvents. Because of the markedly different miscibility of the two solvents with water, different procedures, though based on similar concepts, have been developed.

The ethanol injection method has been used for nearly thirty years (13,20) and has the advantages of simplicity and being free of the risk of lipid oxidation. In this procedure lipid (or lipid mixture) is first dissolved in ethanol solution and then rapidly injected through a fine needle into an aqueous solution in excess volume at high temperature. Under optimum conditions, liposomes in the size range of 20–50 nm can be produced. The major drawbacks of this method are the limited lipid solubility in ethanol (40 mM for PC and much lower for cholesterol) and the maximum proportion of ethanol in the final solution (< 10%). Consequently, the lipid concentration in the final product is rather low, and thus the trapping efficiency for water-soluble materials is very low. Moreover, complete removal of ethanol by dialysis or diafiltration is a lengthy task.

The ether injection procedure is different from ethanol injection in many ways, because ether is a water-immiscible solvent. The lipid-containing ether solution is injected into the aqueous medium rather slowly through a narrow-bore needle, at such a temperature that ether becomes vaporized, and thus liposomes are formed. The advantage of

the ether injection method is the high lipid concentration achievable, since the solvent can be removed at the speed that it is introduced. In order to achieve the best results of liposome size and homogeneity, a mechanical infusion pump is required to control the injection speed. Large-scale preparation, however, is not recommended due to safety reasons.

#### E. Reverse-Phase Method

The method commonly called the reverse-phase method involves the preparation of water-in-oil emulsions, where the lipid is solubilized in the organic phase and the aqueous phase contains the solute to be entrapped (84). The marked differences in the reverse-phase procedure from the solvent injection method are the relative volume ratio of solvent to water and the way that solvent is removed. In the reverse-phase method, organic solvent is in great excess and is mixed with a small amount of aqueous solution (for instance 1/10 of the volume of the solvent). Many solvents have been used in this method, but ether is the most common one. The mixture is then subjected to sonication to produce water-in-oil emulsions, which contain monolayers of lipid surrounding the water droplets. The emulsion droplets are then collapsed and transform into LUVs or MLVs (often called MLV-REVs) after the removal of the solvent, depending on the way that solvent is removed, the amount of excess lipids, and the solvent-to-water volume ratio. A solute trapping efficiency of greater than 50% can be achieved for MLV-REVs under optimum conditions.

Another version of the reverse-phase method is to add an aqueous solution containing the solute to an ethanol solution containing the lipids; the mixture is then dried under vacuum or by rotary evaporation (36,39). This results in a dry lipid film within which the solute is entrapped. Subsequent hydration of the dry lipid film results in the formation of MLVs with efficient entrapment of the solute initially presented in the system. Other solvent systems, such as ethyl ether, ethyl acetate, and ethanol/ethyl acetate mixtures, have also been used (21). Alternatively, the solvent in the reverse-phase emulsions can also be removed by blowing of nitrogen gas while continuously sonicating the emulsions. In the presence of an excess of lipids, MLVs called stable plurilamellar vesicles (SPLVs) can be produced (36). The effect of sonication during solvent removal is to disrupt the lipid bilayers continuously and cause redistribution and equilibrium of solutes between adjacent bilayers within each SPLV. The trapping efficiency of SPLVs can be only around 30%.

It is important to understand the differences in the structure of MLVs and the nature of solute distribution within the vesicle for different type of MLVs prepared by the vari-

ous methods that have been described so far. In MLV-REVs a single large aqueous core is surrounded by several or more bilayers, because the MLV formed is originated from a water droplet. In comparison, both types of MLVs (produced from direct hydration) and SPLVs lack such a large aqueous core. The solute distributions are also very different for these vesicles. Most of the solute entrapped in MLV-REVs is mainly enclosed in the center aqueous cores. SPLVs differ from MLVs in the way that the solute distributes evenly throughout each SPLV, because of the constant rupture to the bilayers by sonication, while in MLVs the solute might be more concentrated near the center of the MLV and depleted in the outer compartments. Certainly for membrane-permeable solutes, eventual equilibrium distribution within MLVs will be reached after a certain period of time.

#### F. Detergent Dialysis

Detergent dialysis involves the solubilization of lipids (and proteins) in nonionic or ionic detergents, such as OGP and bile salts (51,68,71,85). Liposomes form gradually during the process of detergent removal either by passing the sample through a gel filtration column or by dialysis in a large volume of solution. This method suffers the serious drawback that the size of the liposomes formed cannot be easily controlled and often depends on factors like lipid type and composition, the nature of the solute, and the type of detergent and the process for detergent removal. Detergent dialysis procedure is not very practical for trapping water-soluble agents, because that the process is cumbersome and time consuming, but it is the method of choice for the reconstitution of biological transmembrane proteins, because of its nondestructive conditions.

#### G. Mechanism of Lipid Vesicle Formation

Dilution and energy-accompanied dispersal of lyotropic liquid crystals can result in rather homogeneous suspensions of stable colloidal particles, which can retain the short-range order of the parent liquid crystalline phase. In the case of diacyl amphiphiles, such as phospholipids, sphingolipids, and many synthetic polar lipids, one can form either liposomes upon the dispersal of lamellar phases or hexosomes upon homogenization of hexagonal phase in excess water.

Although methods for the preparation of well-defined liposomes have existed for almost thirty years, the exact mechanisms are still not known. Because identical structures can be made by very different preparation methods, several different mechanisms operate, depending on the experimental conditions, as illustrated in Fig. 7 (49,50).

The most widely used methods are high-energy treatment of large multilamellar liposomes formed by hydration of lipids or their mixtures. In these aggregates, lipid molecules are already organized into bilayers, and high-energy treatment, such as sonication, homogenization, or extrusion, simply breaks down large bilayers into smaller bilayered fragments. Such fragments are unstable due to the exposure of the hydrocarbon chains to an aqueous environment and tend to eliminate this unfavorable interaction. This can be done by bending and closing. This process is opposed by bending elasticity of the bilayer. For large enough lipid fragments, however, the bending energy is smaller than the unfavorable edge interaction and they close into self-closed vesicles. This means that in the beginning small fragments fuse into larger ones, because at constant area this reduces the circumference. Because bending elasticity scales linearly with the number of molecules ( $N$ ) in the fragment ( $E_b \propto N$ ) till it reaches a constant value, and edge interaction scales parabolically ( $E_e \propto N^{1/2}$ ), one can see that for sufficient size  $E_b < E_e$  and the fragment self-closes.

This mechanism operates also in the case of detergent depletion. In this case, however, the edge is shielded by detergent molecules, and larger fragments are stable, resulting in the formation of larger liposomes.

Liposomes can also be made from preexisting bilayers by fission of bilayers. This, the so-called budding off mechanism, operates when self-closed multilamellar vesicles are subjected to asymmetric changes that cause the area change of the outer monolayer in the bilayer. For instance, change in the pH can result in ionization of the outer monolayer. The charges repel, and the area of the outer monolayer increases with respect to the inner one. This creates a bud, and when the mismatch reaches the critical area ratio the budding off occurs. This mechanism operates in the liposome preparation by the change of pH, addition of amphiphiles (lysolecithin, short chained lipids, which distribute in the outer monolayer), and exchange of counterions in some cationic lipids. The process is thoroughly studied in giant unilamellar vesicles, which can bud off daughter vesicles under temperature changes, as monitored in the optical microscope (51).

Reverse-phase methods, in which liposomes are formed from water-in-oil or oil-in-water-in-oil emulsions upon removal of the organic solvent, operate by the dispersal of bicontinuous phases into the aqueous phase. For instance, upon removal of organic phase, lipid gel is formed. It consists of connected bilayered structures (cubic phases, similarly to foam, etc.) that disintegrate into bilayered colloidal particles upon their dilution and breakage in the aqueous phase.

Many different liposome preparation methods exist, and all can be described by the mechanisms above or their

**Figure 29.7** Mechanisms of liposome formation by various techniques.

combination(s). The exception is spontaneous vesicles, which are formed by simple mixing of appropriate amphiphiles. These liposomes, however, have very soft bilayers, and because they are very unstable upon application, and because they cannot stably encapsulate (hydrophilic) molecules, we will not describe them further.

### III. METHODS FOR DRUG LOADING

All the techniques described above are useful for solute encapsulation. The primary considerations for choosing a suitable loading method are the physical and chemical properties of the solutes. For water-soluble drugs, active or remote loading procedures are preferred, due to the high trapping efficiency and high drug-to-lipid ratio achievable. However, for most water-soluble solutes that do not respond to the active loading process, passive loading procedures have to be used.

Hydrophobic solutes can be incorporated into the hydrocarbon chain region, either by direct hydration of the solute-lipid mixtures or by the reverse-phase procedure. Detergent dialysis is very useful, especially for the reconstitution of membrane proteins. The most troublesome solutes to load are these having very low water solubility and at the same time cannot be solubilized in organic solvent due either to low solubility or to chemical instability. Examples of this type of drug are cisplatin and amphotericin.

The primary variables to consider in drug loading are trapping (or encapsulation) efficiency, drug-to-lipid ratio, and drug retention (or release). The trapping efficiency is defined as the percentage of solute encapsulated, and the maximum trapping efficiency achievable depends on the loading technique. The drug-to-lipid ratio is determined after loading and is usually expressed as a weight ratio or a mole ratio.

Drug retention refers to the capability of liposomes to keep the drug from leaking out under defined conditions and is usually determined by incubation tests at 4°C and 20°C or by *in vitro* serum stability tests at 37°C. It should be noted that liposomes that provide satisfactory shelf stability do not necessarily always pass the serum stability test. This is because possible interactions of serum proteins with lipid components can significantly change the membrane integrity and therefore alter the drug leakage profile.

### A. Passive Loading of Water-Soluble Solutes

In the process of passive loading, lipids and solute are co-dispersed in an aqueous medium, so solute entrapment is achieved while the liposomes are being formed. Typically lipid or lipid mixtures used in passive loading are in the form of thin films on glass walls, lyophilized powder, or simply dry cake in glass test tubes. The aqueous medium containing the water-soluble solute is then added to the lipid. Liposomes are generated by agitation at temperatures above the phase transition temperature. In order to achieve high trapping efficiency and drug-to-lipid ratio, a high concentration of solute is used whenever possible. Normally the trapping efficiency in a passive loading process is less than 10–20%. However, the trapping efficiency can be increased to the 30–50% range by the freeze-thaw (23,64) and the dehydration-rehydration (45) procedures. A high drug-to-lipid ratio is difficult to achieve unless the solute to be entrapped is extremely water soluble (e.g., >100 mg/mL). The trapping efficiencies can also be significantly improved using procedures involving organic solvents such as the stable plurilamellar vesicles (36) and the reverse-phase evaporation (84).

### B. Passive Loading of Hydrophobic Molecules

Hydrophobic agents that are compatible with organic solvents can be passively loaded by the direct hydration procedure. Normally the solute and lipids are codissolved in organic solvents, such as chloroform or ether, and dried to form thin films or powdered cakes as described above. An aqueous solution is then added to hydrate the lipid mixture by agitation at temperatures above the main phase transition temperature. The loading efficiency and maximum drug-to-lipid ratio achievable depend on the structure of the solute.  $\alpha$ -helical peptides, for instance, that match the lipid acyl chain length can be incorporated into lipid bilayers with near 100% efficiency (97,98). For solutes that are only soluble in aprotic solvents, a modified reverse-phase method can be used, where the solute and the lipids

are dissolved in a mixture of ethanol and DMSO (or DMF) and then injected into the aqueous phase (83).

In case liposomes need to be downsized to LUVs, sonication and extrusion procedures can be applied. However, it is usually more difficult and sometimes troublesome to downsize solute-containing vesicles. This is because hydrophobic molecules are usually less flexible than the lipid hydrocarbon chains, and therefore the lipid bilayers are hardened and more difficult to break by the shear force applied by the sonication or extrusion procedures. Moreover, more solute may be spit out of lipid bilayers, since bilayers with high curvature can accommodate less solute.

### C. Reconstitution of Proteins

The reason that detergent is used for protein separation and purification from biological membranes is to maintain the proteins in their native conformations. Similarly, for purposes of simulating the native membrane environment and maintaining protein conformation and biological activity, the characterization of membrane proteins can be carried out by solubilizing the proteins in detergent micelles. However, the ultimate ideal environment for protein characterization is provided by small phospholipid vesicles, and obviously the most suitable method for protein reconstitution is the detergent dialysis procedure (22,85). In this procedure, both protein and phospholipids are cosolubilized in appropriate detergent micelles so that the protein hydrophobic region (i.e., the part of the protein that is normally embedded in the membrane core) traverses the acyl chain region of the micelles. The detergent molecules are then slowly replaced with lipids by dialysis or column chromatography. The resulted lipid vesicles will contain the proteins embedded in the bilayer acyl chain region as illustrated. The choice of detergent mostly depends on the nature of the protein. When there is no specific head group requirement, nonionic detergents become the first choice because of the well-known tendency of long-chain ionic detergent to be protein denaturants. Polyoxyethylene derivatives are the most common type of nonionic detergents. It is essential to use detergents, such as C<sub>12</sub>E<sub>8</sub> and Tweens (polyoxyethylene-sorbitan-alkyl esters), that form small micelles at high concentration. Another important consideration is the matching of the hydrophobic lengths of the protein and the detergent micelles to minimize the distortion of the proteins.

Some membrane proteins may require an anionic head group for maintaining their native conformation. In these cases, mixtures of anionic and neutral lipids can be used, since anionic lipids alone do not form stable vesicles, particularly when there are interactions with the protein. Simi-

larly, anionic or mixtures of anionic and nonionic detergents can be used for the solubilization of proteins and lipids. It is worthwhile to mention that the commonly used ionic detergents sodium dodecyl sulfate (SDS) and alkyl trimethylammonium salts will normally stabilize the conformation of the hydrophobic region of the protein, but at the same time they may have a tendency of denaturing the water-soluble portions of the protein. Caution should also be taken when deoxycholate and cholate are used, since the  $\text{COO}^-$  groups become protonated below pH 7.8 and the micelle size increases greatly.

#### D. Active Loading Procedures

In one major type of active loading procedure, the solute is loaded after the liposomes have been formed, and the accumulation of solutes inside liposomes is mediated by certain active transportation mechanisms. For this reason it is also often called remote loading. Lipophilic amino-containing solutes can be loaded with near 100% efficiency into liposomes exhibiting transmembrane pH gradients, specific chemical gradients, or membrane potential ( $\Delta\Psi$ ).

In another type of active loading procedure, very different strategies are used for improving the trapping efficiency: special lipid components are deliberately incorporated to initiate the association of the solute with the carrier. Such a strategy has been extensively explored for the anticancer agent doxorubicin (Adriamycin), which is positively charged and has low water solubility. The trapping efficiency can be improved from less than 10% for neutral liposome systems by the passive loading procedure described above to 50–90% when anionic lipids are included in the lipid composition (23).

##### 1. Active Loading by pH Gradient

Many lipophilic amino agents can be actively driven into the interior of liposomes in response to a pH gradient (inside acidic) (26,53,62,65,67) as illustrated in Fig. 8. LUVs are first prepared by extrusion in the presence of a low pH buffer (i.e., sodium citrate, pH 4.0). The transmembrane pH gradient is then established by adjusting the external pH value to three units higher than the internal pH. The loading of drug is simply achieved by introducing the drug into the liposome solution followed by incubation at temperatures above the  $T_m$ . Many lipophilic amino drugs have been successfully loaded by the pH gradient method. Doxorubicin, an antineoplastic agent, is the best characterized in the pH remote loading process, and greater than 95% trapping efficiency and a 0.29:1 drug-to-lipid ratio (wt/wt) have been achieved. The loading process is rather fast, and maximum drug loading is usually achieved in about

**Figure 29.8** Mechanisms of active drug loading by pH gradient (A) and ammonium sulfate gradient (B). Lipophilic amino agents can pass through the liposome membrane in neutral form A. Once inside the liposome, the liposome membrane is neutral charged,  $\text{AH}^+$ , due to the low internal pH. The drug will be retained inside the liposome provided sufficient  $\Delta\text{pH}$  is maintained. When loaded with the ammonium sulfate gradient procedure, the positively charged drug  $\text{AH}^+$  can form a complex with sulfate,  $[(\text{AH})_2\text{SO}_4]_n$ , and precipitate inside the liposomes.

30–60 min incubation time (Fig. 8) and may vary from drug to drug. It should be noted that the loading time should be well controlled: a prolonged incubation at temperature above the  $T_m$  may cause drug leakage as well as lipid degradation. A potential drawback for some drugs in the pH remote loading procedure is the buffer/drug incompatibilities, which can lead to drug precipitation or degradation. Moreover, the addition of the alkalinizer for adjusting the external pH can cause a transmembrane osmotic gradient that can decrease the liposome stability. This problem can be overcome by exchanging the external buffer at constant osmolarity using column chromatography. However, such a procedure is cumbersome and has the limitations of scale-up and maintaining sample sterility.

## 2. Loading by Specific Chemical Gradient

Lipophilic amino drugs can also be efficiently loaded into preformed liposomes by the chemical gradient method (Fig. 8). In this procedure, an ammonium salt (i.e., ammonium sulfate, ammonium citrate, or ammonium phosphate) is enclosed in the hydration medium, and the ammonium gradient is established by the subsequent exchange of the external ammonium salt by means of dialysis/diafiltration or gel filtration column chromatography. Drug is then added to the liposome solution, and the accumulation of drugs inside the liposomes is achieved by incubation at a temperature above the  $T_m$ .

## 3. Ionophore-Mediated Loading by Membrane Potential

Another important type of active drug loading procedure involves the use of ionophores in the presence of a membrane potential (8,66). Ionophores are a class of organic molecules that vastly increase the permeability of membranes to particular ions and are mostly antibiotics of bacterial origin (88). The carrier type (the other type is the membrane channel formers, such as Gramicidin A) ionophores, such as  $K^+$ -valinomycin and  $Ca^{2+}$ -A23187, have been used for liposome drug loading. In the ionophore loading procedure, a membrane potential generated by an ion gradient needs first to be established, which can be easily achieved by passively trapping the ions, for instance, potassium glutamate, and subsequently exchanging the external  $K^+$  with  $Na^+$ . Solute loading occurs in the presence of an appreciable concentration of ionophore molecules. Several lipophilic cationic molecules, such as safranin, methyltriphenylphosphonium, chlorpromazine, and vinblastine, have been successfully loaded by  $K^+$ -ionophore valinomycin.  $Ca^{2+}$  can also be successfully loaded into li-

posomes by the  $Ca^{2+}$ -A23187-mediated pH (i.e.,  $H^+$ ) gradient procedure (89). Similarly, ionophore A23187 can also be used for loading of  $Fe^{2+}$  and  $Ba^{2+}$ , because of the significant affinity of A23187 with the two ions (19).  $Fe^{2+}$ - and  $Ba^{2+}$ -loaded liposomes have some interesting properties, such as increased densities, which enable them to be isolated from serum and can be used for identifying serum proteins that associate strongly with liposomes. The  $Ba^{2+}$ -loaded liposomes have enhanced EM contrast, which could allow the direct detection of extracellular and intracellular liposomes and determine their integrity and metabolic fate. One serious problem with ionophore loading is that these ionophores are toxic, and complete removal of ionophores after loading can be difficult to accomplish.

The mechanism of carrier ionophores for transporting ions involves binding to the ion, diffusing through the membrane, and releasing the ion on the other side of the membrane. It should be noted that solute transport into liposomes also occurs in the absence of an ionophore, though at a much slower rate. Studies using the membrane potential probes safranin and methyltriphenylphosphonium indicate that solute accumulation inside liposomes is an energy-dependent process in which solute is exchanged with  $K^+$  on a 1:1 basis (8). In the case of ionophore-A23187-mediated loading of  $Ca^{2+}$  by pH gradient, exchange of  $Ca^{2+}$ - $2H^+$  occurs. It is conceivable that the role of ionophores in solute loading is simply to increase the efflux rate of ions across the membrane.

## 4. Theoretical Explanation of Remote Loading

The accumulation of drugs as well as the entrapment efficiency in the case of pH gradient loading can be simply explained and calculated by a Henderson–Hasselbalch equation (26). Unlike pH gradient, the ammonium sulfate (or exchange) gradient loading is based on an influx of the drug molecules from exterior into interior and a simultaneous efflux of appropriate weak base molecules into the opposite direction. Due to this, there is a constant reduction of concentrations of related neutral species on both sides of the membrane. At the same time, following the law of mass action, both processes are accompanied by a simultaneous redissociation of the  $H^+$ -charged drug and the corresponding inner charged exchange-related weak base molecules. During the loading, these processes determine the level of the protons as well as the amount of the corresponding influxed/effluxed molecules in either compartment: the dissociations are coupled and drive the molecules in opposite directions until the concentration equality of neutral species on both sides of the membrane is established.

For the theoretical approach (37), we shall assume that

the permeability of charged species is negligible, although we have shown that this requirement can be lifted, and by using permeability and diffusion coefficients the kinetic nature can be incorporated into the model. Below, we shall define the equilibria that dictate the drug encapsulation and allow one to calculate drug loading as a function of experimental parameters and  $pK$  value(s) of the drug molecules.

Assuming that each compartment consists of an aqueous solution, and taking into account that each of them contains an optional number of acid/base and inert species (strong ions), the time-dependent equilibria during the simultaneous uptake and efflux of different permeable molecules can be described by the following two electroneutrality equations:

$$\sum_{m,I} c_{mI}(1 - B_m \beta_m) \frac{g_{mI}(x)}{f_{mI}(x)} + K_v \sum_{k,O} (A_k c_{kO} \alpha_k) \frac{g_{kO}(x)}{f_{kO}(x)} + v_I(x) = 0$$

for the inner compartment and

$$\sum_{k,O} c_{kO}(1 - A_k \alpha_k) \frac{g_{kO}(y)}{f_{kO}(y)} + \frac{1}{K_v} \sum_{m,I} (B_m c_{mI} \alpha_m) \frac{g_{mO}(y)}{f_{mO}(y)} + v_O(y) = 0$$

for the outer solution. Here, I and O refer to the inner and outer compartment of the liposomes,  $m$  and  $k$  to the inner- and outer-compartment sister-species, respectively;  $x$  and  $y$  are the concentrations of the inner and outer  $H^+$  ions,  $A_k$  and  $B_m$  are factors that allow the particular species to permeate the membrane ( $=1$ ) or not ( $=0$ ),  $a_k(t)$  and  $\beta_m(t)$  represent the time-dependent percentages of the entrapped and released species,  $c_{mI}$  and  $c_{kO}$  are the starting concentration of the corresponding inner/outer species,  $K_v$  is an outer-to-inner liposome compartment volume ratio, and the functions  $u_I(x)$  and  $u_O(y)$ , respectively, refer to  $H^+$  and inert ions that do not cross the membrane. For details with regard to  $x$ - and  $y$ -dependent  $f$  and  $g$  functions the reader is referred to Ref. 18.

Before the chemical equilibration between the compartments is established, the concentrations of the particular uptaken and/or released molecules are time dependent. Assuming a homogenous liposome solution, the portion of an outer  $k$ -species influxed can be expressed by the differential equation

$$\frac{d\alpha_k}{dt} = \frac{S_O P_k \prod_{j=0} K_{ij}}{K_v v_I} \left( (1 - \alpha_k) \frac{1}{y^{l_k-1} f_{kO}(y)} - K_v \alpha_k \frac{1}{x^{l_k-1} f_{kI}(x)} \right)$$

and a similar expression is valid also for inner  $m$ -molecules effluxed:

$$\frac{d\beta_m}{dt} = \frac{S_I P_m \prod_{j=0} K_{ij}}{v_I} \left( (1 - \beta_m) \frac{1}{x^{l_m-1} f_{mI}(x)} - \frac{1}{K_v} \beta_m \frac{1}{y^{l_m-1} f_{mO}(y)} \right)$$

Here,  $S_I/S_O$  refers to the inner/outer liposome bilayer surface,  $P_k/P_m$  is a permeability of  $k/m$ -species,  $v_I$  is the volume of the liposome vesicle, respectively, and  $\prod K_{ij}$  is a product of the corresponding acid-base dissociation constants. By introducing of an appropriate set of initial conditions (for  $t = 0$ ,  $a_k(0) = \beta_m(0) = 0$ ), the above four equations can be solved using numerical methods.

The entirely equilibrated system (for  $t \rightarrow \infty$ ) is described by two equations. The first one,

$$\sum_m c_{mI} \frac{g_{mI}(x)}{B_m K_v \left(\frac{y}{x}\right)^{l_m-1} f_{mO}(y) + f_{mI}(x)} + \sum_m A_k c_{kO} \frac{g_{kI}(x)}{\left(\frac{y}{x}\right)^{l_k-1} f_{kO}(y) + k_v f_{kI}(x)} + v_I(x) = 0$$

is valid for the exterior solution, and the second one, for the interior solution.

$$\sum_k c_{kO} \frac{g_{kO}(y)}{A_k k_v \left(\frac{x}{y}\right)^{l_k-1} f_{kI}(x) + f_{kO}(y)} + \sum_m B_m c_{mI} \frac{g_{mO}(y)}{\left(\frac{x}{y}\right)^{l_m-1} f_{mI}(x) + K_v f_{mO}(y)} + v_O(y) = 0$$

Now these general equations will be applied to a concrete example: uptake of the drug under simultaneous synergetic action of pH and bidirectional ammonium sulfate (exchange) gradient loading. The outer solution is buffered with a monovalent weak acid/salt of concentration  $c_{oa}/c_{os}$  and with a dissociation constant  $K_{oa}$ . It contains a drug of concentration  $c_d$ . In its molecular form the drug molecule is a weak base with the acid dissociation constant  $K_d$ . Similarly, the interior of the liposomes is filled with an aqueous solution containing also a monovalent weak acid/salt buffer (concentration  $c_{ia}$  for acid and  $c_{is}$  for salt with the acidity constant  $K_{ia}$  and a monovalent weak base of concentration  $c_i$  and constant  $K_i$  which is simultaneously al-

lowed to release during the uptake of the drug molecules. For the situation in the exterior during the loading/release one obtains

$$c_d(1 - \alpha) \frac{1}{1 + K_d/y} + \frac{1}{K_v} c_i \beta \frac{1}{1 + K_i/y} - (c_{oa} + c_{os}) \frac{K_{oa}/y}{1 + K_{oa}/y} + (c_{os} - c_d) + \left(1 - \frac{K_w}{y}\right) = 0$$

and the following is valid for the interior,

$$c_i(1 - \beta) \frac{1}{1 + K_i/x} + K_v c_d \alpha \frac{1}{1 + K_d/x} - (c_{ia} + c_{is}) \frac{K_{ia}/x}{1 + K_{ia}/x} + (c_{ia} - c_i) + \left(1 - \frac{K_w}{x}\right) = 0$$

When time-dependent portions of the uptaken drug- and exchange-related molecules,  $\alpha$  and  $\beta$ , in the above equations are set to 0, one can calculate the pH in both compartments before loading. Here,  $K_w$  is the autodissociation constant of water. The time dependency of the portions of the drug taken up and released molecules is given by

$$\frac{d\alpha}{dt} = \frac{3}{r} \left(1 + \frac{2d}{r} + \frac{d^2}{r^2}\right) P_d K_d \left(\frac{1}{K_v} (1 - \alpha) \frac{1}{K_d + y} - \alpha \frac{1}{K_d + x}\right)$$

and

$$\frac{d\beta}{dt} = \frac{3}{r} P_i K_i \left((1 - \beta) \frac{1}{K_i + x} - \frac{1}{K_v} \beta \frac{1}{K_i + y}\right)$$

When loading is finished, one obtains for the exterior compartment,

$$c_d \frac{1}{k_v \left(\frac{x}{y}\right) (1 + K_d/x) + (1 + K_d/y)} + c_i \frac{1}{\left(\frac{x}{y}\right) (1 + K_i/x) + K_v (1 + K_i/y)} - (c_{oa} + c_{os}) \frac{K_{oa}/y}{1 + K_{oa}/y} + (c_{os} - c_d) + \left(y - \frac{K_w}{y}\right) = 0$$

and similarly for the interior solution,

$$c_i \frac{1}{K_v \left(\frac{y}{x}\right) (1 + K_i/y) + (1 + K_i/x)} + c_d \frac{1}{\left(\frac{y}{x}\right) (1 + K_d/y) + k_v (1 + K_i/x)} - (c_{ia} + c_{is}) \frac{K_{ia}/x}{1 + K_{ia}/x} + (c_{is} - c_i) + \left(x - \frac{K_w}{x}\right) = 0$$

### E. Strategies for Improving Drug Retention

Perhaps the most challenging task in using liposomes as drug carriers is not to maximize the trapping efficiency and drug-to-lipid ratio, but to achieve acceptable drug retention. While loading technology can always be improved and new techniques may be developed, drug retention depends mostly on factors at the molecular level. Drug retention refers to the capability of liposomes for keeping the drug from leaking out and is usually determined by an incubation test or in in vitro serum stability tests. Drug retention is influenced by many factors including the membrane affinity of the drug, the water solubility, and the physical properties of the lipid matrix. With a given drug, the lipid composition has the most effect on drug retention. Lipids with long saturated acyl chains offer the possibility of good drug retention, because of their high phase transition temperatures. Cholesterol is often used for increasing drug retention and blood circulation because it increases the rigidity of bilayers. However, drugs with high membrane partitioning coefficients tend to leak out of liposomes very fast even with well-designed lipid compositions. Nevertheless, there are some strategies that can be used for improving drug retention. The best example is the commercial product DOXIL<sup>®</sup> (doxorubicin HCL liposome injection, ALZA Corp., Mountain View, CA), which is a liposomal doxorubicin loaded by the ammonium sulfate method. Excellent drug retention is achieved in part by the formation of crystals of the doxorubicin/sulfate complexes (see Fig. 9A) (54).

### IV. CHARACTERIZATION OF LIPOSOMES

Liposome preparations need to be characterized, and in many cases the quality needs to be controlled, before their usage. Table 2 shows the most important parameters for liposome characterization and quality control. Some of the major characterization parameters include visual appearance, turbidity, size distribution, lamellarity, trapped volume,

**Figure 29.9** Cryoelectron micrographs. (A) Doxorubicin encapsulated in sterically stabilized liposomes. In the interior of the liposomes, fibers of  $(\text{DoxH}^+)_2\text{SO}_4$  crystals can be observed that also change the shapes of the liposomes from spherical into oval. Higher magnification (not shown) shows that fibers in the bundles exhibit a helical arrangement. (B) DOTAP: Chol (50/50, mol%)-DNA (2/1, +/- charge) complex formed with extruded 100 nm liposomes. On the upper left, an unreacted liposome with a typical invaginated shape can be observed. A high degree of DNA encapsulation is characteristic for these complexes, which may originate in the invaginated liposome shape. (C) DDAB:Chol (50:50, mol%)-DNA (2/1, +/- charge) complex prepared by mixing with sonicated liposomes. An intercalated lamellar phase, in which lipid bilayers in fluid state sandwich two-dimensionally condensed DNA, can be observed. (Courtesy of P. Fredrik.) (D) Freeze-fracture electron micrographs of stabilized plasmid-lipid particles (SPLP) prepared by the dialysis method (see Section VII.C.4) with lipids (DODAC/DOPE/PEG200-Cer-C20, 20:70:10 mol%) and CMVLuc plasmid. The photo shows the DNA containing the SPLP population isolated by the sucrose density gradient. The purified SPLPs have an average size of around 70 nm, while the empty vesicles are less than 30 nm (not shown).

composition, trapping efficiency, and stability. The extensiveness of physical characterization obviously depends on the purpose of the liposome application. For cationic liposomes prepared for DNA complex formation, for instance, a simple general characterization to ensure liposome homogeneity should be adequate, since liposomes will disintegrate after complexation with DNA. Also, liposomes for topical and oral applications may not have to

undergo the stringent sterility requirement of parenteral samples.

#### A. Visual Examination

As in any formulation's specification data sheets, visual observation is important in liposomal preparations. While most of the stability parameters cannot be controlled, obser-

**Table 29.2** Liposome Characterization and Quality Control Parameters

<i>General characterization</i>	<i>Technique</i>
pH, conductivity, and osmolarity	pH meter, conductivity meter, osmometer, respectively
Phospholipid concentration	Lipid phosphorous content (Bartlett method)
Phospholipid composition	TLC (combined with the Bartlett method), HPLC
Cholesterol concentration	Cholesterol oxidase assay, HPLC
Trapped volume	Measurement of liposomal internal aqueous phase by membrane-impermeable markers
Trapped solute concentration	Spectrophotometry, spectrofluorometry HPLC, GC,
Residual organic solvents and heavy metals	NMR, GC
Trapped solute/lipid ratio	Determination of solute and lipid concentrations
Liposomal internal pH	Fluorescent indicators, ESR indicators, <sup>31</sup> P-NMR, <sup>19</sup> F-NMR
<i>Physical characterization and stability assays</i>	
Vesicle size distribution—submicron range	Dynamic light scattering (DLS), static light scattering (SLC), gel exclusion chromatography, specific turbidity, electron microscopy
—micron range	Coulter counter, light microscopy, light diffusion, specific turbidity
Electrical surface potential and surface pH	Membrane-bound electrical field probes and pH-sensitive probes
Zeta ( $\zeta$ ) potential	Electrophoretic mobility
Lipid phase transition temperature, lipids miscibility/phase separation	DSC, x-ray diffraction, membrane fluorescent probes, Raman spectroscopy, NMR, ESR, FTIR
Trapping efficiency and percentage of free solute	Gel exclusion chromatography, ion exchange chromatography, dialysis, diafiltration, precipitation by polyelectrolyte
Membrane/aqueous phase partition coefficient ( $K_p$ )	Dilution effect (up to 10,000-fold) on liposomal solute/lipid ratio at equilibrium
Drug retention stability ( $K_{eff}$ )	Monitoring change in solute/lipid ratio as a function of time
<i>Chemical stability assay</i>	
Phospholipid acyl chain autoxidation	Conjugated dienes, lipid peroxides, TBARS, and fatty acid composition (GC), UV/VIS
Phospholipid hydrolysis	TLC, HPLC, total PL and/or free acid concentration
Cholesterol autoxidation	TLC, HPLC
Antioxidant degradation	TLC, HPLC
Solute degradation	TLC, HPLC, spectrophotometry
<i>Biological assay</i>	
Sterility	Aerobic and anaerobic bottle cultures
Pyrogenicity and endotoxin	Rabbit and/or limulus amebocyte lysate (LAL) test
Medium-induced solute leakage	Incubation with buffer, serum and plasma and assay for solute leakage by chromatography
Toxicity	In vitro and/or in vivo tests
Pharmacokinetics and biodistribution	In vivo animal tests

vations such as color change, presence of aggregates or sediment, or phase separation can definitively show that something went wrong with the formulation. Optical observations (phase contrast and polarization) are very useful for the size determination of large liposomes or the contamination of liposome dispersions with large particles or aggregates.

## B. Size Determination of Liposomes

The sizes of liposomes can be measured directly by electron microscopy (EM) techniques or by dynamic light scattering.

In negative staining EM, liposomes are deposited on a film of formvar, which is then stained by a hydrophilic electron dense solution (38). When the film is examined in an electron beam, the relatively electron-transparent liposomes will appear as bright areas against a dark background, hence the term negative stain. In addition to size distribution, it can also reveal information regarding whether the liposomes produced are multi- or unilamellar. However, caution must be exercised due to possible artifacts of sample drying and coalescence.

Freeze-fracture (FF) EM procedures (Fig. 2), providing that the freezing was fast enough, can provide very useful

data on sample heterogeneity and lamellarity of liposomes, especially on contamination with larger liposomes (23). Cryo-EM (Fig. 9) is sophisticated, but is the most artifact-free method for yielding the size distribution and the lamellarity of vesicles. It also allows the detection of entrapped material that is electron dense. It is based on the direct observation of rapidly frozen biological samples and therefore does not require any staining or preparation of replicas, as in FF-EM. Its limitation is the inability to observe particles larger than  $\sim 0.5 \mu\text{m}$ .

In contrast, light scattering techniques are usually used for determining liposome size due to their simplicity. Particle sizers from manufacturers such as Coulter, Malvern, and NICOMP are based on quasi-elastic light scattering (QELS), where the time-dependent coherence of light scattered by particles is sensitive to their diffusion, which is dependent on the viscosity of the medium and particle size. Therefore QELS only measures the average size distribution of the bulk of the liposomes. For unimodal liposome systems the results are in good agreement with electron microscopic measurement. However, the size distribution profile can be severely skewed by the presence of a small number of extra-large liposomes or aggregates, and, on the other hand, the presence of very small liposomes, which may be significant in number, may be underweighed. A common and reliable approach is that the QELS size result is compared with EM examination first, and once a consistency has been achieved for an established liposome system, QELS can be reliably used as a day-to-day method.

### C. Lamellarity of Liposomes

Electron microscopy as described above is the most convincing way that allows one directly to visualize the membrane lamellarity as well as the organization of the internal lamellae. However, negative staining is subject to artifacts and sometimes misleading indications that arise with the collapse of vesicles on top of each other. FF-EM can provide a unique view of internal lamellae when cross-fracturing occurs (Fig. 2). However, cross-fracturing is usually rare, particularly for small vesicles, and in such case thin-section EM (39) and especially cryo-EM are the methods of choice (Fig. 9). The measurement of trapped volume (see the following section) can be used as a good indicator for liposome lamellarity. If the measured value of trapped volume is substantially lower than the theoretical value for the LUV of the same size, it can be assumed that an appreciable proportion of the vesicles is multilamellar.

Alternatively, the liposome lamellarity can also be estimated by measuring the proportion of phospholipid exposed on the outside surface of the liposomes. For LUVs this will be exactly 50%, and for SUVs this will be higher than 50%. For MLVs the proportion will be much smaller

than 50%. This proportion of outside lipid can be quantified spectroscopically using liposomes containing trace amounts of derivatizing PE with trinitrobenzene sulphonic acid (TNBS) (70).  $^{31}\text{P}$  NMR spectroscopy can be used to provide an indication of the lamellarity of liposomes by measuring the signal of the PC head groups of liposomes before and after the addition of membrane-impermeable manganese ions ( $\text{Mn}^{2+}$ ) to the external medium (40). Phospholipids facing the external medium interact with  $\text{Mn}^{2+}$  such that the resonance signal is broadened beyond detection. Thus direct comparison of the size of phosphorous signals before and after the manganese addition readily reveals the percentage of phospholipids on the outer leaflet.

### D. Measurement of Trapped Volume, Trapping Efficiency, and Solute Release

In practice the trapped volume can be much lower than that expected for unilamellar vesicles with identical size distribution, due to the presence of multilamellar vesicles. The trapped volume of the liposome population can be determined by measuring the amount of the solute entrapped inside liposomes. The use of radioactive markers, though separation of free markers is necessary, offers advantages of being nondestructive and accurate. Optical, fluorescent, or HPLC measurements are also often used for trapped volume measurement (see following section).

It is clearly essential to determine the solute trapping efficiency before going on to investigate the physical and biological properties of the trapped material in a liposomal form, since the effects observed experimentally will usually be dose related. The trapping efficiency is measured as the percentage of trapped solute with respect of the total amount of solute added. This analysis therefore requires the separation of the liposome-encapsulated solute from the external medium, which can be carried out by several methods, including column chromatography, dialysis, and diafiltration. The gel filtration column, particularly the Sephadex G-50 spin column method (31), is rapid, requires small sample quantities, and can be performed on many different samples simultaneously. The ion exchange column can also be used for charged solutes. Dialysis offers the advantages of being able to retain 100% of the liposomes and being easy to scale up. However, this method is only applicable for solutes that have a leakage profile significantly longer than the time course of dialysis. Diafiltration is mostly used in pharmaceutical industries for removing untrapped drug from large-scale liposome formulations. Therefore the drug trapping efficiency and the drug-lipid ratio of the final products can be evaluated. It should be noted that the measurement of trapping efficiency by the separation method is based on the assumption that after separation the remaining solute is 100% en-

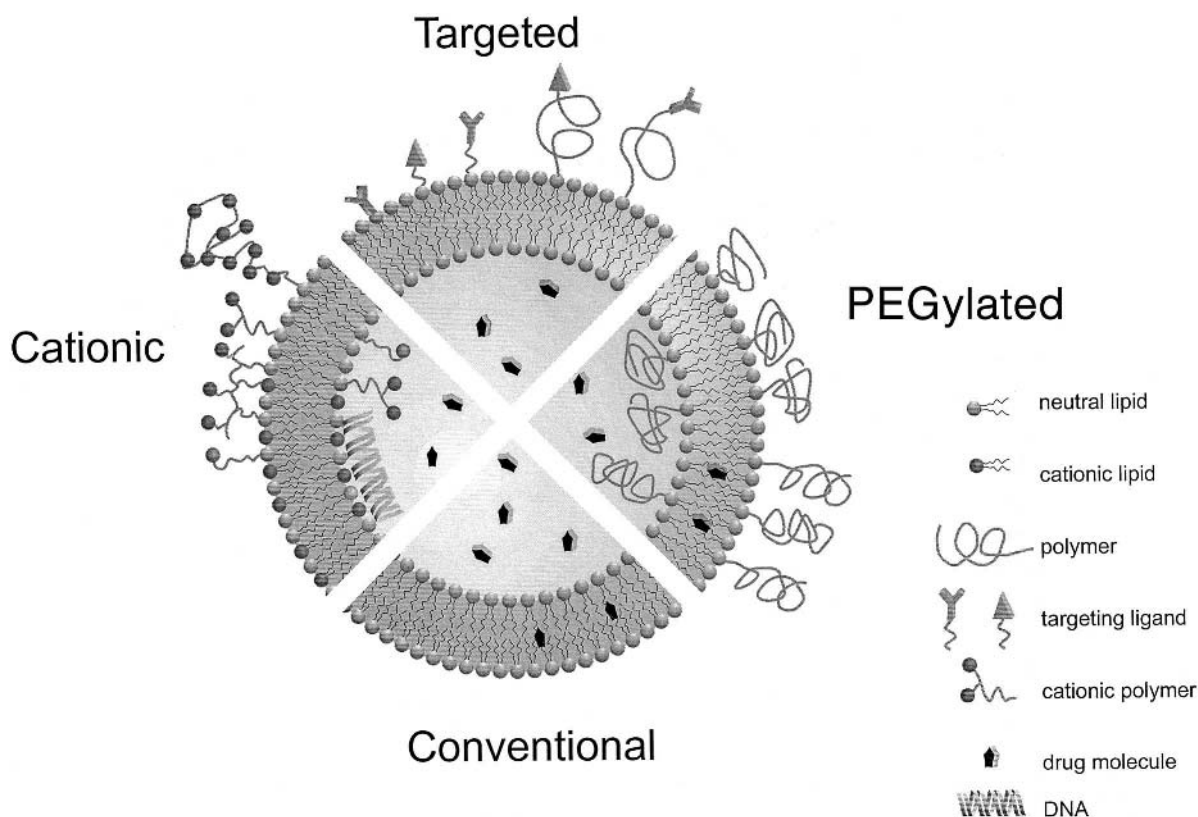

trapped inside liposomes, which may not be true for many drugs.

There are fundamentally two different types of release studies emphasizing different aspects of liposomal systems, one being to characterize the ability of liposomes prepared with a particular lipid composition or a method to retain water-soluble markers and the other being to monitor the leakage rate of a primary drug that has been entrapped inside liposomes. The former is often used when release is induced deliberately as a result of a biochemical or biophysical change. In such case it is desirable to use special markers designed for the purpose, which normally do not leak out from intact membranes and do not associate with membranes, to simplify measurements and interpretation of these experiments. Various types of water-soluble markers have been used by researchers. Fluorescence markers such as calcein, carboxyfluorescein, and fluorescein dextrans, and radiolabeled markers such as glucose,

sucrose, DTPA, and inulin, have been commonly used (76). On the other hand, when the objective of a particular liposome formulation is for delivery or targeting of the drug of interest, the marker for drug release and long-term stability is naturally the entrapped solute itself. Many cationic lipophilic drugs, such as doxorubicin and camptothecins, are strong chromophors and fluorophors, and therefore spectroscopic methods can be used for the detection of drug concentration.

## V. TYPES OF LIPOSOMES ACCORDING TO FUNCTIONALITY

Several different classes of liposomes have been developed (Fig. 10). This development was based mostly on liposome reactivity with the environment. In order to explain that, we shall briefly introduce forces between liposomes

**Figure 29.10** Four different classes of liposomes as defined according to their functionality. Conventional liposomes interact with the biological milieu nonspecifically. Sterically stabilized liposomes can avoid the uptake by the RES system due to surface coating with inert hydrophilic polymer. Liposomes with attached targeting ligands react specifically. Polymorphic liposomes, including cationic liposomes, pH-sensitive, temperature-sensitive liposomes and PEGylated liposomes with cleavable polymers, change their phase upon interaction with a specific agent or medium. Drugs can be entrapped inside liposomes or be incorporated into the hydrocarbon chain region, depending on their hydrophobicity.

themselves and other macromolecules. Attractive forces in these systems can be electrostatic in the case of oppositely charged colloids, van der Waals attraction and ion–ion correlation forces, as well as specific interactions in the case of the surface attached ligands. Weaker attractive forces are hydrogen bonds. Repulsive interactions are electrostatic repulsion between colloids of the same charge, steric and hydration repulsion and undulation forces of fluid bilayers.

In a biological milieu, liposomes interact by lipid exchange with surrounding membranes and lipoproteins or by adsorption of proteins and other macromolecules. In the presence of cells liposomes can adhere to cells or be either endocytosed by cells, or they fuse with cell membranes.

It seems that the main application of liposomes will be in systemic drug delivery. Therefore we shall briefly describe their interaction in the human body. Upon systemic (intravenous or intra-arterial) injection, liposomes are recognized as foreign particles and are quickly opsonized, i.e., tagged by proteins of the immune system for the subsequent uptake in the fixed macrophages in the liver, spleen, and bone marrow by adsorption of various proteins, such as immunoglobulins or proteins of the complement cascade.

For a particular application, liposomes can be optimized and programmed for optimal efficiency. This rational design is based on the knowledge of interactions upon their application. Along those lines, several different types of liposomes have been developed, as discussed below (Fig. 10).

### A. Conventional Liposomes

Although relatively stable in the test tube, conventional liposomes are in general not stable upon application. It was realized early in the 1980s that the successful use of liposomes for drug delivery in most applications depends on two basic aspects of the carrier: quantitative retention of the entrapped drug and sufficiently long blood circulation time (7,46,56). Now it is well known that the *in vivo* pharmacokinetics of liposomes can be dramatically altered by the size of the liposomes as well as the lipid composition. Unilamellar vesicles of 100–200 nm size have much longer circulation time than MLVs (34). Drug retention and liposome circulation can be increased by the incorporation of cholesterol, which increases the packing of lipids in the bilayer. Another reason that cholesterol increases circulation is believed to be that the more rigid cholesterol-rich bilayer is more resistant to phospholipid removal by plasma high-density lipoproteins (HDL). With the same principle, the use of lipids with high phase transition tem-

peratures, such as DSPC or sphingomyelin (SM), also produces liposomes with increased drug retention and circulation. In summary, for conventional liposomes, the blood circulation half-life decreases with increasing size, charge density, and fluidity. Thus the longest circulation achievable with conventional liposomes is with small unilamellar vesicles (< 150 nm) prepared from DSPC (or sphingomyelin) with saturated cholesterol (45 mol%).

While mechanical stabilization of liposomes can decrease interactions with proteins and consequently increase their stability and blood circulation times, it cannot prevent long-range van der Waals forces and subsequent uptake by macrophages.

### B. Sterically Stabilized Liposomes

Because conventional liposomes are characterized by relatively poor stability in the blood circulation, many researchers tried to prepare biologically stable liposomes. After numerous trial-and-error experiments, which concentrated on various liposome compositions, it was finally realized that coating of liposomes with a steric shield of inert polymers can reduce adsorption of various blood proteins and extend their circulation times. Nowadays, PEGylated liposomes, i.e., liposomes coated by (polyethylene) oxide chains, are almost exclusively used. PEGylated lipids with various PEG chains covalently attached to various hydrophobic anchors are commercially available. These liposomes are sometimes referred to as STEALTH® liposomes because of their ability to avoid the defense systems of the body. The general question is normally the amount of PEG-lipid in the formulation and the degree of polymerization, *N*, of the polymer chain. Typically the half-life in blood circulation is used to optimize the two parameters: typically formulations contain 1–5 mol% of PEG-lipids with *N* between 30 and 110 (molecular mass 2000 or 5000). The polymer is anchored on a hydrophobic moiety, such as diacyl phospho- or sphingo-lipid or cholesterol. Because PEG-lipids are more hydrophilic than other lipids in the membrane, they slowly dissociate from the membrane. Longer hydrocarbon chains result in longer residence time in the bilayer and better stability. In some cases prolonged liposome stability is not desired, and shorter chains are used, resulting in temporarily predictable liposome destabilization. Below we shall briefly discuss the theoretical basis of sterical stabilization (55).

In agreement with the hypothesis that repulsive steric pressure is responsible for the stabilization of liposomes, osmotic stress and surface force apparatus measurements have found increased repulsion between bilayers with grafted PEG chains (48). In the simplest picture one would like to understand the stability of sterically stabilized sys-

tems as a function of two controlling parameters: chain grafting density and chain length.

The corona of an attached polymer causes repulsion because the entropy of the chains is reduced upon approach (loss of configurational entropy) as well as excluded volume repulsion (osmotic repulsion). Depending on the size of the polymer ( $R$ ) and the distance between attachment/grafting points ( $D$ ), a polymer can have different conformations. At very low surface coverage ( $D > R$ ), the polymer forms either a pancakelike structure or an inverse dropletlike structure, depending on whether it forms an adsorption or a depletion layer on the surface. At  $D > R$  the so-called mushroom conformation is present, while for  $D \approx R$  and  $D < R$  the polymer chains starts to interact, forcing its extension into the so-called brush conformation (24). In the mushroom conformation, repulsive pressure ( $p$ ) at a distance  $h$  is proportional to  $(h_c/h)^{8/3}$ , where  $h_c$  is the chain extension, while in the brush conformation,

$$p \approx \left[ \left( \frac{h_c}{h} \right)^{9/4} - \left( \frac{h}{h_c} \right)^{3/4} \right]$$

and

$$h_c = N \cdot a \cdot \left( \frac{a}{D} \right)^{2/3}$$

where  $a$  is the size of the monomer.

The hypothesis of increased repulsive pressure above the membrane and reduced adsorption on the blood circulation lifetimes was tested by measuring the repulsive pressure between membranes with and without incorporated polymer-bearing lipid by using the osmotic stress technique, which can measure force (distance) profiles. Results showed that bilayers containing PEG-lipid show much larger interbilayer spacings, and even upon strong osmotic compression the bilayers are still 4 nm apart as compared to surface unmodified bilayers, which show practical collapse to the hard wall (Born) repulsion upon compression (74,75).

Theoretical analysis of polymers at interfaces defines two regimes: mushroom at low coverage and brush at higher. These simple calculations, however, do not take into account the solubility of PEG-lipid in the aqueous phase. In closed systems, however, this assumption is good because the solubility is below  $\mu\text{M}$ .

The interbilayer repulsion is calculated from the repulsive pressure of surface attached polymer in a mushroom configuration, i.e., from

$$P = \left( \frac{5}{2} \right) \frac{kTN}{aD^2} \left( \frac{a}{(h/2)} \right)^{8/3}$$

For  $N = 44$ ,  $a = 0.35$  nm, and  $D = 3.57$  nm, this is in nice agreement with experimental data. For distances  $> h_c$  the repulsive pressure is zero (57).

Similar results were obtained also by the surface force apparatus (47). These results also show increased repulsion with increasing amount of PEG polymer. Surface force measurements have found reversible repulsive force at all separations, and the thickness of the steric barrier was found to be controlled by  $N$  and  $D$ .

At low coverages (dilute mushroom), the Dolan and Edwards mean-field theory of steric forces and their scaling model described experimental data satisfactorily, while at higher coverages the Alexander–de Gennes theory based on scaling concepts described the data better. A more complex mean-field treatment did not bring any better fit. At low coverages, in the mushroom regime, the Dolan–Edwards expression for force between two curved cylindrical surfaces of radius  $R$  is

$$\frac{F_c(h)}{R} = 72 \left( \frac{kT}{D^2} \right) \exp \left( \frac{-h}{R_g} \right)$$

where  $R_g$  is the radius of gyration of the polymer in a theta solvent and corresponds to the thickness of the extending polymer; it can be in good solvents substituted by  $R_F$ . Despite an underestimation of the polymer layer thickness in the low coverage regime, both models are able to fit the force–distance profiles rather well. The scaling analysis fit, which also describes the measured dependence rather satisfactorily, can be expressed as

$$\frac{F_c(h)}{R} = 1.6 \left( \frac{2kT}{D^2} \right) \left[ \left( \frac{R_F}{h} \right)^{5/3} - 1 \right]$$

where the numerical prefactor is close to expected unity.

At higher grafting densities, i.e., in the brush regime, the force can be described by

$$\frac{F_c(h)}{R} = \frac{16kT \pi h_c}{35D^3} \left[ 7 \left( \frac{2h_c}{h} \right)^{5/4} + 5 \left( \frac{h}{2h_c} \right)^{7/4} - 12 \right]$$

where

$$h_c = D \left( \frac{R_F}{D} \right)^{5/3}$$

The force between two cylindrical surfaces ( $F_c$ ) and the repulsive pressure ( $P$ ), as measured by the osmotic stress technique, can be calculated using then Derjaguin approximation,

$$\frac{F_c(h)}{R} = 2\pi \int P(h) dh$$

The agreement with theory was good up to the distance of two polymer layers. At larger separations, the theory, however, predicts a steep decrease that was not observed. Obviously, simply taking into account the polydispersity of the polymer as well as polymer configurations would alleviate this inconsistency. Good agreement with this simple scaling concept was observed also in the regime of the interacting mushrooms (47).

Experimental measurements using the osmotic stress technique, zeta-potential measurements, and surface force apparatus have shown that a polymer extends, in agreement with theoretical calculation, for a typical sterically stabilized liposome composition (5 mol% of mPEG<sub>2000</sub>-lipid), about 5 nm above the bilayer.

Other attempts to prepare sterically stabilized liposomes include the use of single-chain detergents such as Tween 80 (a nonionic detergent with about 20 total ethylene glycol groups in four branches), which is somewhat effective (5). The use of PEG-SA was proven to be ineffective (92). The difference is due to higher dissociation rates of PEG-lipids containing a single acyl chain from the bilayers. However, PEG-lipid dissociation can be exploited for liposome destabilization, which is sometimes needed in drug delivery. Recently, mPEG conjugated to ceramides with acyl chain length of C14:0 and C20:0 (the other chain is C18:1) was shown to be another effective PEG-lipid, with stabilization related to the hydrophobicity of PEG the anchors. Recently, mPEG conjugated to ceramides with various acyl chain lengths was shown to be another effective PEG-lipid, with stabilization related to the hydrophobicity of PEG anchors (90). Longer acyl chains on the PEG-Cer were associated with longer circulation lifetimes of the liposomal carriers and, consequently, higher plasma drug concentration. This study also demonstrated the potential for developing controlled release formulations by manipulating the retention of the PEG-Cer conjugate in liposome bilayers.

Besides PEG, other hydrophilic polymers, particularly biodegradable and natural polymers, have been tested for liposome stabilization. The use of dextrans is only slightly effective, possibly due to the polymer being negatively charged. The conjugation of more hydrophilic carboxylic acid end group derivatives of mPEG-PE reduces liposome stability (14). Successful results have been achieved with polyvinyl alcohol (PVA), polylactic acid (PLA), and polyglycolic acid (PLG) (92). Other reports also indicated polyvinylpyrrolidone and polyacrylamide as effective (51,87). However, none of these new polymers tested could provide the same extent of liposome circulation as that did by PEG-lipids. An exception is polyaxozline, an entirely new class of hydrophilic polymer, which appears to be able to provide comparable circulation extension to

mPEG-PE (93,94). This finding of polyaxozline is significant in a way that further confirms that the increase of circulation by hydrophilic polymers is indeed a steric effect rather than a specific chemical effect of PEG.

### C. Targetable Liposomes

One of the major goals of liposome medical applications was the targeting of specific cells by specific ligands attached to the liposome surface. This is Ehrlich's idea, almost a century old, of the selective destruction of diseased cells. In the 1970s and 1980s researchers attached antibodies to liposome surfaces and achieved very nice liposome binding and uptake into target cells expressing targeted ligands. None of these experiments, however, was successful *in vivo*. Nonspecific interactions with the immune system resulted in very quick liposome clearance in the liver and spleen, regardless of the attached antibody or lectin. The development of PEGylated liposomes, however, renewed interest in specific targeting, because the polymer layer reduced nonspecific interactions. It was quickly discovered that binding ligands to the far end of surface attached PEG chains improves binding (4). In addition to antibodies and their fragments, single-chain antibodies, lectins, oligosaccharides, and polypeptides are used as targeting moieties, typically at a surface density between 20 to 100 ligands per 100 nm of liposome.

Liposomes with attached ligands can also be used in diagnostics to enhance the signal-to-noise ratio (51). Normally one ligand carries one or a few markers, while liposomes can encapsulate thousands of fluorescent or radioactive probes. Liposomes loaded with radioactive, radiopaque, sonoreflective, or paramagnetic substances can be delivered in ways similar to other types of drugs and can improve contrast.

### D. Activosomes or Polymorphic Liposomes

These types of liposomes are designed for specific reactions or interactions. The goal is either to disintegrate the liposomes under particular conditions or enhance nonspecific, such as electrostatic, interactions with a target molecule.

Temperature sensitive liposomes are designed to release their content at a particular temperature. Liposomes become very leaky in the temperature region where the gel-to-fluid phase transition occurs. By mixing appropriate lipids, such as DPPC and DPHC (diacyl partial hydrogenated PC), one can vary the phase transition. One of the applications would be in the therapy of a particular organ which is heated to 41°C; circulating liposomes release their contents when they pass through the heated region. In addition to drug leakage, these liposomes can also be prepared to

disintegrate into a nonbilayer structure and release their contents immediately. Similarly, laser sensitive liposomes (hydrolysis of light sensitive lipids) can be designed. Because the leakage is not instantaneous, however, it might happen that the encapsulated cargo is released too late.

pH sensitive liposomes are designed so that they release the encapsulated cargo upon an increase or decrease of pH. Some organs and organelles might be at lower pH and typically release of the liposome cargo in these conditions is desired. For such application lipids that are weak acids are used in mixtures with membrane destabilizing lipid, such as DOPE. For instance, oleic acid/DOPE mixtures form liposomes at  $\text{pH} > \text{pK}_a$  of fatty acid because ionized fatty acid forms a conelike molecule ( $P < 1$ , see Section I.A) and neutralized the inverse cone shape of DOPE ( $P > 1$ ) giving rise to  $P \geq 1$ . Upon protonation at lower pH, however, the area of the polar head of fatty acids is reduced ( $P$  increases) and it cannot compensate for the propensity of DOPE to form inverted phase and liposome disintegrates, because  $\langle P \rangle$  increases and causes a lamellar–inverse hexagonal phase transition.

The opposite case, in which a weak basic lipid protonates at higher pH and disrupts the liposomes, is not generally used. Another strategy is possible by using PEG-lipids which have  $P \ll 1$ . Mixing them into bilayer and controlling either their dissociation from the bilayer or chemical degradation of the PEG attachment can again change  $P$  from  $< 1$  to  $> 1$  and cause liposome break up.

Another group of active liposomes are fusogenic liposomes, which are designed to fuse with cells. They can either carry fusogenic proteins or peptides, or can be the instability built into the bilayer by special lipid compositions, as discussed above. For instance, stable bilayers containing PEG-lipid and DOPE become fusogenic upon the loss of PEG or PEG-lipid from the bilayer.

### E. Cationic Liposomes

Cationic liposomes are primarily used for preparing liposome/DNA complexes for gene delivery into cells (52). These liposomes are prepared in similar procedures (such as sonication and extrusion) as conventional or sterically stabilized liposomes. Normally they contain 50 mol% of neutral lipid, such as DOPE or cholesterol. The former proved to increase DNA delivery in vivo, while the latter was shown to be more efficient in in vivo DNA expression (52). In later sections we will discuss in detail the applications of cationic liposomes in gene delivery.

There are many other functionalized liposomes. We briefly mention virosomes, which are reconstituted vesicles containing viral lipids and proteins and are used in vaccination (17,69).

## VI. LIPOSOMES AS DRUG DELIVERY VEHICLES

With respect to structure and composition, liposomes resemble cell membranes. They are typically made from natural, biodegradable, nontoxic and nonimmunogenic lipid molecules, and they can encapsulate or bind a variety of drug molecules into or onto their membranes. All these properties make them attractive candidates for applications as drug delivery vehicles.

Liposome applications in drug delivery depend, and are based on, physicochemical and colloidal characteristics such as composition, size, loading efficiency, and the stability of the carrier, as well as their biological interactions with the cells. There are four major interactions between liposomes and cells. Lipid exchange is a long-range interaction that involves the exchange of liposomal lipids for the lipids of various cell membranes; it depends on the mechanical stability of the bilayer and can be reduced by “alloying” the membrane with cholesterol (mixing it in the lipid bilayer, which gives rise to greatly improved mechanical properties, such as increased stretching elastic modulus, resulting in stronger membranes and reduced permeability). The second major interaction is adsorption onto cells, which occurs when the attractive forces (electrostatic, electrodynamic, van der Waals, hydrophobic insertion, hydrogen bonding, specific “lock-and-key”, etc.) exceed the repulsive forces (electrostatic, steric, hydration, undulation, protrusion, etc.) and can be nonspecific or specific. Adsorption onto phagocytic cells is normally followed by endocytosis or, rarely, by fusion. Endocytosis delivers the liposome and its contents into the cytoplasm indirectly via a lysosomal vacuole in which low pH and enzymes may inactivate the solute. During fusion, however, the liposome contents are delivered directly into the cell, and the liposomal lipids merge into the plasma membrane. Therefore a substantial effort to utilize this mode of drug entry is being undertaken. Efforts range from the incorporation of fusogenic proteins into the bilayer to the preparation of metastable bilayers and pH sensitive polymer coatings (1).

For drug delivery, liposomes can be formulated in a suspension, as an aerosol, or in a (semi)solid form such as a gel, cream, or dry powder; in vivo, they can be administered topically or parenterally. After systemic (usually intravenous) administration, which seems to be the most promising route for this carrier system, liposomes are typically recognized as foreign particles and consequently endocytosed by cells of the mononuclear phagocytic system (MPS), mostly fixed Kupffer cells in the liver and spleen. This fate is very useful for delivering drugs to these cells but, in general, excludes other applications, including site-

specific drug delivery by using ligands expressed on the liposome surface in order to bind to the receptors (over)expressed on the diseased cells. For this reason, a search for liposomes that could evade rapid uptake by the MPS started, and a few lipid compositions that prolonged liposome blood circulation times were discovered, culminating in the development of PEG-coated, sterically stabilized liposomes.

Based on the liposome properties introduced above, several modes of drug delivery can be envisaged; the major ones are enhanced drug solubilization (e.g., amphotericin B, minoxidil), protection of sensitive drug molecules (e.g., cytosine arabinose, DNA, RNA, antisense oligonucleotides, ribozymes), enhanced intracellular uptake (all agents, including antineoplastic agents, antibiotics, antivirals), and altered pharmacokinetics and biodistribution of the encapsulated drug. The latter accounts for the decreased toxicity of liposomal formulations, because liposome-associated drug molecules cannot normally spill to organs such as the heart, brain, and kidneys as well as to increased targeting of the encapsulated drug to certain cells and tissues. As discussed above, normal, or conventional, liposomes are taken up by macrophages and can therefore serve as excellent drug delivery vehicles to these cells. However, sterically stabilized liposomes, which are not avidly taken up by MPS cells, have different biodistribution properties and have shown enhanced accumulation in sites of trauma, such as tumors, infections, and inflammations, which are characterized by leaky capillaries. This accumulation is due simply to their prolonged liposome circulation and small size (<100 nm), which enable them to extravasate (51). Very small neutral and mechanically stabilized liposomes (by preparing a bilayer with high mechanic strength as can be measured via stretching elasticity of the membrane) also exhibit prolonged circulation times and may also accumulate in sites of trauma. In a first approximation, we can simply view this as a statistical problem: the longer a liposome can circulate (by avoiding uptake in the liver), the greater the possibility that it extravasates (leaves the vascular system) at the sites where the blood vessels are porous (51).

## VII. MEDICAL APPLICATIONS OF LIPOSOMES

In many cases, effective chemotherapy is severely limited by the toxic side effects of the drugs. Liposome encapsulation can alter the spatial and temporal distribution of the encapsulated drug molecules in the body, which may significantly reduce unwanted toxic side effects and increase the efficacy of the treatment. Although many drugs have

been studied in preclinical settings in numerous animal disease models, at present, in human therapy, liposomal therapeutics are used only in systemic fungal infections and cancer therapy. However, in preventative medicine, liposome-based vaccines show great promise. Table 3 lists liposomal products on the market and in advanced phases of clinical development. Before discussing their application in anticancer therapy, we shall present their use in parasitic infections.

### A. Liposomes in Infectious Diseases

In infectious disease, liposomes were proven to be efficacious in the treatment of parasitic and fungal infections (2). Bacterial infectious antibiotics are in general effective and safe, while for viral disease there are not many potent drugs available. The main modes of liposome action are reduced toxicity and targeting of the drug to macrophages. Recently, small stable and long-circulating liposomes have been shown to be effective in targeting parasitic infections in the lung and in systemic treatment with the antibiotic amikacin. Tropical parasitic diseases like leishmaniasis and malaria are ideally suited for treatment with liposomal drugs. Indeed, early results have shown up to 700-fold improved therapeutic index in the case of leishmaniasis. Unfortunately, these formulations have never been fully developed, possibly due to a low marketing potential.

Targeting the drug to macrophages, where the infectious agents often reside, and the reduced toxicity of the formulation that results from the limited spillage of drug to other tissues, increases the therapeutic efficiency of the treatment. The drug of choice in the treatment of systemic fungal infections is amphotericin B, which is, owing to its aqueous insolubility, typically formulated into detergent micelles. However, micelles are unstable upon systemic administration, and severe neuro- and nephrotoxicity limit the dose that can be administered. If the drug is formulated in a stable colloidal particle, it is delivered much more efficiently to macrophages, and toxicity can be significantly reduced. Following this rationale, three lipid-based amphotericin B formulations are commercially available (Table 3): AmBisome® (Gilead, Foster City, CA) contains the drug formulated into small, negatively charged liposomes; Amphotec® (InterMune Inc., Burlingame, CA) is a stable mixed micelle of drug complexed with cholesterol sulfate; and Abelcet® (Elan Co., Dublin, Ireland) is a homogenized liquid crystalline suspension of drug and lipids.

Although these products are getting increased shares of the market, a number of improvements can be envisaged, including more potent antifungals (in a free form that is

**Table 29.3** Liposomal Products on the Market or in Advanced Clinical Studies

Company	Product	Status
ALZA Corp.	DOXIL <sup>®</sup> —dox in STEALTH <sup>®</sup> liposomes for Kaposi's sarcoma for ovarian cancer AMPHOCIL <sup>®</sup> —ampB in mixed micelles	On the market (1995, USA and 1996, Europe) On the market (1999, USA) On the market (1996, USA and 1993, Europe) (sold to InterMune 2/01)
Gilead Sciences	Ambisome <sup>®</sup> —ampB in liposomes DaunoXome <sup>®</sup> —dauno in lip's. MiKasome <sup>®</sup> —liposomal amikacin NX 211—liposomal lurtotecan	On the market (1997, USA and 1990, Europe) On the market (1996, USA and Europe) Phase II Phase I (Canada)
Elan Co.	Myocet <sup>®</sup> —liposomal dox VENTUS <sup>®</sup> —liposomal PGE1 ABELCET <sup>®</sup> —ampB in lipid dispersion EVACET <sup>®</sup> —liposomal doxorubicin for breast cancer	Phase III not successful Phase III not successful On the market (1995, USA and 1993, Europe) Phase III
Asta Medic. Aronex Pharm. Inc.	Topical anticancer cream Nyotran <sup>®</sup> —liposomal nystatin Liposomal annamycin for refractory breast cancer for leukemia ATRAGEN <sup>®</sup> —liposomal retinoic acid (tretinoin) for Acute promyelocytic leukemia (APL), non-Hodgkin's lymphoma and prostate cancer; and renal cell carcinoma and bladder cancer	On German market Phase III (USA and Europe) Phase II Phase I/II Phase II Phase I/II
Inex Pharm. Corp.	Aroplatin <sup>®</sup> —liposomal platinum for lung cancer ONCO TCS—liposomal vincristine for non-Hodgkin's lymphoma	Phase II Phase II/III
Swiss Serum Inst.	INX-3280—liposomal oligonucleotide Epaxal <sup>®</sup> —hepatitis A vaccine Trivalent influenza vaccine Hepatitis A and B vaccine Diphtheria, tetanus, hep A vaccine Diph., tet., infl., hep. A vaccine	Phase II/III On Swiss market since 1994 Phase III Phase I Phase I Phase I
Skyepharma PLC	DepoMorphine <sup>®</sup> , morphine sulfate for acute post-surgical pain DepoCyt <sup>®</sup> for neoplastic meningitis DepoAmikacin <sup>®</sup> for bacterial infections	Phase II Phase II Phase III Phase I (completed)
Biomira Inc.	Liposomal BLP25, a MUC1 based vaccine, for breast cancer	Phase I
Neopharm Inc. Vical Inc.	Liposomal paclitaxel Leuvectin <sup>®</sup> —DNA/lipid complex of IL-2 for kidney and prostate cancer Leuvectin-7 <sup>®</sup> —DNA/lipid complex of HLA-B7 gene	Phase II Phase II Phase II/III
Valentis Inc.	Cationic lipid formulation of IL-2, IL-12, and IFN- $\alpha$ Cationic lipid formulation of VEGF <sub>165</sub> for angiogenesis	Phase IIa (USA and Germany) Phase II

Abbreviations: dox-doxorubicin HCl, dauno—daunorubicin, ampB—amphotericin B.

too toxic for systemic treatment) and sterically stabilized liposomal antifungals and antibiotics for the targeting of targets away from the MPS system. Additionally, such liposomes can act as long-circulating platforms to bind and neutralize pathogens or reduce inflammation by blocking appropriate receptors overexpressed at the site of trauma. Liposome expression of oligosaccharides or antibodies increases their circulation times and, additionally, the multivalency of binding. For instance, sialyl Lewis x liposomes (liposomes with attached oligosaccharides to target inflammation receptors) were shown to be 750 times more effective in inhibition of selection-E mediated cellular adhesion than the free ligand, while antibodies expressed on stealth liposomes targeted to the same receptors on cultured endothelial cells have shown 275-fold higher selectivity and can be used to deliver drugs to these cells effectively with increased specificity (6).

In general, saturation of various receptors may be an important new modality in liposome applications, and such systems may become useful in treating inflammation, autoimmune diseases, and cardiovascular diseases. Owing to their systemic accessibility, these applications of targeted liposomes may be more important than in cancer therapy, for here most of the tumors are rarely directly accessible.

## B. Liposomes in Anticancer Therapy

Most of the medical applications of liposomes that have reached the preclinical stage are in cancer treatment. Very early studies showed reduced toxicity of liposome-encapsulated drug, but in most of the cases the drug molecules were not bioavailable, resulting in reduced toxicity but also in severely compromised efficacy. Unfortunately, this was also found to be true for primary and secondary liver tumors. Although most of the drug ended in the liver, it did not diffuse into malignant cells (2,32).

Several clinical studies did not support the use of conventional liposomes in cancer treatment. Although it is still not clear whether such liposomes can be beneficial in the therapy of some cancers, it has been demonstrated that small, stable liposomes can passively target several different tumors because they can (owing to their biological stability) circulate for prolonged times and (owing to their small size [ $<50$ – $150$  nm]) extravasate in tissues with enhanced vascular permeability, which is often present in tumors.

Two liposomal formulations have been approved by the Food and Drug Administration (FDA, Washington DC, USA) and are commercially available in the USA, Europe, and Japan (Table 3). DOXIL<sup>®</sup> (ALZA) is a formulation of doxorubicin precipitated in sterically stabilized liposomes

(see Fig. 9A), while DaunoXome<sup>®</sup> (Gilead) is daunorubicin encapsulated in small liposomes with very strong and cohesive bilayers, which can be referred to as mechanical stabilization (2).

DaunoXome is a small liposome (distearoyl phosphatidylcholine/cholesterol—DSPC/Chol, 2/1,  $\approx 27$  mM, size SUV) with daunorubicin (1 mg/mL) loaded by a pH gradient. These liposomes are relatively stable in the circulation because they are small, and their membrane is electrically neutral and mechanically very strong. This reduces the charge-induced and hydrophobic binding of plasma components but does not protect against van der Waals adsorption. Also, uncharged liposome formulations are colloiddally less stable than charged ones.

DOXIL is a liquid suspension of 80–100 nm liposomes (mPEG<sub>2000</sub>-DSPE/HSPC/Chol, 20 mM) with doxorubicin HCl at 2 mg/mL. The drug is encapsulated into preformed liposomes by an ammonium sulfate gradient technique and is, additionally, precipitated with encapsulated sulfate anions (see Fig. 9A). These liposomes circulate in patients for several days, which increases their chance to extravasate at those sites with a leaky vascular system. Their stability is due to their surface PEG coating, as well as to their mechanically very stable bilayers. DOXIL was the first liposomal drug approved by the FDA and has been on the market since 1995, while DaunoXome was approved approximately half a year later. Both formulations are used in the treatment of Kaposi's sarcoma. In 1999, Doxil was approved for the treatment of ovarian cancer refractory to paclitaxel- and platinum-based chemotherapy regimens.

DaunoXome was shown to be equally effective to conventional therapies with reduced drug toxicity and improved patient quality-of-life. The use of DOXIL in Kaposi's sarcoma has shown a high response rate in comparison with standard treatments: 58.7% response rate as compared to 23.3% for bleomycin–vincristine therapy and 46.2% vs. 23.3% for adriamycin–bleomycin–vincristine. Owing to a different biodistribution of DOXIL, the toxicity profile is quite different from that of the free drug or of conventional liposomes. While the dose-limiting toxicity is hand–foot syndrome and stomatitis (liposomes that are not taken by the MPS or do not extravasate eventually end up in the skin, especially in areas where the vascular system is constantly under pressure and slightly damaged), but nausea, vomiting, and alopecia, which are usual after conventional therapy, are notably mild after liposomal (DOXIL) treatment. DOXIL has also been shown to have a 4.5-fold lower medium pathology score for doxorubicin-induced cardiotoxicity than free drug, while neutropenia is similar to the free drug. Despite these convincing results, however, it seems that, in the long run, the potential of this formulation is greater for the treatment of solid tumors.

For instance, in salvage therapy of ovarian carcinoma in patients refractory to platinum and paclitaxel, a 13.8% overall response was recorded with DOXIL®.

The difference between the various formulations can be explained by the pharmacokinetic data and biodistribution reports, which have shown significant drug accumulation in tumors in the case of small and stable liposomes; free drug distributes to a large volume (causing systemic toxicity) and is quickly washed away, and because no specific tumor targeting occurs, the activity is relatively low. Conventional liposomes are distributed to a smaller volume (which depends on the drug leakage from liposomes, which is a function of lipid composition and the method of drug encapsulation, and in this case decreases in the following formulations: PC/PG > PC/Chol > PC/CL; CL is cardiolipin). Correspondingly, with improved liposome encapsulation, the volume of distribution decreases and the clearance rates are smaller. Because such liposomes typically do not target tumors (short blood circulation times and larger size) and end up in the MPS, the drug activity in most tumor models is compromised and generally, the reduction in drug toxicity does not justify the use of such formulations. When the drug is encapsulated in small and stable vesicles, the volume of distribution is very small (mostly blood, some in the liver and in tissues with leaky vasculature), reducing toxicity, and if accompanied by liposome accumulation in tumors, resulting in increased activity. Clearance rates are slow because the drug is stably encapsulated. The elimination times of the drug are not a good indicator of their activity, because typically they represent a second phase, in which smaller amounts of the drug are involved. The elimination times are calculated from the clearance rate and the volume of distribution and do not correlate to liposome stability. It is actually the blood circulation time that, in the case of small, stable liposomes, determines the accumulation in tumors. From this simple pharmacokinetic analysis, we can conclude that long clearance times, which are associated with low volumes of distribution and small changes in biodistribution toward tumors, characterize good liposomal anticancer formulations. Of course, for drug to remain active, it must not be encapsulated too stably. When liposomes accumulate and become trapped in the tissue, they start to disintegrate, and the drugs leak into the surroundings, as can be inferred from observed drug degradation products, fluorescent microscopy, as well as anticancer activity. The origin of liposome disintegration is one of the least understood processes, but it is very likely that various phospholipases degrade the lipids, and the softer bilayers start to disintegrate. PEG-lipids are lost slowly owing to their greater hydrophilicity, which allows the close approach of enzymes to liposomes and internalization by the

cells. In parallel, gradients can dissipate, and the drugs can leak from topologically intact liposomes. Also, mechanical damage and lipid phase transitions in regions with reduced liquid concentration can occur. Although the real situation is far more complex, this simplified explanation of pharmacokinetic and biodistribution data may explain the differences between different formulations. Briefly, while the selectivity of free drug means only that it is more damaging to rapidly dividing cells (such as tumor, but also hair, blood, and nonsomatic cells), some drug delivery vehicles can deliver drug closer to the tumor and, in the process, spare some other tissues. Liposomes containing targeting ligands, however, can be internalized into the cell by the endocytic receptors.

Because of the complexity of systemic drug delivery, the potency of the immune system, and the anatomy of tumors, it is difficult to anticipate that formulations will be prepared that will be much more effective from the drug delivery perspective. The next developments may instead rely on combination therapy, which has been found to be effective in the treatment of AIDS. Consequently, liposomal vincristine (phase II) and annamycin (phase II) are being developed by Inex (Burnaby, BC, Canada) and Aronex (The Woodlands, TX, USA), respectively. A second liposomal agent in the combination therapy may be one of various cytokines, such as interferons, interleukins, or tumor necrosis factor (TNF), which are very active, but also very toxic, anticancer agents. Preliminary data on combination therapy of TNF in sterically stabilized liposomes and DOXIL® have shown arrested tumor growth, whereas either agent alone only decreased the growth rate.

Since the early days of liposome applications, scientists have been trying to develop liposomes that would target specific cells via surface attached ligands. Promising *in vitro* experiments however were not reproduced *in vivo* because of nonspecific liposome clearance by the MPS. PEGylated liposomes have revived the concept. The immunogenicity of current formulations can be reduced by using fragments of humanized antibodies, so the remaining problems are the accessibility of tumors and cellular uptake of the liposomes. Solid tumors are rather inaccessible and the therapeutic benefit can be expected mostly within the vascular endothelium or in other body fluids, especially in the case of targeting internalizing epitopes. If the therapy proves to be effective, we must also be aware that large-scale manufacturing of targeted liposomes is technically considerably more demanding, and the economics of this will be more critical than on nontargeted liposomal formulations.

Because of their accumulation in tumors and sites of infection and inflammation, sterically stabilized liposomes

can be used to deliver other agents to these sites: antisense oligonucleotides and ribozymes are very potent agents, but the major problem is their delivery to and into the appropriate cells. It is very likely that encapsulation of these agents in PEGylated liposomes may not only dramatically improve the therapeutic index but also be the optimal way to deliver these molecules.

### C. Liposomes in Gene Therapy

Recombinant DNA technology and studies of gene function and gene therapy all depend on the delivery of nucleic acids into cells *in vitro* and *in vivo*. Although *in vitro* techniques can rely on a number of physical and chemical methods, *in vivo* delivery is more demanding. DNA carrier systems include several colloidal particles; cationic liposomes have been shown to complex (negatively charged) DNA, and such complexes were able to transfect cells *in vitro*, resulting in the expression of the protein, encoded in the DNA plasmid, in the target cells. Obviously, for gene therapy (treatment of diseases on the molecular level by switching genes on or off), *in vivo* delivery is preferred. It was discovered that cationic lipid-based DNA complexes can transfect certain cells *in vivo* upon localized (mostly lung epithelial cells upon intratracheal instillation) and systemic (endothelial cells in the lung) administration (52). However, the first series of *in vivo* studies yielded rather low levels of gene expression. Improvements were sought both on the molecular level, where many novel lipids were synthesized and many different combinations of lipids tried, and on the colloidal level, where the DNA–lipid-complex structure–activity relationships were studied. Despite the fact that quantitative structure–activity relationship (QSAR) is still not understood, developments in DNA plasmid design, synthesis of novel cationic lipids, cholesterol stabilization of complexes, and improvements on the colloidal structures have resulted in more than a 1000-fold increased gene expression as compared to the first experiments. Although these developments are impressive, the absolute expression levels are still rather low and the duration of expression short; before initiating realistic clinical trials, more research on the delivery vehicles and the DNA vector will be required. For example, the latter may include DNA sequences that would give rise to nuclear localization. Lipid-based gene delivery is the focus of several specialized high-tech companies, among which Vical (San Diego, CA, USA), Genzyme (Framingham, MA, USA) and Valantis (Burlingame, CA, USA) have products in clinical trials.

Several types of lipid vectors for DNA delivery have been developed and, according to the way they are prepared and the structures of the final products, they fall into

three major categories: (1) DNA complexed with preformed cationic liposomes, (2) DNA packed in a lipid-based carrier in particle form, and (3) DNA encapsulated in liposomes.

As the first-generation lipid-based DNA vector, DNA-cationic liposome complexes, have been playing a leading role in the area of gene vector development. A great deal has been learned about many respects of gene delivery, including the construction of the delivery vectors, vector–cell interactions, gene construction and expression, pharmacokinetics, and the *in vivo* aspects of gene delivery. The search for better-defined and commercially viable gene vectors has led to the development of several novel and interesting lipid-based vectors that have shown advancement in one or more aspects over the existing ones. However, being at their early development stage, these systems are yet to be more extensively investigated.

#### 1. The Formation of Genosomes (Lipoplex)

The use of liposome–DNA complexes (genosomes or lipoplexes) for transfer of plasmids into cells was first described by Felgner et al. in 1987 (30,52), who observed gene expression *in vitro*. Genosomes are formed by mixing plasmid DNA with preformed liposomes containing around 50% of cationic lipid, the rest being the so-called helper lipids, which normally are neutral lipids such as DOPE and cholesterol. Genome formation is a very complex process, which depends on thermodynamic as well as kinetic factors. Thermodynamic factors include charge ratio, concentration, ionic strength, pH, the presence of impurities, and temperature. Other important parameters are the type of cationic and to a lesser extent the neutral helper lipid, the degree of supercoiling, and the size of the DNA.

The procedure for genome formation involves simple mixing of DNA and liposome solutions. Over the years, researchers have adopted various protocols. At low lipid concentrations, genosomes are often made by pouring lipid and DNA solutions together and then incubating for 5 to 15 min and applying onto the cell culture. Some papers also reported separate addition of plasmid DNA and liposomes to the cell culture. For *in vivo* applications, however, larger concentrations of colloiddally suspended DNA are preferred, and different protocols are used. Complexes are normally prepared by rapid pipette injection of one solution into the other and quick aspiration–ejection cycles. In many cases the speed and the sequence of addition (DNA into liposomes or vice versa) critically influences the characteristics of the complexes formed. Normally a small-scale sample is used (50–200  $\mu\text{L}$ ), as scaling up to milliliter volumes often results in precipitation. There is

also large variation between different operators. All these observations indicate that the interaction of DNA with liposomes is clearly a kinetic phenomenon. To increase consistency, automation is strongly recommended.

It is obvious that the charge ratio is the most important and influential thermodynamic parameter. Typically, precipitation occurs near charge neutralization ( $\rho = 1$ ), and optimal charge ratios for transfection have been reported to be in the 1.2–1.5 range (cationic complexes) in most cases. In preparing anionic complexes, liposomes are injected into DNA and vice versa for the cationic complexes. Moreover, the process of complex formation is normally carried out in nonelectrolyte solutions such as water or 5 to 10% sucrose, because the presence of even a low concentration of electrolytes dramatically increases precipitation. The stability of the formed complexes depends on many factors, including lipid concentration, pH, ionic strength, temperature, and in particular charge ratio and can vary from minutes to up to several months (52).

## 2. Lipid–DNA Particles (LDPs)

It has been envisioned that the ideal carrier for gene delivery would be one that contains densely packed DNA, preferably the particle form, with a protective coating material, such as neutral and PEG lipids, on the outer surface. Such a carrier system would possess the basic characteristics of the long-circulating pegylated liposomes and other functional liposome systems. In recent years, several types of lipid–DNA particles have been developed.

The above-described preparation methods give rise to several different genome topologies. Researchers have typically described samples that are heterogeneous with respect to particle size, shape, and density. EM and small-angle x-ray scattering studies have established mostly two types of complexes—random structures of aggregated spherical particles containing elongated fibrils (the so called “spaghetti-meatball” structures) and ordered intercalated lamellar phases, in which two-dimensionally condensed DNA is sandwiched by lipid bilayers (Fig. 9C) (78). Obviously, in the limit of lipid excess, the latter structures are prevalent, and the former ones at higher DNA–lipid ratios. However, we believe that the structure of these particles is kinetically controlled and a real sample may contain a large number of different structures ranging from the two extremes—lipid-coated DNA helices and intercalated lamellar phases.

A novel type of liposome–DNA complex has been reported by Templeton et al. (86). The invaginated liposomes used in the procedure are bilamellar (two concentric bilayers) and are produced by a stepped extrusion process using the Whatman Anotop filter, which has long cylindrical

pores. The liposome–DNA complexes have a very different structure compared with the complexes prepared using the single-bilayered liposomes. In this case DNA molecules are entrapped inside the invaginated liposomes, and there is an intact outer bilayer around the complex (see Fig. 9B.). This type of genome appears to be very stable upon storage and very efficient in transfecting cells.

## 3. Formation of Lipid–DNA Particles via Hydrophobic Intermediates

One of the significant advancements in gene delivery is the lipid–DNA particle (LDP) system (9,99). The procedure for LDP preparation is the direct outcome of the Bligh & Dyer extraction process, where polyanionic plasmid is extracted from the aqueous phase into the solvent phase by cationic lipids (79). The driving force for DNA into organic solvent ( $\text{CHCl}_3$ ) is the electrostatic interaction of the cationic lipid with negatively charged DNA. The resultant stable DNA–lipid complex in organic solvent is thus hydrophobic. Such DNA–lipid complexes can serve as self-assembling intermediates for the formation of a well-defined LDP carrier.

It was first attempted to hydrate directly such lipid–DNA complexes after the removal of the solvent. This was not successful because the complexes stuck to the glass, even in the presence of excessive amounts of neutral and mPEG<sub>2000</sub>-DSPE. Then an alternative route was taken, where plasmids were introduced to the cationic lipid presented in mixed micelles formed with nonionic detergent. This system of mixed micelles is in fact a microscopic version of the aqueous-solvent biphasic system where the DNA–lipid interaction occurs at the extended aqueous-solvent interface (Fig. 11). In the micellar system, the hydrophilic–hydrophobic interfaces are provided by the surface of the micelles. Studies indicated that the instant and spontaneous interaction of DNA with cationic micelles upon the addition of DNA to the cationic micelles lead to the formation of well-defined small particles in the range of 50–70 nm in diameter. Detergent concentration appears to be a crucial parameter that determines the physical properties of the LDP formed. Under the optimum detergent concentration, which is near the critical micelle concentration (CMC = 20 mM for octyl glucoside), the LDP formed are small, uniform, and reproducible. The detergent in the system can be easily dialyzed away without affecting the size of the LDPs. Negative stain and freeze-fracture electron microscopic studies revealed that these particles are rather uniform in size, but not necessarily spherical in shape (99).

In contrast, at high detergent concentration (>50 mM), no indication of LDP was observed before dialysis, and large aggregates were seen 2–3 hours into dialysis. The

**Figure 29.11** Model describing the intermediates that may be involved in the formation of cationic lipid/DNA particles (99). Small lipid/DNA particles (<100 nm) form spontaneously, driven by electrostatic interactions, when the detergent concentration is near the critical micelle concentration of OGP (approx. 20 mM). The formation of LDPs might involve the following steps. Mixed detergent micelles containing the cationic lipid and the helper lipid are mixed with DNA (step A). The binding of the mixed micelles with DNA is instant (step B), and such binding will likely cause asymmetric distribution of lipids on the micelles and a decrease in micelle stability. The next step (step C) is the fusion of micelles along the DNA strand into larger bilayered intermediates that serve as DNA condensation agents and lead to the formation of LDP (steps C to D). Detergent molecules are then removed by dialysis.

detergent concentration effect on the particle formation could be a kinetic effect resulting from the fast detergent removing process, and the result could be different if the rate of detergent removal is slower and controlled.

Another observation is that the LDPs formed by the above procedure are only stable in a nonelectrolyte solution in the absence of a stabilizing agent. Further investigation showed that stable LDPs can be produced using the same procedure in PBS buffer or saline, when a sufficient amount of mPEG<sub>2000</sub>-Cer (5–10%) is incorporated in the system. Regarding the DNA loading capacity of this LDP system, the DNA-to-lipid ratio can be maximized by lowering the amount of cationic lipid to a level that is slightly greater than charge neutralization (1.2:1–1.5:1, +/-). Neutral lipids (SM or PC) can be incorporated with the aim of reducing the charge density on the outer surface.

It appears that efficient formation of lipid–DNA particles by the above procedure requires a significant proportion of the cationic lipid in the system, which clearly poses a major hurdle for such a carrier system to be used for systemic delivery. However, it might be possible to overcome this problem by the use of pH sensitive cationic lipids. In such a case LDPs can be formed at a low pH where the lipid

is charged, and then the surface charge can be reduced by increasing the pH to a level where the lipid becomes neutral.

With regard to the mechanism of the formation of LDPs, a working model has been proposed as illustrated in Fig. 11 (99). The formation of LDP is spontaneous and nearly instantaneous. However, sequential steps might be involved during the process. The initial binding of the small cationic mixed micelles to DNA molecules is driven by electrostatic interactions. Such binding will likely cause asymmetric distribution of lipids, particularly the cationic lipid, on the micelles, being cationic-lipid enriched for the side binding to the DNA. This process will probably lead to the growth of larger bilayered intermediates due to the fusion of micelles along the DNA. These bilayered intermediates, at the same time, serve as DNA condensation agents and lead to the formation of LDP.

In vitro transfection studies in the CHO cell line indicated that LDPs (with  $\beta$ -galactosidase plasmid) prepared with SM/DODAC (1:1 to 8:1, +/-, SM/DODAC, 50:50 mol%) are effective in delivering DNA into cells. The transfection level increases with increasing charge ratio (maximum at 4:1 +/-), as is expected, as for other lipid-based DNA carriers. In vivo transfection of tissues and

solid tumors in animals are currently under investigation (personal communication).

#### 4. Stabilized Plasmid–Lipid Particles

Stabilized plasmid–lipid particles (SPLP) constitute a novel system in which DNA is truly encapsulated inside liposomes (81,91,95). The process for SPLP preparation appears to be similar to the conventional detergent dialysis method, but it differs significantly in the mechanisms of DNA entrapment. Consequently, the plasmid encapsulation efficiency achieved in this method is much higher than that normally achievable with conventional dialysis procedure, in which solute is passively entrapped. The plasmid trapping efficiency appears to be a sensitive function of the cationic lipid content (i.e., DODAC mol%) in the lipid composition, and 50–70% encapsulation can be achieved with only minimal amount of DODAC (6–8 mol%), which is insignificant enough so that the pharmacokinetic profiles of these liposomes are identical to conventional liposomes bearing no DODAC. The presence of a sufficient amount of mPEG-Cer, acting as a stabilizer, appears to be critical, and in its absence aggregation occurs during dialysis. Although mPEG-Cer is advantageous over mPEG-PE, because it is noncharged and will not interfere with the interaction between DNA and cationic lipid, mPEG-DSPE can be used as the stabilizer lipids.

An attempt to increase the content of cationic lipid in the system was made first by increasing the ionic strength of the dialysis medium. However, raising the NaCl concentration to 1 M was not effective in samples containing 10 mol% of DODAC. The use of polyvalent anionic counterions (i.e., citric acid and phosphoric acid), with an expected stronger shielding effect against the cationic lipid, can increase the amount of cationic lipid to as high as 45 mol% without significantly losing the encapsulation efficiency. It has been shown that citrate is more effective in the low range of DODOC content (7–30 mol%) (95) and phosphate is more effective in the high end of DODAC content (20–45 mol%) (81). There is basically a linear relationship between the percentage of cationic lipid in the lipid composition and the optimum citrate concentration. Above the optimum citrate concentration, empty liposomes are produced, and DNA encapsulation efficiency is low. In contrast, when the citrate concentration used is too low, the strong interaction of the cationic lipid with plasmid leads to aggregation.

SPLPs can be purified by removing the empty vesicles using procedures such as sucrose density gradient isolation, and a high DNA-to-lipid ratio ( $>60 \mu\text{g}/\mu\text{mol}$ ) can be obtained. The formulation can be concentrated to at least 1 mg DNA/mL with no compromise in stability. The SPLPs

exhibit shelf stability of at least 6 months upon storage at 4°C. Moreover, plasmids encapsulated inside the SPLPs are protected from degradation enzymes as tested in serum and DNase (91).

The purified SPLPs have a consistent size distribution of 80–100 nm between preparation as observed by QELS and confirmed by both freeze-fracture (see Fig. 9D) (95). In contrast, the empty vesicles are much smaller ( $<20$ –40 nm in diameter). Cryo-EM investigations (81) of the purified SPLPs revealed a dense internal structure that is present neither in extruded liposomes nor in the empty liposomes with the same lipid composition prepared by the same dialysis procedure, suggesting that the plasmids are entirely entrapped inside the liposomes.

With regard to the mechanism whereby SPLPs are formed as facilitated by the presence of polyvalent anionic counterions, a working model has been proposed as illustrated in Fig. 12 (91,95). This model is based on the proposed processes of micelle-to-vesicle transformation occurring during dialysis (see Section II.G.). Prior to detergent removal, plasmids probably do not directly associate with the mixed micelles, due to the extensive dilution of the positive charge density on the surface of the mixed micelles.

The next step of micelle–vesicle transition is believed to be the formation of various lipid-detergent intermediates, including cylindrical micelles, lamellar sheets, or open leaky vesicles. It is proposed that it is at one of these stages that DNA–micelle association starts to occur, as the size and the charge density of these intermediates grow to a significant level. The fact that only a minimal amount of cationic lipid is required in the formation of SPLPs indicates that the association of DNA with the intermediates is not a charge neutralization effect but rather a loose association facilitated by a minimal number of binding sites along the DNA molecule and the intermediates. At optimum cationic lipid concentration (i.e., 6–8% DODAC in the absence of counterions), DNA association possesses little interference with the natural growing process of the intermediates into open vesicles, which eventually close up as the detergent is depleted, resulting in the encapsulation of DNA. In the case of increased cationic lipid content, anionic counterions are needed to shield the surface charge density effectively on the intermediates to a level equivalent to the minimum cationic lipid situation (i.e., 6–8% of DODAC). In either case, low content of cationic lipid or higher concentration of the counterions, the association of DNA with these intermediates is not sufficient for efficient encapsulation. On the other hand, increased cationic lipid content or a too-low concentration of counterions will lead to the association of DNA with multiple lipid–detergent intermediates and/or the collapse of open vesicles, eventually resulting in lipid–DNA aggregation.

**Figure 29.12** Mechanism of SPLP formation. Prior to detergent removal, DNA does not directly associate with the mixed micelles, due to the extensive dilution of the positive charge density on the surface of the mixed micelles. Plasmid DNA–micelle association starts to occur, as the size and the charge density of the bilayered intermediates grow to a significant level. At optimum cationic lipid concentration (i.e., 6–8% DODAC in the absence of counterions), DNA association possesses little interference with the natural growing process of the intermediates into open vesicles and eventually closes up as the detergent is being depleted, resulting in the encapsulation of DNA. In the case of increased cationic lipid content, anionic counterions are needed effectively to shield the surface charge density on the intermediates to a level equivalent to the minimum cationic lipid situation (i.e., 6–8% of DODAC). In either case, low content of cationic lipid or higher concentration of the counterions, the association of DNA with these intermediates will not be sufficient for efficient encapsulation. On the other hand, increased cationic lipid content or too low a concentration of counterions will lead to the association of DNA with multiple lipid–detergent intermediates and/or the collapse of open vesicles, eventually resulting in lipid–DNA aggregation.

#### 4. Other Applications: Vaccination and Diagnostics

As a result of their special properties, liposomes are being studied for treating other diseases and for vaccinations (51). Examples are liposomal antibiotics, antivirals, prostaglandins, steroid and nonsteroid anti-inflammatory drugs and insulin. Administration routes being investigated include pulmonary, topical, and other parenteral administration routes. Although several approaches look promising, more basic research is necessary before meaningful clinical studies can be initiated. Some promising concepts are described below.

Infections and inflammations are characterized by a leaky vascular system. Therefore sterically stabilized liposomes may be an effective vehicle for the delivery of appropriate drugs in such circumstances. Many infectious agents reside in cells, such as deep tissue macrophages, which are practically inaccessible to chemotherapy. A large fraction of PEGylated liposomes ends up in the skin, where many are ultimately taken up by macrophages. It is also believed that these cells harbor many bacterial and viral infections and therefore the potential of long-circulating liposomes should be thoroughly exploited.

A liposomal vaccine against hepatitis A has been successfully launched by the Swiss Serum Institute (Bern). Purified hepatitis A virion capsule, viral phospholipids, and envelope glycoprotein from the influenza virus are mixed with phosphatidylcholine and phosphatidylethanolamine in the presence of excess detergent (octyl glucoside). Upon detergent removal, liposomes containing antigen as well as some viral lipids and proteins, including fusogenic glycoprotein (influenza hemagglutinin) are formed. The liposomes act as an adjuvant and carrier of adjuvants (viral glycolipids and glycoproteins) and potentiate an immune response to the vaccine antigen. The same company is developing vaccines for influenza, hepatitis B, diphtheria, and tetanus. Other companies, such as Orasomal Technology (Chicago, IL, USA) are working on the development of other vaccines, including oral vaccination and drug delivery by polymerized liposomes.

A significant barrier to the development of liposomes formed from commonly available lipids for oral or mucosal delivery of macromolecules has been their susceptibility to enzymatic degradation, due to low pH in the stomach, and bile-salt dissolution in the intestine. Hence, common liposomes fail to protect macromolecules against enzymatic degradation in the gastrointestinal tract. Mechanically and sterically stabilized liposomes can survive these conditions but are consequently too stable in the intestine to deliver the encapsulated drug via the normal absorption process. A possible solution to this problem would be to design liposomes with time-dependent stability. Direct uptake by M cells in Peyer's patches, which sample the surroundings for antigens, is too low for a substantial absorption of drugs but may be effective for vaccination, where low concentrations of antigens may be adequate to stimulate an immune response. Recently, the potential of utilizing polymerized liposomes as oral drug and vaccine vehicles has been explored. Such liposomes survive intestinal transit intact and can be rapidly taken up by M cells and subsequently by macrophages. Providing M-cell targeting molecules by the covalent attachment of lectins and other ligands provides further increases in intestinal liposome uptake. Very stable liposomes and polymerized liposome vehicles may provide a route for the commercial development of liposome technology for oral vaccination, and eventually, for a wide variety of macromolecular drugs.

In conclusion, the synergistic input from colloid science, physics, chemistry, biology, pharmacology, and medicine has resulted in the successful development of liposomal drug delivery in less than thirty years, and a solid theoretical and experimental basis has developed promising novel products. Only time will tell which of the above applications and speculations will prove to be successful.

However, based on the already available products, we can say that liposomes have definitely established their position in modern technology.

### I. INTRODUCTION

Drugs developed for diseases caused by pathogenic infections have the advantage that there are numerous physical and functional differences between the pathogens and the cells of their human host. As a result, most of these therapeutic agents can be administered chronically at relatively high doses with typically few side effects. This is not the case in diseases such as cancer, which arise from transformed or dysregulated growth/function of the body's own cells. Here, the differences between healthy and diseased tissues are often quite subtle and rarely are cellular features truly disease specific. It is not surprising then that for these diseases a very narrow window exists between drug doses that are effective and drug doses that are toxic. Although our increased understanding of the genetic alterations associated with diseases such as cancer will no doubt improve our ability to design better drugs, it is likely that we will continue to be faced with therapeutic targets that are differentially expressed in disease cells rather than

uniquely expressed. This suggests that manipulating drug pharmacology/distribution to enhance tumor selectivity will continue to be an important feature in the development of new anticancer drugs.

In view of the above considerations, it is not surprising that the potential utility of liposomes for delivery of cancer drugs was identified very quickly after the first descriptions of ordered spherical membrane structures spontaneously forming upon hydration of purified lipids were made by Bangham in the 1960s (1,2). It was thought that encapsulating highly toxic anticancer agents could alleviate many of the life-threatening side effects associated with conventional chemotherapy. Since that time, our understanding of the chemical and biophysical properties of bilayer membrane vesicles has increased dramatically as has our knowledge of how the body handles systemically administered liposomes. Through this process, liposome researchers developed anticancer drug formulations based on first-generation, conventional phospholipid/cholesterol-based liposomes followed by second-generation, sterically stabilized systems and more recently third-generation, multi-functional liposomes (see Fig. 1).

Although significant advances in the generation of novel liposome-based delivery systems were demonstrated

in laboratory studies, several hurdles regarding the production of homogeneous liposomes as well as effective entrapment and stability properties had to be overcome before liposomes could be considered as viable pharmaceutical delivery systems. These obstacles were overcome in the 1980s with the development of various liposome production procedures amenable to large-scale production including extrusion (3), dialysis (4), homogenization (5), and dehydration/rehydration techniques (6, see also 7 for a review). Also at this time efficient drug entrapment procedures were developed based on transmembrane ion gradients that provide nearly quantitative encapsulation efficiencies and extended drug retention stability (8,9). In addition, significant advances were made in the production of inexpensive, high-purity synthetic lipids that could support commercial-scale liposome production. Together, these accomplishments enabled liposomal cancer drugs to move not only from the bench to the bedside but also into the market place, where currently there are four approved liposome-based cytotoxic agents and one photodynamic agent (see Refs. 10 and 11 for reviews of clinical liposomal anticancer drug development). In addition, several liposomal anticancer drug formulations are in various stages of clinical testing for a range of tumor applications.

In the sections to follow, the different components that can be designed into liposomal anticancer drug formulations will be discussed in terms of the structural, physical, and functional properties that they impart to the carrier system. In addition, the biological processes and mechanisms

whereby liposomes exert their pharmacological benefits will be reviewed.

## II. COMPONENTS OF GENERATION-BASED LIPOSOMAL ANTICANCER DRUGS

### A. Drug Permeability Barrier and Solubilization Properties of the Bilayer Membrane

The basic structure that is the foundation for the construction of virtually all liposomes is the bilayer membrane, which forms upon hydration of polar lipids such as phospholipids and sphingolipids in an aqueous medium. There are two key features associated with lipid bilayers that are particularly suited for drug delivery applications. The spherical lipid envelope formed by bilayer membranes constitutes a very effective permeability barrier that limits movement of highly polar or charged molecules between the internal and external aqueous compartments of liposomes. This is due to the presence of the hydrophobic bilayer core associated with the hydrocarbon chains of phospholipids and sphingolipids, which presents a very energetically unfavorable environment (dielectric constant of approximately 5) for polar compounds. Consequently, when very water soluble anticancer drugs are encapsulated in the internal aqueous compartment of liposomes, they remain there for extended times, the duration of which will

be dictated by the polarity/charge of the drug and the composition of the bilayer membrane.

Since a number of commonly used chemotherapy agents are polar (amphipathic at a minimum) and water soluble, most early efforts in liposomal anticancer drug development focused on entrapping agents such as doxorubicin and cytosine arabinoside in an attempt to (a) prolong systemic exposure of drug (increase AUC) and (b) decrease drug accumulation in susceptible healthy tissues (e.g., cardiac tissue for doxorubicin). At that time it was unclear how tumor tissue would handle liposomes, and the working hypothesis was that liposomes would increase the therapeutic index of anticancer drugs by decreasing toxicity while maintaining or possibly increasing antitumor potency. These early investigations identified a number of key structure/biological function relationships for liposomal anticancer drug formulations that provided the basis for subsequent optimization studies. First, large (> 500 nm diameter) liposomes are cleared from the blood far more rapidly than small (100 nm diameter) liposomes (12). Second, liposomes containing < 30 mol% cholesterol are rapidly destabilized in the circulation, leading to significant drug release (13). Third, liposomes with charged surfaces (particularly negatively charged liposomes) are cleared from the circulation more rapidly than neutral liposomes (14).

Detailed investigations into the *in vivo* behavior of liposomes showed that many of the above relationships were the results of interactions of liposomes with blood components and cells of the reticuloendothelial system. When liposomes are injected intravenously they are immediately exposed to a plethora of circulating cells, lipoproteins, and soluble factors including proteins, carbohydrates, and small ions ( $\text{Na}^+$ ,  $\text{Cl}^-$ ,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ , etc.). Assuming that liposomes contain sufficient amounts of cholesterol to avoid the bilayer destabilization effects of lipoproteins (15,16), the fate of liposomes in this compartment is dictated primarily by interactions between the liposome surface and serum protein components. Two deleterious responses can result when proteins adsorb to liposomes; (i) increased membrane permeability, which compromises drug retention in the liposomes, and (ii) recognition and subsequent clearance of liposomes by the RES.

The ability of adsorbed blood proteins to increase liposome permeability properties has been demonstrated by several laboratories (16–19). Such interactions can be simply modeled by determining the drug release kinetics for liposomes suspended in serum compared to protein-free buffer. An example of this is shown in Fig. 2. The leakage of vincristine from DSPC/Chol liposomes is approximately five fold faster in the presence of serum. Interestingly, comparison of these results with the release kinetics

**Figure 30.2** Release of vincristine from 100 nm DSPC/cholesterol (55:45 molar ratio) liposomes in buffer, in serum, and in the circulation after iv injection to BDF1 mice. Vincristine was encapsulated at a drug-to-lipid ratio of 0.05:1 (wt:wt) using the citrate-based pH gradient entrapment procedure, where trapping efficiencies were > 95%. The values represent the percent vincristine release after 24 h. *In vitro* experiments were conducted at 37°C.

of vincristine from DSPC/Chol liposomes after iv administration (as determined by monitoring changes in the circulating drug-to-lipid ratio) reveals that drug leakage is further increased *in vivo* (Fig. 2). These differences are not simply due to the presence of a “tissue sink” into which the released vincristine is absorbed, since increased dilutions or extended dialysis times in the presence of serum do not increase *in vitro* drug release rates (L. Mayer, unpublished observations). Consequently, we believe that *in vivo* drug retention properties as well as comparisons of drug release kinetics for different liposomes cannot always be predicted simply on the basis of *in vitro* data.

In addition to increasing the permeability of liposome bilayers in the blood, protein adsorption can also lead to increased susceptibility to transmembrane stresses caused by ion gradients or high levels of encapsulated drugs. The high concentrations of buffer components and/or drug entrapped in liposomes often result in significant osmotic gradients across the liposome membrane when exposed to physiological fluids. While most liposomes can withstand a significant transmembrane osmotic gradient in the absence of extraneous proteins, exposure of liposomes exhib-

iting large osmotic gradients to plasma or purified lipoprotein fractions results in a burst of leakage from the liposomes while osmotic balance is reestablished (20). This effect is more pronounced with less ordered membranes, where, for example, DSPC/Chol liposomes can withstand osmotic gradients of far greater magnitude than EPC/Chol liposomes in the presence of proteins (20). This may, in part, explain the differences observed between DSPC/Chol and EPC/Chol liposomal doxorubicin formulations *in vivo* where the circulating drug-to-lipid ratio (used to assess drug leakage) observed for EPC/Chol liposomes drops approximately 50% within 1 h of injection and subsequently decreases to a release rate comparable to that observed for DSPC/Chol (21).

The RES has long been recognized as the major site of liposome accumulation after systemic administration. The primary organs associated with the RES are the liver, spleen, and lung. The liver exhibits the largest capacity for liposome uptake, while the spleen can accumulate liposomes so that the tissue concentration (liposomal lipid/gm tissue) is 10-fold higher than that which can be achieved in other organs. Assuming that liposomes are designed to minimize protein binding and cell interactions, the extent of liposome accumulation in the lung is typically below 1% of the injected dose. Early studies demonstrated that large as well as charged liposomes (particularly those containing negatively charged lipids like PS, PA, or cardiolipin) were removed very rapidly by the liver and spleen with clearance half-lives of less than 1 hour (22,23). The rate of clearance from the circulation could be reduced to some extent by increasing the administered lipid dose, however, only when small (approx. 100 nm), neutral liposomes containing  $\geq 30\%$  cholesterol were utilized at doses of at least 10 mg/kg or more, could circulation lifetimes in the range of several hours be achieved (24). The removal of liposomes from the blood is attributed to phagocytic cells that reside in the RES and appears to be mediated through direct interactions between the phagocytic cell and the liposomes. *In vitro* studies have shown that liposome uptake into macrophages can occur in the absence of serum proteins, but recognition mediated by protein elements that associate with liposome surfaces likely plays a dominating role on interactions with the RES.

Once the processes dictating liposome drug retention and clearance in the central blood compartment were elucidated, several liposomal anticancer drug formulations using previously approved therapeutic agents were entered into formal developmental programs aimed at testing in human clinical trials. The liposomes in these formulations had the common features of being approximately 100 nm in size, being unilamellar, and containing 35–50 mol%

cholesterol. In general, these preparations exhibited significantly reduced toxicity in preclinical models compared to the same drug administered in conventional, unencapsulated form (25–27). In the case of doxorubicin, dose-limiting cardiotoxicity was significantly reduced by liposome entrapment, and this correlated with decreased accumulation of doxorubicin in heart tissue when administered in liposome-encapsulated form (28,29). Similar observations were made with doxorubicin concerning other toxicity target organs such as the kidneys and GI tract (30,31) as well as for other drugs exhibiting significant nonhematological toxicities such as cisplatin (32). In addition to the benefits of reduced toxicity, early indications suggested that these liposomes also preferentially accumulated in sites of tumor growth. This was initially revealed by imaging and drug distribution studies that demonstrated increased liposome and entrapped anticancer drug uptake into solid tumors compared to other, healthy tissues (33,34). Subsequent studies investigated the mechanisms involved in this tumor selectivity in order to improve further the therapeutic potential of liposomal anticancer drugs (see Section III.B). These observations taken together with the toxicity buffering effects brought renewed enthusiasm into the development of liposome-based cancer therapeutics.

Although the majority of liposome technology applications for cancer treatment have been on the delivery of existing cytotoxics already approved for use in free (non-entrapped) form, interest is increasing on examining liposome formulations for investigational agents at earlier stages of development. An emerging trend in the development of new small-molecule anticancer agents is that the most potent and promising molecules are often very hydrophobic and insoluble in conventional aqueous pharmaceutical vehicles for systemic administration. Examples of such compounds include the taxanes, camptothecins, porphyrin-based photosensitizers, and podophyllotoxins. Given the adverse reactions associated with surfactant-based vehicles such as Cremophor EL utilized to solubilize paclitaxel, increasing attention has focused on formulating these types of compounds in liposomes. This is due to the hydrophobic core of the bilayer membrane, which can accommodate high levels of various hydrophobic drugs, depending on the membrane intercollation properties of the specific compound being formulated. As such, the solubilization capabilities of liposomes represents a second basic property of these carriers that can be applied beneficially for many anticancer drugs.

For hydrophobic drugs, liposomes can serve two purposes. First, the bilayer membrane can simply serve as a biocompatible solubilization vehicle where drugs can be

incorporated and subsequently administered in an aqueous diluent such as saline or 5% dextrose in water (D5W). Second, the liposomes can act as true drug delivery carriers *in vivo* and dictate the pharmacodistribution properties of the drug if they are capable of retaining the agent for extended times (hours). Intuitively, one would predict that hydrophobic drugs would be ideally suited for liposomal delivery systems, perhaps even more so than hydrophilic drugs. Clearly, very hydrophobic drugs will be dependent on some form of solubilization system such as liposomes for *iv* use, and the DMPC/EPG formulation of the recently approved photosensitizer benzoporphyrin derivative (BPD) is one such example. This compound has water solubility below 1  $\mu\text{g/mL}$  but can be constituted at several  $\text{mg/mL}$  when formulated in small DMPC/EPG liposomes (35). Interestingly, however, shortly after *iv* administration, BPD exchanges out of the liposome carrier and partitions into other hydrophobic domains, most notably lipoproteins, which may act as secondary carriers of the drug to disease sites (36).

The limitations that are often experienced with liposomal formulations of hydrophobic drugs can be grouped into two general categories. These are (1) low drug incorporation capacity and (2) poor drug retention after injection. Some agents, such as paclitaxel, although hydrophobic, are not readily incorporated into phospholipid-based liposome bilayers, and capacities on the order of 3 mol% of the total lipid are observed (37,38). Such formulations have been tested and shown to have extended drug circulation times and antitumor activity (39). However, the very high lipid dose required to deliver therapeutic amounts of paclitaxel may artificially maintain elevated plasma drug levels by virtue of the amount of liposomal membrane in the circulation and not be able to be utilized in a clinical setting. By analogy, cyclosporins have been incorporated into liposomes with similar incorporation capacities and have also been shown to be released rapidly from the lipid carrier in the circulation, resulting in drug pharmacokinetic properties that are comparable to unencapsulated drug (40,41). It should be noted that the rapid release of hydrophobic drugs often experienced *in vivo* is rarely observed *in vitro*. This is likely due to the presence of the large lipid pool existing in animal tissues that can act as a membrane "sink" into which hydrophobic drugs can partition, which is absent in *in vitro* test systems utilized to monitor drug release. Also, the permeability energy barrier provided by the liposomal bilayer for polar, water-soluble drugs is virtually nonexistent for hydrophobic agents, which can readily move across phospholipid membranes. Consequently, although aqueous concentrations of hydrophobic drugs are very low at equilibrium, their redistri-

bution in the body is driven kinetically through the rapid exchange of drug between hydrophobic lipid pools.

In addition to being used for formulating drugs that are inherently hydrophobic, liposomes have also been used to deliver hydrophobic derivatives of otherwise water-soluble drugs. The rationale of this approach is based on speculations that decreased toxicity/increased antitumor potency may arise from favorable alterations of drug tissue distribution in favor of disease tissue, increased duration of exposure, or decreased metabolic degradation. Alkylated derivatives of Ara-C formulated in liposomes have been shown to be significantly more potent than free Ara-C against some tumor models (42,43). Methotrexate conjugated to phosphatidylethanolamine incorporated in liposomes was shown to be equally active against sensitive and MTX resistant tumor cells (44). Also, palmitoyl-asparaginase incorporated into liposomes exhibited significantly extended circulation longevity and reduced immunogenicity compared to native L-asparaginase. One of the most advanced lipophilic drug derivative formulations is liposomal NDDP, a diaminocyclohexane platinum analog (45,46). Perez-Solar and coworkers have studied this compound extensively and have demonstrated improved pharmacokinetic and therapeutic characteristics compared to conventional cisplatin (47). In addition, clinical trials with this formulation indicated that nephrotoxicity often observed with cisplatin was not dose limiting for liposomal NDDP (48). These examples demonstrate how the hydrophobic properties of liposomes can be utilized in various ways to enhance the therapeutic index of a wide variety of anticancer agents.

As a final comment on the *in vivo* drug retention and distribution properties of liposomes, it should be noted that, while liposomes clearly can provide sustained exposure of therapeutic agents in the blood compartment through controlled release kinetics of encapsulated drugs, currently it is difficult to justify development of liposomal drugs using a rationale that involves only sustained systemic exposure. This is largely due to significant advances made in the area of drug infusion technology. Compact and cost-effective infusion pumps are now widely used, and these can provide well-controlled systemic drug exposure over several days. We maintain that the most significant advantage for the use of liposome drug carriers arises as a consequence of disease-specific changes in vascular permeability that favor the accumulation of the intact liposome and associated drug into sites of tumor growth. We differentiate this property from the benefits of drug infusion technology, which are primarily concerned with the maintenance of circulating blood levels of free drug. However, this does not detract from the utility of liposomes to

protect labile anticancer agents such as the camptothecins (49,50), nor does it discount the value of formulating drugs that would be otherwise incompatible for systemic administration regardless of the pharmacodistribution characteristics imparted by the liposomes.

### **B. Effects of Steric Stabilizing Lipids on PK and Therapeutic Properties of Liposomal Anticancer Agents**

Incorporation of steric stabilizing lipids reflects the “second generation” of liposome development, where components were included in the basic phospholipid/cholesterol bilayer in an attempt to improve the tumor selective delivery of encapsulated agents. These developments arose as we began to understand how liposomes interacted not only with proteins and phagocytic cells of the RES but also with the vasculature of healthy tissues and solid tumors. While in the circulation, liposomes are continually exposed to cells lining the vasculature. The inner lining, or intima, of blood vessels is composed primarily of endothelial cells, which form a contiguous layer on the interior surface of all blood vessels. Underlying this layer is the basement membrane, and in larger (noncapillary) vessels the vasculature is supported by smooth muscle cells (51). The endothelial cells in most normal vasculature exhibit intact intercellular junctions, and only small molecules are able to permeate readily across capillaries of this type. However, this structure is significantly altered in certain normal tissues, most notably the liver and the spleen, as well as in disease sites such as infection and tumor growth. The latter are characterized by the presence of capillaries that exhibit fenestrae or larger intercellular openings and can be devoid of the basement membrane layer. The gaps in these endothelial layers can range in size from 30 nm for fenestrated capillaries to greater than 500 nm in liver and tumor vascular beds (52–54). In the liver, these openings provide access to sinusoids, wherein the phagocytic Kupffer cells lie. In solid tumor sites, the fenestrated/discontinuous capillary beds and postcapillary venules allow direct exposure of the underlying epithelial cells to the circulation. It is the unique nature of vascular structures, that particularly exist in solid tumors, that significantly impacts the pharmacological behavior of liposomal anticancer drug delivery systems.

The mediators that lead to increased permeability of the vascular barrier in solid tumors appears related to hypoxic environments arising from rapid tumor cell proliferation, which causes increased distances of cells from vascular sources of nutrients and oxygen. Such conditions appear to induce release vascular endothelial growth factor (VEGF) from tumor cells (55,56). VEGF is an endothelial cell-

specific mitogen, and its release from tumor cells can lead to the angiogenic development of neovasculature by inducing proliferation and migration of existing vascular endothelial cells towards regions of tumor hypoxia. Interestingly, VEGF has proven to be identical to vascular permeability factor (57,58), a protein first identified as a factor capable of inducing defects in the permeability barrier of blood vessels. The end result of these conditions is the presence of blood vessels that are permeable to large molecules. This may be a consequence of fenestrae or larger “gaps” occurring between adjacent endothelial cells through which macromolecules can pass (59) or, alternatively, may involve increases in endothelial cell mediated transcytosis (60).

Increases in vascular permeability give rise to the selective accumulation of small liposomes in sites of tumor growth. However, this is not a selective process, and there is also a general increase in extravascular fluids in these regions. The hydrostatic pressure within these sites is elevated relative to the vascular pressure, resulting in a pressure gradient that impedes movement of molecules from the blood into the tissue interstitium (61,62). We must therefore assume that additional features lead to selective accumulation of macromolecules in the diseased extravascular space. Studies, for example, have demonstrated that the lack of a developed lymphatic system in conjunction with the large openings in the vascular endothelial cell lining may lead to an extravascular “trapping” phenomenon (62). In the absence of lymphatic drainage, interstitial diffusion of molecules leads to egress from the disease site, and this diffusion rate is dependent on molecule size, small molecules exiting more rapidly than large molecules.

Liposome extravasation and accumulation in solid tumors has been well studied, and there is a great deal of phenomenological evidence demonstrating that liposomes can enter an extravascular site in regions of tumor growth following iv administration. Although evidence for endothelial cell uptake of liposomes and transcytosis across endothelial cells has been documented, videomicroscopy investigations in solid tumor models indicate that the majority of liposome extravasation occurs directly through the openings present in tumor neovasculature (63,64). This extravasation process appears to be quite heterogeneous within the tumor and does not appear to be associated with any specific histological characteristics in the tumor mass. The net result of this phenomenon is that peak tumor drug concentrations achieved are greater, and drug exposure as measured by concentration vs. time AUCs is often dramatically increased when the drug is administered in liposomal compared to free form.

Since the selective uptake of liposomes in solid tumors appears related to a “sieving” phenomenon, the drug con-

centration vs. time curves in solid tumors are very different for liposomal anticancer agents compared to unencapsulated drugs. This, of course, assumes that the liposome serves as a pharmacologically active delivery vehicle and not simply as a formulation excipient. This results from the fact that peak plasma free drug concentrations are observed very shortly after injection, which subsequently fall rapidly due to tissue distribution and elimination processes. Small-molecule therapeutics readily access extravascular sites (including tumors) without significant impediment due to the vascular lining. Consequently, peak tumor drug levels are also observed soon after injection, and the retention (e.g., AUC) of the anticancer agent is dictated primarily by the drug binding avidity of the tumor cells/interstitium, since the egress of most small-molecule drugs from tumor sites is minimally hindered. In contrast, liposome extravasation in solid tumors is much slower, being limited by the abundance of leaky fenestrae in the tumor neovasculature, and demonstrates an ascending accumulation curve that may peak between 4 and 48 h, depending on the plasma pharmacokinetics of the liposomes and the permeability properties of the tumor vasculature. Therefore at early times (i.e., 1 h after drug administration), tumor-free drug levels may actually be elevated compared to liposomal drug, but this relationship soon reverses: later peak concentrations and AUCs for liposomal anticancer agents can be 15-fold and 100-fold greater, respectively, than for free drug (65–67).

Given the nature of liposome extravasation and retention within solid tumors, a great deal of effort has been placed on developing liposomes that circulate at elevated concentrations in the blood for extended times. The underlying hypothesis of this approach is that the extravasation process is driven by mass action diffusion of small liposomes across the leaky tumor neovasculature. Consequently, increasing the plasma concentration of liposomes should theoretically increase tumor uptake levels of liposomal anticancer drugs. This provided impetus for the development of liposomes with extended circulation times. Early observations identified certain gangliosides, particularly GM<sub>1</sub>, that reduced the elimination rates of conventional PC/cholesterol liposomes (68,69). A significant breakthrough was achieved with the demonstration that liposomes containing surface grafted polyethylene glycol (PEG) were cleared 2- to 5-fold slower than conventional liposomes of similar size and bulk lipid composition (70–72). This appears to be due to the ability of the PEG polymer (typically 2000 MW) to form a “steric stabilizing” shield on the liposome surface that inhibits protein binding and cellular recognition (73–75). This effect is optimal at incorporation levels of approximately 5 mol%, which also coincides with the transition of the PEG polymer from a

random coil, mushroomlike conformation to a more ordered brushlike conformation. The details of this phenomenon are presented by Dr. Lasic in this book. Using this technology, numerous anticancer drugs have been encapsulated in sterically stabilized liposomes to generate formulations that can provide significant circulating drug concentrations over several days. It is important to note that as the ability to extend the blood residence time increases, so does the need to retain encapsulated anticancer drugs over similar times. Therefore most sterically stabilized formulations employ more impermeable saturated phospholipid/cholesterol bilayer compositions that minimize drug leakage in the circulation (see Section III.A).

Although steric stabilization technology has clearly been able to provide increased circulation lifetimes of liposomal anticancer agents, the design of liposomes that will exhibit maximal extravasation in tumor sites is an area of some controversy. It has generally been assumed that increases in the concentration of liposomes in plasma over time will lead to increased accumulation of liposomes in the extravascular disease sites, and experimental evidence supporting this has been reported (76). Videomicroscopy has also suggested that the permeability coefficient of tumor vasculature is greater for PEG-PE containing liposomes than for conventional liposomes (77). In contrast, studies conducted in our laboratories as well as others have demonstrated that although plasma levels of PEG containing liposomes are several times higher than for comparable conventional liposomes, this often does not result in increased extravasation and accumulation in solid tumor tissue (66,78,79).

We have examined the tumor uptake properties for conventional and steric stabilized liposomal formulations of doxorubicin in a variety of solid tumor models. Three important observations can be made on the basis of the comparative biological properties of conventional and sterically stabilized liposomes. First, sterically stabilized liposomes uniformly display increased circulation longevity compared to conventional liposomes, regardless of the presence of encapsulated drug. Second, the rate and extent of liposome accumulation in tumor tissue are often comparable for both conventional and sterically stabilized liposomes, although the PEG containing systems typically exhibit a slight increase. Third, the tumor accumulation efficiency or TAE (defined as the AUC in the tumor divided by the AUC in plasma) is higher for conventional liposomes than for sterically stabilized systems. It is important to note that the relationship between tumor liposome uptake and plasma liposome AUC is linear for conventional and sterically stabilized liposomes, respectively (M. Bally, unpublished observation). This suggests that mass action does appear to drive the accumulation of spe-

cific types of nontargeted small liposomes into tumors. However, inclusion of lipids such as PEG-DSPE appears to decrease the efficiency of liposome extravasation from the blood into tumor tissue, or alternatively increase the rate of egress from the tumor as indicated by the decreased TAE values observed for sterically stabilized liposomes in several solid tumor models (Fig. 3).

The basis for discrepancies in tumor extravasation comparisons between conventional and sterically stabilized liposomes may be related to one of several potential explanations. The tumor models utilized may exhibit different vascular structures (80), and it is reasonable to assume that increases or decreases in conventional liposome extravasation in comparison to sterically stabilized liposomes may be tumor specific. However, many different tumor types have been evaluated, and it would appear that preferential accumulation efficiency of conventional liposomes is prevalent in most tumor types, regardless of differences in vascular structure. Our comparisons are typically based on extended AUC measurements of total tumor liposome uptake (following a nonexchangeable, nonmetabolizable lipid label and correcting for blood volume contributions), and we place great emphasis on measuring both liposomal lipid and drug over the specified time course. It should be noted that the lipid compositions utilized in our studies for con-

ventional and sterically stabilized liposomes contain 45 mol% cholesterol, whereas studies by others often utilize liposomes with 33 mol% cholesterol. Reduced cholesterol content may result in increased drug permeability (see Section III.A). Several comparative studies demonstrating improved tumor accumulation for sterically stabilized liposomes have relied on the use of entrapped aqueous markers such as  $Ga^{67}$ , which are rapidly cleared when released from the liposomes. Consequently, it is difficult to determine if differences in tumor accumulation are due to altered elimination and/or extravasation properties affected by lipid composition or a result of lipid composition effects on drug retention. It is important to resolve these issues, and this will require a concerted effort to standardize the tumor models, liposome compositions, and methods/parameters for evaluating liposome extravasation into tumors.

It should not be unexpected that conventional and sterically stabilized liposomes exhibit different efficiencies in extravasation. Videomicroscopy studies with steric stabilized liposomal doxorubicin systems have shown that some endothelial cells can take up liposomes (63,77). Endothelial cell interactions may contribute to the extravasation process either directly via transcytosis or indirectly by facilitating an increase in the local liposome concentration at the endothelial cell surface, thereby increasing access to openings in the vasculature. Given the effects of PEG on inhibiting liposome–cell interactions, this polymer may reduce endothelial cell interactions, and this in turn would reduce the rate of extravasation. In contrast, conventional liposome extravasation could be facilitated through increased interactions with the endothelial cell lining of the neovasculature in tumors. This is, of course, highly speculative but is consistent with the surface properties of conventional liposomes compared to steric stabilized liposomes. A logical extension of this argument, however, is that improved extravasation may be possible by designing liposomes that interact more extensively with vascular endothelium in tumors.

Although there are areas where additional information will be required in order to optimize the pharmacological properties of sterically stabilized liposomal anticancer agents, the utility of such systems has been clearly demonstrated for liposomal formulations of anthracyclines, vinca alkaloids, camptothecins, and platinum compounds. In all cases, significant increases in therapeutic index have been achieved through decreased toxicity and typically increased antitumor activity, which is associated with significantly increased circulating drug concentrations (81). The ability to control interactions with liposome surfaces using steric stabilizing lipids provides the added advantage of opportunities to engineer specific components into the liposomes to select for specific, desired interactions while

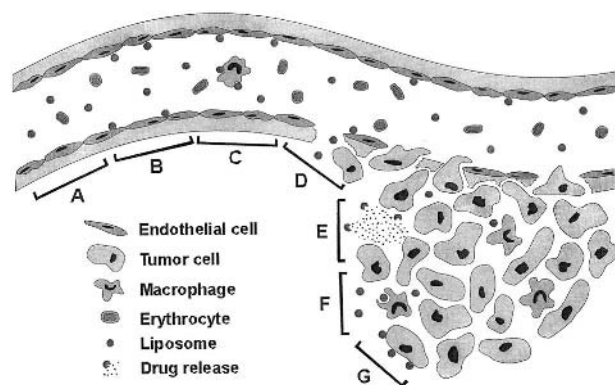

**Figure 30.3** Relative tumor accumulation efficiency (TAE) of conventional (open bars) and sterically stabilized (closed bars) after iv injection to mice bearing the indicated solid tumor type. The tumor accumulation efficiency was determined for 100 nm liposomes by dividing the AUC in the tumor with the AUC in plasma for DSPC/cholesterol (55:45 molar ratio) and DSPC/PEG-DSPE/cholesterol (50:5:45 molar ratio) liposomes.

avoiding nonspecific, and often undesirable, reactions with the biological milieu.

### C. Multifunctional Liposomes; Targeted, Fusogenic, and Controlled Release Systems

As noted above, the distribution of liposomes that have extravasated into the tumor interstitium is heterogeneous. This is not unexpected, given the irregular and often redundant organization of tumor vasculature. Tumor vascular structure often engenders highly variable blood flow properties, and evaluation of histological sections from tumors reflects this heterogeneity. This would be more apparent for liposomes than for unencapsulated small molecules due to the decreased diffusion through the interstitial space for large macromolecules. Importantly, evaluations of drug accumulation properties suggest that drug release from the liposomes in the extravascular site results in greater drug penetration into the tissue and more rapid loss of the drug from the site when compared with the loss of liposomal lipid (66). The prolonged residence of liposomes in tumors significantly increases the duration of tumor drug exposure and AUC relative to free agents (66). In some tumor models, such properties have been shown to correlate with increased antitumor activity for liposomal formulations of drugs such as doxorubicin and daunorubicin.

The consensus emerging from studies in several laboratories on the mechanism of action of liposomal anticancer drug formulations is that liposomes exert their effect on therapeutic activity by providing an *in situ* drug infusion reservoir within the tumor. Once released, the anticancer drug can diffuse through the tumor and has direct access to tumor cells, where it can act in a manner that presumably is similar to drug in the absence of a liposomal carrier (Fig. 4). *In vitro* studies have demonstrated that macrophages can engulf doxorubicin loaded liposomes, process them, and rerelease doxorubicin extracellularly in free form (82). In view of the high macrophage content residing in some tumors (83), such phenomena led to the proposal that liposomal anticancer drug release may involve macrophage processing after extravasation. However, we have shown that in solid tumors there are limited interactions between tumor associated macrophages and extravasated liposomes (78). Although macrophage enriched tumors do accumulate higher levels of liposomal doxorubicin, this effect appears more related to increased vascular permeability rather than to direct uptake and processing of the liposomes by the macrophages. This was further supported by the fact that both conventional and sterically stabilized liposomes displayed comparable distribution properties (as determined by fluorescence microscopy of tumor thin sections) after extravasation into the tumor.

**Figure 30.4** Model of tumor site infusion mechanism for improved therapeutic activity of conventional and sterically stabilized liposomal anticancer drug formulations. (A) Liposomes circulating freely in the blood. (B) Liposomes interacting with endothelial cells. (C) Liposomes interacting with circulating white blood cells. (D) Liposomes passively extravasating through the leaky vasculature of solid tumors. (E) Liposomes releasing entrapped drug in the tumor interstitium. (F) Liposomes being taken up by phagocytic cells in the solid tumor. (G) Liposomes associating with the surface of tumor cells.

In view of the heterogeneous tumor distribution of liposomes and the apparent *in situ* free drug infusion model of activity for most liposomal anticancer drug formulations, increasing interest and effort has been given to developing liposomes that can increase the intracellular delivery of anticancer agents to tumor cells. Two general approaches have been taken in this regard, namely (1) targeting to internalizable epitopes expressed preferentially on the surface of tumor cells so that the liposomes deliver their entrapped anticancer drugs directly to the tumor cell interior, and (2) increasing tumor site selective release of encapsulated drugs to increase bioavailable drug pools.

Targeting of liposomes to tumor cells has long been investigated as an avenue to improve the delivery of anticancer drugs to tumors. Unfortunately, many early attempts to employ targeted liposomes suffered from the increased clearance experienced by liposomes containing surface-derivatized proteins (e.g., antibodies). Consequently, accumulation into solid tumors for these liposomes was often less than obtained for conventional systems. This improved somewhat upon the implementation of steric stabilizing lipids, but it was observed that tumor uptake still was marginally improved compared to nontargeted sterically stabilized liposomes.

It is important to note that tumor cell directed targeting information does not inherently alter the extravasation events required for the liposomes to reach their cellular target. Consequently, the pharmacodistribution benefits

provided by targeted liposomes should arise from a decreased rate of egress from the disease site (rather than increased influx) and cell specific binding. Given that nontargeted liposomes migrate slowly through interstitial spaces in solid tumors, it may not be surprising that pharmacological improvements are typically very modest. In addition, the avidity of liposome binding to target cells may actually inhibit liposome migration and subsequent drug exposure in areas more distant from blood vessels. This is anticipated on the basis of binding barrier effects that have been described by Saga et al. (84). Therefore targeting approaches may be most appropriate for small foci of disease where extensive interstitial diffusion is not required to expose all of the diseased cells to the therapeutic agent. This has been demonstrated with immunoliposomes targeted to lung cancer metastases growing in mice, where small tumors could be treated much more effectively with targeted liposomes than with conventional liposomes or free drug (85).

More recently, very encouraging signs of significant benefits associated with tumor targeted immunoliposomes containing doxorubicin have been obtained using a human breast cancer xenograft model. These studies conducted in the laboratories of the late Demetri Paphadjopoulos utilized an antibody fragment directed against the Her-2 receptor present on some breast cancer cells. Doxorubicin loaded sterically stabilized liposomes derivatized with this protein were internalized and endocytosed upon binding to tumor cells expressing this receptor (86). Preclinical xenograft solid tumor model studies showed that such formulations could provide significantly increased antitumor potency compared to free doxorubicin or doxorubicin entrapped in nontargeted sterically stabilized liposomes (87). These reports are some of the first to provide solid evidence that targeting of liposomes to tumors may lead to enhanced therapeutic activity. However, in view of the numerous other failed attempts to achieve this result, it would appear that successful application in this technology will require very careful consideration of the tumor antigen to be targeted, the specific nature of the targeting ligand, and the cellular processing that occurs subsequent to the liposomes binding to the tumor cells in order to achieve intracellular release of encapsulated drug.

In the case of targeted liposomal anticancer drugs directed at internalizable tumor surface proteins, additional lipid components can be included to make the liposomal carrier pH sensitive (88) or fusogenic (89). Release of entrapped contents or fusion with the endocytic/lysosomal membranes can be designed to occur when the liposomes are exposed to the low pH of the late endosome/lysosome. This has been shown to increase dramatically the potency of liposomal anticancer drugs *in vitro* (90). A second approach for intracellular delivery is based on the use of fusogenic lipids.

In this case, introduction of liposome encapsulated agents into the cytoplasm of targeted cells is via membrane fusion of the liposome bilayer with the disease cell's plasma membrane. This first requires binding to the cell surface. Recent reports suggest that highly fusogenic lipid mixtures can be stabilized by incorporation of small amounts of exchangeable or cleavable PEG lipids (91,92). Loss of the PEG moiety leads to destabilization of the liposome membrane, which in turn will have the potential to fuse with nearby cell membranes. While these novel approaches for intracellular delivery of liposomal contents are providing exciting data in cell culture systems, their utility *in vivo* will depend on maintaining or increasing access and delivery of the liposomal carrier and encapsulated drug to the disease tissue. It should also be noted that the exchangeable/cleavable PEG containing liposomes can also be used to provide controlled release of the entrapped anticancer drug in the tumor interstitium after the liposomes have accumulated at the tumor site. This has been shown to be advantageous with a controlled release liposomal formulation of mitoxantrone (93). The key feature here is that the timing of increased drug release from the liposomes (dictated by PEG exchange rates) must coincide with the kinetics of liposome accumulation at the tumor site.

Another approach being investigated to achieve tumor site selective anticancer drug release from liposomes is the use of membrane systems whose permeability properties are sensitive to a physical/chemical property that can be manipulated in sites of tumor growth from extraneous sources. In particular, thermosensitive and photosensitive liposomes have been investigated in an attempt to achieve triggered drug release specifically at the tumor site (94,95). Liposomal doxorubicin preparations, for example, can be prepared such that there is an increase in drug release at 42°C, compared to 37°C. These liposomes are administered *iv* to tumor bearing mice, and the tumor site is then heated using a topical microwave heating device placed on the subcutaneous tumor. Application of a transient heating pulse after the liposomal doxorubicin had accumulated into the solid tumor resulted in a significant increase of therapeutic activity compared to free drug with hyperthermia and liposomal doxorubicin in the absence of heating. Very recently (95), lysolipid containing liposomal doxorubicin formulations have been developed that undergo a dramatic increase in drug release upon very mild hyperthermia (from 37°C to 39°C). These liposomes exhibit more extensive drug release than previous thermosensitive systems, and early results with the application of mild hyperthermia have provided solid tumor cure rates in excess of 75%, whereas free doxorubicin or doxorubicin entrapped in sterically stabilized or lysolipid-free thermosensitive liposomes yielded modest reductions in tumor growth rates

and cure rates between 0 and 10% (95). These results highlight the importance of controlling the bioavailability of liposome entrapped anticancer drugs at the tumor site and emphasize the importance of this area for further improvements in the therapeutic activity of liposomal anticancer drugs.

### III. THE APPLICATION PARADIGM FOR LIPOSOMAL ANTICANCER DRUG DEVELOPMENT

#### A. General Comments

Now that we have progressed from the conventional and sterically stabilized generations of liposomal anticancer drugs to third-generation multifunctional liposomes, we have at our disposal a wide range of properties that can be engineered into liposome formulations. We have the ability to trap drugs at nearly quantitative efficiencies, retain liposomes and their entrapped drugs in the circulation for days, effectively target liposomal drugs to tumor cells, and control the release of encapsulated cytotoxics for selective exposure. This sophistication provides numerous options for generating effective liposome-based anticancer agents, but it is unlikely that increased design complexity will be necessary in all applications, and in some instances it may be undesirable. Consequently, it would appear that increased attention to formulation design based on specific applications will be required in order to optimize the therapeutic potential of new liposomal anticancer drug formulations.

It is important at this point to reflect on the usefulness of preclinical model systems in predicting the behaviour of liposomal anticancer drug formulations in humans. Clearly, a focus on application-based development of therapeutic liposomes relies heavily on the dependability of *in vitro* and *in vivo* testing systems to show which formulation characteristics affect biological performance parameters important for human use. We and other laboratories have observed that most *in vitro* systems are of limited utility, because improvements provided by liposome encapsulation are typically related to alterations in drug pharmacodistribution, which is very difficult to predict with *in vitro* assays. In contrast, most *in vivo* models for determining toxicity and efficacy profiles of liposomal anticancer agents have been quite accurate predictors of activity in humans. For example, the liposomal doxorubicin formulation TLC D-99 exhibited significantly reduced cardiac and GI toxicity compared to conventional nonencapsulated doxorubicin, whereas hematological toxicities were modestly effected in preclinical studies (28,29). In addition, ascitic and solid tumor models demonstrated comparable antitumor potency between the two drug forms, and im-

proved therapeutic activity was obtained at elevated doxorubicin doses allowed by the less toxic liposome formulation. These characteristics were consistent with the clinical performance of this liposomal formulation, where toxicity and therapeutic response comparisons with nonencapsulated doxorubicin mirrored the results from preclinical studies (10). Similar situations occurred with the liposomal daunorubicin formulation Daunoxome developed by Nexstar and the sterically stabilized liposomal doxorubicin formulation Caelyx, where clinical trial results were comparable to those from preclinical investigations (11). This strongly suggests that the therapeutic performance of liposomal anticancer drugs in humans can be predicted with reasonable accuracy using conventional preclinical animal toxicity and efficacy models. Consequently, emphasis on liposome design/biological performance optimization using animal models appears to be appropriate for identifying formulations that will likely provide significant therapeutic benefits in humans.

Whereas historically researchers have generated liposomal formulations of anticancer drugs and subsequently looked for tumor types where they may be most useful, an application-based development approach focuses on important problems existing in cancer chemotherapy and then identifies active agents and liposome properties that are best suited to meet these needs. That does not mean that attention to anticancer applications has been absent in generation-based liposome research programs, but rather that more emphasis was placed on developing formulation technology than on identifying biological problems or mechanisms for which liposomes could provide a unique solution. There will no doubt continue to be a need for additional liposome technology development in order to improve on existing design parameters and generate additional novel functional capabilities. However, it is suggested here that this development should be dictated by deficiencies that exist in current technology for specific anticancer applications of liposomes. Two examples of how liposome design attributes can be systematically matched to specific cancer treatment applications are presented in the following sections.

#### B. Development of Liposomal Vincristine

Vincristine is a potent cell cycle specific vinca alkaloid that is widely utilized in the treatment of many human malignancies such as lymphomas. It has a very steep dose-response curve, but its clinical use is limited by neurotoxicity that can be debilitating if the dose exceeds 2 mg in a single course of treatment. Its sensitivity to the tumor cell cycle is demonstrated by the fact that varying the duration of drug exposure to tumor cells in culture from 4 h to 72 h results in a  $10^5$ -fold increase in cytotoxic potency, whereas

other agents such as doxorubicin are affected by less than 50-fold (95). Given our *in situ* tumor drug infusion model of liposomal anticancer drug activity, we postulated that the cytotoxic potency of vincristine *in vivo* may be dramatically increased if we could increase the level and duration of drug exposure in tumors using small (100 nm) liposomes.

We found that increasing the retention of vincristine inside 100 nm liposomes by changing the phosphorylcholine containing lipid component from EPC to DSPC to sphingomyelin (while maintaining cholesterol content at 45 mol%) led to dramatic increases in antitumor activity, particularly when compared to the efficacy obtained with free vincristine (96). This is consistent with the steep dependence of vincristine antitumor potency on the duration of drug exposure as well as the fact that retention of vincristine in most tissues, including tumors, is rather poor (96). In this case it appeared that the ability to prolong the exposure of vincristine *in vivo* was more important than peak drug concentrations. Interestingly, although inclusion of PEG-PE in the liposomes increased the circulating liposomal lipid levels at extended time periods, this steric stabilizing lipid did not improve the vincristine pharmacokinetic or therapeutic properties over conventional DSPC/Chol or sphingomyelin/Chol systems (67). This was because PEG-PE increased the permeability of the lipid bilayer to vincristine, thus offsetting the potential benefits provided by increased longevity of the liposomal carrier. The reasons for this increased drug leakage are not well understood. It may be related to the fact that PEG-modified phosphatidylethanolamine is negatively charged, and this may alter drug partitioning properties at the inner monolayer membrane surface. In addition, it is not yet clear whether this phenomenon is specific for vincristine encapsulated via pH gradient techniques employing citrate buffers, compared to ammonium sulfate entrapment systems (97). Nonetheless, for vincristine, we determined that the optimized formulation for improving therapeutic activity consisted of a SM/cholesterol conventional liposome using pH gradient drug entrapment. This formulation is currently in Phase II clinical trials for non-Hodgkin's lymphoma and is exhibiting very promising therapeutic response rates in addition to evidence of toxicity buffering effects compared to conventional (nonencapsulated) vincristine.

### C. Liposomes for Multidrug Resistance (MDR) Applications

Multidrug resistance is a significant obstacle to the successful treatment of many human malignancies with chemotherapy, affecting as high as 50% of all cancer patients (98). The phenomenon of MDR is the simultaneous resis-

tance of tumor cells to a broad range of structurally and functionally unrelated drugs. Some tumor types such as colorectal, pancreatic, and renal are inherently resistant to chemotherapy, whereas other tumors initially respond only to relapse with tumors exhibiting MDR. Although it is clear that MDR is a multifactorial problem associated with various alterations in the biochemical makeup of resistant tumor cells, one very common and well-characterized mediator of MDR is the plasma membrane protein P-glycoprotein (PGP). This protein is often over-expressed in MDR tumor cells and acts by pumping anticancer drugs out of tumor cells in an energy dependent fashion (98). Consequently, numerous researchers have attempted to develop therapeutic treatment strategies whereby PGP could be either blocked or bypassed in order to circumvent MDR and improve the antitumor activity of drugs against such tumors.

Many properties of liposomal delivery systems described in the previous sections appear well suited to solving the problems associated with therapeutic strategies utilizing conventional anticancer drugs and MDR modulators. Liposomes have been applied to the treatment of MDR tumors in three basic approaches. These are (1) the use of liposomes alone as carriers for anticancer drugs to provide increased dose intensity and intracellular delivery, (2) inclusion of PGP modulators in the lipid bilayer or entrapped inside liposomes for delivery to MDR tumors, and (3) combining potent conventional MDR modulators with long circulating liposomal anticancer drugs.

#### 1. Liposomal Anticancer Drugs Alone

One of the early indications that liposomes can be beneficial for MDR reversal was observed in a study that demonstrated enhanced activity of a long-circulating liposomal formulation incorporating either the ganglioside GM1 or PEG-DSPE for doxorubicin and epirubicin against the murine C26 colon carcinoma (99,100). These C26 colon carcinoma cells are known to express moderate levels of PGP, and doses of free doxorubicin up to 10 mg/kg are rendered ineffective (99) *in vivo*. Results indicated that mice receiving sterically stabilized formulations of doxorubicin or epirubicin resulted in tumor regression to nonmeasurable sizes. In comparison, free drugs did not have any effect on delaying tumor growth. The authors attributed this enhanced activity in a relatively resistant tumor model to be due to enhanced localization of the drug in tumor tissue, drug release from liposomes into the extravascular spaces, and uptake of the released contents by the tumor. Similar results were observed with free and sterically stabilized liposomal formulations of epirubicin (100).

This ability of the liposomes to inherently overcome a certain degree of MDR stems from the fact that liposomes can markedly enhance (between 3 and 10 times) the amount of drug that can be delivered to tumors compared to free drug. For example, if the tumor exhibits a resistance factor of 5-fold, this could theoretically be overcome by increasing anticancer drug dose intensity through liposomal delivery. The fact that stealth liposomes were able to provide tumor regression in C26 colon carcinoma cells by delivering higher amounts of the drug supports this argument. However, for tumors exhibiting higher resistance levels, liposomes by themselves may be unable to circumvent MDR significantly, as demonstrated in a rat glioblastoma tumor model (101). In further support of this argument, DSPC/Chol liposomal DOX alone at a dose of 10 mg/kg was unable to circumvent PGP mediated MDR in a murine P388/ADR solid tumor model, where resistance factors are in the order of 50- to 100-fold (102).

Antibody-coated liposomes have the ability to provide targeting and selective toxicity towards tumor cells, and this has been demonstrated in KLN-205 squamous cell carcinoma *in vivo* (85). By targeting tumor cells expressing a specific internalizable surface epitope, these immunoliposomes provide a unique approach of providing intracellular tumor delivery of the drug (103). This is exemplified by a study that reported that doxorubicin resistance was modulated by an immunoliposome targeting transferring receptor in MDR human leukemic cells (104). However, site-directed targeting may not result in enhanced antitumor activity unless targeting leads to endocytosis, since most tumor cells do not actively internalize nontargeted liposomes. In addition, given the penetration difficulties experienced for immunoliposomes in larger solid tumors, it is likely that this application to circumvent MDR may be limited to circulating hematopoietic malignancies, as has been suggested by Allen and coworkers (103,105).

## 2. Liposomal MDR Modulators

Studies with liposomes composed of certain acidic phospholipid-based systems such as phosphatidylserine (106,107) or cardiolipin liposomes (108) have shown that these lipids are able to increase the cytotoxicity of encapsulated or complexed anticancer drugs against MDR cells. MDR reversal using such phospholipids has been related to increased intracellular delivery of anticancer agents as well as a direct PGP blocking effect (109,110). While these results provided encouraging data implicating certain lipids as PGP modulating agents, acidic lipids such as cardiolipin and phosphatidylserine are readily recognized by phagocytic cells of the reticuloendothelial system, and liposomes containing these lipids are cleared within minutes

from the circulation offering little systemic availability *in vivo*. Given the rapid clearance of negatively charged liposomes from the plasma, it is yet to be demonstrated that such liposome systems will be of use in treating solid tumors. Liposomes have also been employed to deliver antisense oligonucleotides and ribozymes against *mdr-1* mRNA, and studies demonstrated increased therapy when the antisense was encapsulated in liposomes (111,112). However, effective reduction in *mdr1* mRNA and protein levels is often only obtained when used in conjunction with cationic liposomes (113). Currently, the therapeutic utility of such cationic liposomes is limited to local delivery, since these systems are also cleared very rapidly after systemic administration and are unlikely to provide any systemic delivery.

We have also investigated the activity of conventional small-molecule PGP inhibitors encapsulated in liposomes as MDR modulators. However, to date such MDR modulators are either not amenable for liposomal encapsulation or exhibit high leakage rates after *iv* injection. We have demonstrated that modulators such as verapamil, prochlorperazine (67), and cyclosporin A (40,41) could be effectively entrapped within liposomes. However, their very high membrane permeabilities resulted in rapid leakage from the liposomes on *iv* administration (41, Mayer, unpublished observations), which compromises any potential advantages of such liposomes to provide improved selectivity of tumor delivery for these agents through the use of long circulating liposomes. It is speculated that stable liposomal modulator formulations will increase the selectivity of their reversal properties in solid tumors. However, in order for such liposomes to be formulated, the modulator must possess either higher affinity for the liposomal membranes or significantly reduced membrane permeability when entrapped in the liposome interior (see Section III.A).

## 3. Liposomal Anticancer Drugs Combined with Conventional PGP Inhibitors

Several compounds from various therapeutic classes already approved for human use were shown to effectively block PGP in tumor cells *in vitro* and restore their sensitivity to anticancer agents. However, virtually all of these first-generation modulators displayed significant toxicities at doses required to achieve PGP blocking concentrations in plasma as a result of their inherent pharmacological activity. Although second-generation agents such as the cyclosporin derivative PSC 833 have alleviated many of the problems experienced with first-generation MDR modulators, they often cause significant alterations in pharmacokinetics and biodistribution properties of the anticancer

drugs when coadministered, which typically necessitates a significant (approx. 50%) reduction in the anticancer dose (reviewed in Ref. 114). Studies have suggested that this is due to PGP blockade in normal tissues, given the localization of PGP in such tissues as the liver and kidney, which have a secretory function. When anticancer drug doses are reduced to accommodate modulator-induced anticancer drug pharmacokinetic alterations and toxicity, it complicates interpreting whether these dose adjustments affect drug exposure to the tumor and antitumor activity compared to anticancer drug administration alone. Consequently, the disappointing results from a number of Phase II clinical trials in patients with colorectal, lung, ovarian, breast, renal cell, myeloma, and leukemic cancers cannot be used to resolve the importance of PGP in these tumor types.

Given the pharmacokinetic changes induced by PSC 833 on conventional (free) doxorubicin, we postulated that liposomes may limit these effects by virtue of their ability to reduce the exposure of encapsulated drug to the kidneys and alter clearance of doxorubicin in the liver. These tissues appear to be key factors involved in PSC 833-induced doxorubicin pharmacokinetic changes (115). This, combined with the ability of small liposomes to extravasate passively in tumors, opened the possibility that liposomal doxorubicin may avoid the adverse pharmacokinetic interactions with PSC 833, which may lead to increased selectivity of PGP modulation drug effects at the tumor site and result in improved therapy of MDR solid tumors.

Our initial studies with DSPC/cholesterol doxorubicin formulations demonstrated that liposome encapsulation using nonleaky liposomes could significantly ameliorate the adverse toxicity effects of PSC 833 on doxorubicin when compared to free drug form (102). This was accompanied by a lack of PSC 833-induced alterations in doxorubicin plasma pharmacokinetics for the liposomal formulation, whereas free doxorubicin displayed dramatic increases in terminal elimination phases and AUC when coadministered with the MDR modulator (102). Subsequent studies showed that protection from PSC 833-induced doxorubicin toxicity was related to the ability of liposomes to reduce the rates of biliary and urinary excretion (116). In this context, sterically stabilized liposome encapsulated doxorubicin displayed the least extent of urinary and biliary doxorubicin excretion compared to conventional PC/cholesterol systems, most likely reflecting the reduced uptake of such liposomes by the liver and minimal doxorubicin release in plasma compared to EPC/cholesterol liposomes. For sterically stabilized liposomal doxorubicin, drug excretion rates were well within the capacity of biliary and urinary doxorubicin clearance even under conditions of PSC 833 impairment.

In addition to the improved toxicity profile of sterically stabilized liposomal doxorubicin combined with PSC 833

compared to other liposomal systems, this formulation also exhibited superior antitumor activity compared to conventional liposomes and nonencapsulated doxorubicin. Solid MDR human breast cancer xenografts were virtually unaffected by combinations of PSC 833 and free doxorubicin. In contrast, the MDR tumors regressed and were kept in remission for weeks when combined with DSPC/cholesterol/PEG-DSPE (55:40:5 molar ratio) entrapped doxorubicin (117). Improved antitumor activity against the MDR tumors was also observed for EPC/cholesterol and DSPC/cholesterol formulations, but the degree of therapy was inferior to that obtained with the sterically stabilized liposomes. Confocal fluorescence microscopy of fresh solid tumor specimens after treatment with doxorubicin and PSC 833 revealed that increased intracellular accumulation of doxorubicin in the MDR tumor cells was observed with coadministration of PSC 833, and the extent of tumor cell drug uptake was significantly greater for sterically stabilized liposome formulations compared to either EPC/cholesterol entrapped or nonencapsulated doxorubicin. These results indicated that the enhanced therapeutic profile of liposomal doxorubicin combined with PSC 833 was related to the maintenance of elevated tumor doxorubicin exposure in conjunction with PGP inhibition by PSC 833. In addition, the ability to achieve increased antitumor activity of liposomal doxorubicin when combined with PSC 833 in the absence of altered total tumor drug accumulation levels strongly supported the direct role of PGP inhibition in sensitizing MDR tumors to doxorubicin. Taken together, the results observed for liposome applications to circumvent MDR suggest that optimal performance will be obtained using sterically stabilized liposomes.

#### IV. FUTURE DIRECTIONS

We now have numerous techniques available to optimize liposomal anticancer drug formulation characteristics such as entrapment efficiency, *in vivo* drug leakage, circulation longevity, protein binding, tumor accumulation, triggered drug release, and intracellular delivery. Since most production and characterization issues have been resolved with the first wave of commercial liposome formulations, it is likely that our success in developing effective liposomal anticancer agents will be limited primarily by matching the correct biological performance properties with the right active agent and applying it to the appropriate tumor population. For example, the exciting recent efficacy results obtained with thermosensitive liposome formulations of doxorubicin suggest that such an ability to control the release and tumor cell exposure of entrapped cytotoxics will dramatically improve the therapeutic activity of liposomal for-

mulations. However, this application may not be straightforward for other cancer drug classes, particularly cell cycle specific drugs (e.g., vinca alkaloids and camptothecins), where duration of exposure may be more important in dictating antitumor activity than peak tumor drug levels. In this case, slower drug release rates or pulsed drug leakage may be required in order to optimize therapy. It remains to be seen whether thermosensitive liposomes can be readily manipulated to provide a range of drug release properties. Based on the results obtained to date, we predict that major improvements in antitumor activity of liposomal anticancer drugs will be obtained if drug bioavailability can be controlled at the tumor site in this fashion.

This review did not address the area of liposomal formulations of plasmids and oligonucleotides for cancer gene therapy. This topic has received tremendous interest in numerous laboratories over the past decade, and several applications have progressed to the stage of clinical trials. However, these trials have utilized formulations for direct tumor injection, s.c. injection, or ex vivo exposure due to the technical complexity of DNA–liposome formulations and their general incompatibility for intravenous administration. These formulations typically exist as large heterogeneous aggregates of DNA–cationic lipid complexes. When lipids are incorporated to generate small DNA–lipid complexes that do not aggregate, these systems tend to exhibit poor transfecting efficiencies. The numerous approaches and applications in this area warrant separate attention, and the reader is directed to informative reviews on this topic in Chapters 34 and 35 in this book. In addition, although some liposome formulations of antisense oligonucleotides (AS-ODN) have been described in the literature (118,119), it remains to be seen whether liposomes provide significant improvements over nonencapsulated AS-ODN other than reducing the dose required to achieve the desired pharmacological effect. Clearly, these two areas will continue to attract the attention of liposome researchers focused on gene modulation approaches for cancer treatment.

Finally, a significant challenge exists in the formulation of hydrophobic anticancer drugs in liposomes so that the benefits of selective tumor delivery can be realized. Achievements to date have focused primarily on utilizing liposomes as aqueous compatible excipients for such agents or as intermediaries for drug transfer to biological carriers like lipoproteins in vivo. Consequently, one may expect to see a fourth generation of liposome technology focused on such applications. Given the historical ability of liposome researchers to overcome significant technological problems to achieve the desired biological behavior, it is likely that these challenges will be successfully met in the near future, leading to further improvements in the therapeutic potential of liposomal anticancer drugs.

## Systemic Cancer Therapy Using Polymer-Based Prodrugs and Progenes

Leonard W. Seymour

*University of Birmingham, Birmingham, England*

### I. SUITABILITY OF POLYMERS FOR SYSTEMIC ADMINISTRATION

Many soluble polymers have been proposed for use in therapeutic systems for treatment of a range of diseases (1). Several have undergone exhaustive examination in animals, and a few have made it through to clinical evaluation. The most extensively developed of these is poly(ethylene glycol) (pEG), which is now being used clinically in treatment of several disorders using polymer-protein conjugates and also forms an important excipient in the formulation of many licensed drugs (2–8). There are no significant toxicities associated with pEG, although doses administered parenterally have usually been fairly small. Poly(vinylpyrrolidone) (pVP) has been evaluated for clinical use as a plasma expander and was administered to several hundreds of soldiers in high doses during the Second World War. pVP does appear to be associated with a storage disease termed “la maladie vinylique,” but the frequency of this is remarkably low and, considering the doses administered and the delay to onset, the overall toxicity profile is very mild (9–12). Copolymers based on poly [N-(2-hydroxypropyl)methacrylamide] (pHPMA) have also seen clinical application in recent years (see below) and there have been no reported instances of any polymer-related toxicities in over 50 cancer patients treated.

One factor common to many well-tolerated polymers in therapeutic use is their lack of biodegradability in the

polymer backbone. Frequently the processes of biodegradation and immunogenicity seem to go hand in hand, probably reflecting either similar principles of macromolecular recognition involved in both processes or the requirement for intracellular degradation to permit cellular presentation of immunogenic epitopes (13). Although backbone-biodegradable polymers may appear to have advantages in terms of good distribution kinetics coupled with efficient renal excretion, they have not yet undergone thorough clinical evaluation. Poor recognition of polymers by enzymes and antibodies is likely to be an important factor contributing to the extended plasma circulation exhibited by large nondegradable polymers (such as pHPMA), and this plays a significant role in the successful application as carriers of drugs, as described in more detail below.

### II. PLASMA CIRCULATION AND EXTRAVASATION OF POLYMERS AND OTHER MACROMOLECULES

Macromolecules showing significant binding to cells, membranes, or plasma proteins are generally cleared quickly from the circulation, often by phagocytes in the spleen or liver or by trapping in fine capillary beds. Conversely, macromolecules not binding biological components can show extended circulation in the bloodstream, being cleared in the fluid phase at rates and locations dic-

tated largely by their physical properties (14,15). One significant clearance mechanism is renal excretion, where passage through the kidney glomerulus is restricted to materials of molecular mass of 50–60 kDa for proteins and 30–35 kDa for dextran and pHPMA (16). The reason for this difference in renal thresholds reflects the more extended structure of these hydrophilic polymers, compared with proteins which tend to form intramolecular bonds and adopt a more globular structure.

Extravasation from the bloodstream can also provide a significant pathway for clearance of macromolecules, with extravasated materials either becoming lodged within extracellular matrix or being recycled to the bloodstream via the lymphatics. The permeability of the blood vessels varies significantly between organs and tissues, although generally the wall of the arterioles are relatively impermeable, with capillaries generally thought to be more permissive to extravasation. Postcapillary venous endothelium shows the highest permeability within an individual tissue, although the low postcapillary blood pressure probably does not promote extravasation; in contrast, these are regions where osmotic force is collecting tissue fluid from the interstitium back into the circulation, and hence the net flow is usually away from the tissues into the blood.

Capillaries are generally described as tight, fenestrated, or sinusoidal. The tightest capillaries in the body are found in the brain, supported on a continuous basement membrane and with very low levels of fluid-phase extravasation. Fenestrated capillaries are found in many places, including the kidney and intestine, where limited extravasation is important. Generally speaking, however, size restrictions prevent extravasation of most proteins. This limited permeability is reflected in the protein content of interstitial fluid, which is about 10% that of whole serum (and underlies the 10% serum conditions employed for culture of most mammalian nonblood cells, where 100% serum is often toxic) and is also important to prevent uncontrolled loss of proteins in the urine. Sinusoidal endothelium is found in the bone marrow, liver, and spleen. In these organs the basement membrane is either highly discontinuous or absent, and the vessels are freely permeable. This complements the phagocytic activity of cells contained within these organs, providing access of blood-borne macromolecules and particles to cells designed to sequester them (17).

### III. INFLUENCE OF PHYSICOCHEMICAL PROPERTIES ON PHARMACOKINETICS OF MACROMOLECULES

The pharmacokinetic of systemically administered macromolecules have undergone extensive study in animals in

order to determine the most promising candidates for use as drug carriers (18,19). Two key factors emerge as determinants of distribution kinetics, molecular weight and molecular charge. Macromolecules smaller than the renal threshold are rapidly cleared from the circulation into the urine. Initially this would appear to indicate in favor of larger molecules, but when the macromolecule is nonbiodegradable, eventual excretion is useful to decrease unwanted toxicities. Hence some agents (such as the doxorubicin conjugates described below) are smaller than the renal threshold, and are therefore applied at high doses to achieve the required systemic exposure.

Macromolecules with significant positive charge show electrostatic interaction with cells, membranes, and connective tissues *in vivo*, undergoing unwanted rapid elimination from the bloodstream. Conversely, macromolecules with strong negative charge act as substrates for the polyanion scavenger receptors of Kupffer cells and other phagocytes and are also cleared quickly from the circulation. Optimum circulation is obtained using macromolecules with a hydrophilic structure, noncharged or slightly negatively charged under physiological conditions. Hence for targeted systemic delivery of therapeutic agents, neutral or slightly negative charged carriers are normally employed.

### IV. TUMOR VASCULAR PERMEABILITY AND THE EPR EFFECT

Tumors are usually thought to arise from uncontrolled proliferation of a single malignant cell, produced by the acquisition of several genetic mutations. Some of the mutations are inherited, and others are caused by environmental factors during the lifetime of the individual. Consequently, the growing tumor is a relatively simple structure, composed of a small mass of proliferating cells. However, such a structure is unable to grow beyond a size of 2 mm approximately, due to the difficulty of obtaining a sufficient supply of oxygen and nutrition that must diffuse an increasing distance from the nearest blood vessel (20–23). Hence successful tumors must mutate to become angiogenic, in other words they must attract capillaries to provide them with blood and nutrients. In order to do this tumors produce various angiogenic factors, secreted from tumor cells and mediating mitogenic and chemoattractant effects through specific receptors expressed on the surface of endothelial cells (21–26). In this way capillary cells can be recruited and induced to differentiate to form capillary tubular sprouts and eventually fully functional capillary structures. This enables the tumor to obtain better nutrition and oxygenation, and hence a larger tumor mass can be viable.

In order to grow, tumors recruit macromolecules from the bloodstream and incorporate them into the extended tumor matrix by clotting them. This matrix extracellular stroma provides a framework for the local migration and growth of new tumor cells and facilitates enlargement of the primary tumour and its invasion of nearby tissues. The tumor usually recruits its extracellular matrix from the bloodstream, but the efficiency of extravasation of proteins such as albumin and fibrinogen is usually very low in normal vasculature. Tumors therefore secrete permeability-enhancing factors, designed to act on endothelial cells and increase the rate of extravasation in tumor vasculature. The best characterised tumor-secreted vascular permeabilizing factor is vascular endothelial growth factor (VEGF), originally also termed vascular permeability factor (VPF). The mechanism of action is not yet completely understood, although the molecule is known to bind specifically to two types of receptors, known as flt-1 and KDR (VEGF-receptors 1 and 2), on the endothelial cell, exerting signaling cascades and mediating several biological responses *in vitro*. *In vivo*, VEGF is known to be a very potent inducer of extravasation, although whether fluid extravasates paracellularly (between the endothelial cells) or by transcytosis (by transcellular vesicular pathways, such as the recently reported vesiculovacuolar organelles (VVOs), is only presently being elucidated (27,28).

Another property of tumors that significantly affects their accessibility to macromolecules is their inadequate lymphatic drainage. The reason for this is unknown, but presumably it involves either a lack of lymphangiogenic agents produced by tumors, or possibly overgrowth of lymphatic vessels by the proliferating tumor cells (29–31). In either case there is deficiency of fluid drainage from many tumors, notably carcinomas, that leads to an interstitial blood pressure that is significantly elevated in tumors compared with the corresponding normal tissues. This in turn may contribute to collapse of capillaries, resulting in poor blood supply in the center of solid tumors, giving rise to hypoxic and necrotic regions. Production of permeability-enhancing VEGF is known to be induced by hypoxia, and hence the residual blood vessels serving the tumor tend to have regions of high vascular permeability (27,28,32).

This combination of enhanced vascular permeability and poor lymphatic drainage has been termed the enhanced permeability and retention (EPR) effect (19,33–36). One result of the EPR effect is that tumors capture substantial levels of circulating macromolecules, which extravasate and then are unable to rejoin the blood circulation in the normal way (35,37). Clearly one role for this capture is to provide the tumor with macromolecules for clotting and formation of new substratum. However, if the macromolecule is actually an anticancer drug, this provides a simple yet effective means of concentrating the therapeutic agent

within the tumor and can mediate significant benefit (19).

## V. PRINCIPLES OF TARGETING MACROMOLECULAR DRUGS

Most anticancer agents are low molecular weight drugs, able to enter cells readily either by simple diffusion or by receptor-mediated capture. Hence they tend to have a relatively high volume of distribution and short circulatory half life, mediating significant systemic toxicities by exerting their effects against any vulnerable cells they encounter. Helmut Ringsdorf proposed in 1975 that linkage of such drugs to a targeted macromolecular carrier, such as a synthetic polymer, could be used to deliver the agents selectively to their targets, simultaneously increasing their activity and decreasing unwanted side effects (38). In his original proposal Ringsdorf envisaged incorporation of drugs, targeting agents, and also solubilizing agents covalently onto the polymer carrier. In practice, incorporation of specific solubilizing agents has proved superfluous, and attempts to target polymers with agents such as antibodies is still under active development. The most advanced exemplification of the Ringsdorf approach is a system where copolymers based on poly[*N*-(2-hydroxypropyl)methacrylamide], derivatized with tetrapeptide spacers (Gly-Phe-Leu-Gly) (36,39–41), have been modified with the anticancer agent doxorubicin and the simple targeting agent galactosamine (42,43). These polymer conjugates, which are effectively macromolecular prodrugs, since they require activation by enzymic cleavage of the Gly-Phe-Leu-Gly spacer, show good anticancer activity in animals (40), and their pharmacokinetics and anticancer activity have recently been evaluated in humans (see below).

## VI. SIGNIFICANCE OF THE DRUG-POLYMER LINKAGE

The linkage of drug to polymer is key to regulating the biological activity of the drug and to providing a trigger for activation of the macromolecular prodrug. Three main types of linkage are normally used, namely those susceptible to hydrolysis at neutral pH (such as ester linkages), those subject to acid-catalyzed cleavage (e.g., based on *cis*-aconityl groups) or those designed for cleavage by target-associated enzymes (such as the Gly-Phe-Leu-Gly linkage mentioned above, which is designed for cleavage by lysosomal cathepsins). Appropriate choice of the optimum linkage, with respect to its required site of activation and the speed of activation achieved, is fundamental to successful design of a macromolecular prodrug. The reader is referred to an excellent recent review of this subject (44).

## VII. CLINICAL PHARMACOKINETICS OF POLYMER CONJUGATES

Clinical studies in the UK have recently been reported evaluating the use of doxorubicin-pHPMA conjugates, either targeted with galactosamine or without, for treatment of cancer (45,46). The incorporation of galactosamine mediates substantial hepatic targeting of the polymer conjugate, determined using an analogue bearing  $^{123}\text{I}$  (45,47). At clinical doses (approximately 1 g polymer conjugate/m<sup>2</sup>), hepatic targeting of 15–18% of the dose could be achieved, measured by gamma camera and single positron emission tomographic (SPECT) imaging. In contrast, nontargeted doxorubicin-pHPMA conjugate showed no measurable liver accumulation. Both agents showed rapid elimination from the bloodstream, with biphasic clearance kinetic and alpha half-life less than 30 min. Therapeutic activity of the agents has also been assessed and will shortly be disclosed.

## VIII. USE OF POLYMERS FOR DELIVERY OF THERAPEUTIC PROTEINS

Targeting of polymer conjugates with antibodies is fraught with difficulties, as the polymer tends to prevent access of the antibody to its cell surface target, and modifications must be performed very carefully (48,49). However, this shielding effect can be turned to major advantage when the target is a low molecular weight agent, rather than a cell surface receptor. For example, conjugates of synthetic polymers with enzymes can stabilize the enzyme, prolonging blood circulation and preventing recognition by cells, without seriously impairing access of low molecular substrates to the active site of the enzyme. The most advanced example of this approach is the use of the conjugate pEG-asparaginase (3–5). Asparaginase has been evaluated and used for many years in the treatment of asparagine-dependent leukaemia, though asparaginase itself is normally immunogenic and displays a relatively short half-life, with complications of frequent dosing. pEG-asparaginase, in contrast, shows a prolonged half-life and can be administered repeatedly when required without significant toxicological complications. Given the success of pEG-asparaginase, other pEGylated enzymes are presently under development (8,50).

## IX. GENE THERAPY: THE PROMISE AND THE HYPE

The concept of gene therapy for treatment of several diseases has attracted considerable attention in recent years, although the considerable promise of this approach is continually frustrated by inadequate systems for gene delivery

(51–55). Systemic delivery of genes is a particular problem and in all of the clinical trials performed to date the gene vector has been administered locally, either by direct injection into the target tissue, into the artery supplying it, or into the body cavity housing it. Many vectors for gene therapy are based on viruses, usually attenuated to make them nonreplicative in order to improve their safety profile. These agents are often highly efficient following arrival at the target cell, but they usually have no intrinsic tropism for the diseased cell and tend to deliver their genes nonselectively. In addition, some virus vectors are attracting concerns over safety, and they are often neutralized by antibodies present in the bloodstream of patients. Consequently, in recent years, attention has largely shifted to the development of fully defined synthetic vectors.

## X. SYNTHETIC VECTORS FOR SYSTEMIC GENE DELIVERY

There are two main types of synthetic vector for gene delivery—those based essentially on cationic lipids (51,52), and those based on cationic polymers (56). The former have the advantage of good ability to disrupt membranes and mediate relatively efficient delivery of DNA, while the latter are more selective in transfection and are more suitable for intravenous administration. Cationic lipid/DNA complexes are usually sequestered by the first capillary bed they encounter, normally the pulmonary bed following intravenous administration (57), and this severely hampers their ability to reach dispersed systemic cellular targets. Polyelectrolyte DNA complexes, on the other hand, show less tendency to occlude capillary beds following intravenous injection, often passing through the lungs into the oxygenated blood and then dispersing throughout the body in the arterial circulation. Factors affecting biodistribution will be assessed for both types of vector in turn.

### A. Systemic Distribution of Cationic Lipid/DNA Complexes

When DNA binds to cationic liposomes, the structures reorientate and the DNA is thought to become coated in a double membrane of cationic lipid, with the outside surface presenting a combination of cationic charge and hydrophobic domains (58). This is thought to mediate the high membrane activity of the complexes, although it also mediates interaction of lipid complexes with proteins in the plasma, leading to the formation of large aggregates. This is likely to constitute a major contributory factor in the pulmonary first pass clearance, although the precise details of the solvent employed and the volume administered can significantly affect biodistribution, probably by regulating the

speed at which the complexes encounter serum proteins, and to some extent affecting the solvent in which the mixing takes place (15,51,59). The organ immediately preceding and also following the pulmonary capillary bed is the heart, and cationic lipid formulations with significant membrane activity can often achieve measurable deposition and even transgene expression within the cardiac endothelium as well as the pulmonary endothelium.

### **B. Systemic Distribution of Cationic Polymer/DNA Complexes**

Most simple cationic polymer/DNA complexes are cleared rapidly from the circulation following intravenous administration, usually becoming sequestered by cells in the liver (60). The precise reasons for this are presently under intensive investigation, although they are usually assumed to include binding of serum proteins to the complexes leading to their destabilization and rapid phagocytic scavenging by Kupffer cells (61). There is evidence that simple polyelectrolyte complexes that remain in the circulation are actually bound to the surface of erythrocytes (Ward and Seymour, unpublished observations), and this may represent one strategy for gaining systemic circulation of such gene delivery vectors; however, passage of complexes through the endothelial layer to gain access to extravascular target cells would present a significant problem.

## **XI. STERIC STABILIZATION OF POLYELECTROLYTE COMPLEXES**

The concept of introducing a surface layer of hydrophilic polymers onto the surface of polyelectrolyte complexes in order to induce a level of stabilization, preventing their interaction with cells and proteins, has been under development for several years. Oriented self-assembly of DNA with cationic-hydrophilic block copolymers can lead to the formation of particles with a shielded surface charge (62,63), although improved pharmacokinetics of these materials have not been reported. Subsequently Ogris et al. (1999) were the first to examine the biodistribution of sterically stabilized particles following intravenous injection (64). These authors worked with pEGylated pEI/DNA complexes including also transferrin; compared with complexes lacking the pEG layer, pEGylated materials showed extended plasma circulation leading to detectable accumulation and gene expression in subcutaneous B16F10 melanoma tumors (64,65). This achievement paves the way for gaining extended circulation of sterically stabilized polyelectrolyte gene vectors that are further modified to carry target-specific ligands in order to mediate their association and uptake by preselected target cells and tissues (66).

Probably the greatest challenge in this field is to design a sterically stabilized vector that is capable of extended plasma circulation, but which incorporates a powerful trigger mechanism capable of activating strong transfection activity following arrival at the vector at the desired target site. Such systems, analogous to the design of macromolecular prodrugs, could be regarded as inactive chemical precursors of transcriptionally active DNA, or "progenes." Suitable triggers might involve selective processing by target-associated enzymes, or they could involve the falling endosomal pH after endocytic internalization of complexes into cells. Design of effective triggers in many ways reflects the development of effective drug-polymer spacers, described above, and it may be that the most effective systems are based ultimately on the same principles.

## **XII. SURFACE MODIFICATION AND STERIC STABILIZATION OF ADENOVIRUSES**

Recent studies have shown that viruses, specifically adenoviruses, can be surface modified with hydrophilic polymers in order to decrease binding of antiadenovirus antibodies that often restrict clinical usefulness. Judicious application of the polymer can either maintain binding to the normal adenovirus receptor (CAR) or ablate it (67,68). Preventing CAR-mediated infection of cells essentially prevents normal infection, and the introduction of new targeting ligands onto the polymer-coated virus can then promote its infection of chosen cells by target-associated receptor-mediated endocytosis. These polymer-coated virus vectors offer considerable steps forward for gene therapy, combining the great infective power of adenoviruses with the versatile targeting and low antibody binding activity of nonviral vector systems.

## **XIII. CONCLUSIONS**

It is enlightening that soluble polymers are finding useful applications through the fields of systemic therapies. At one level they can enhance solubility of hydrophobic drugs and change their pharmacokinetics, simultaneously endowing them with the possibility of targeting to desired sites of action. With larger molecules, such as proteins, they are capable of steric stabilization, preventing interaction with proteases and extending plasma circulation. In the context of polyelectrolyte complexes for gene delivery, hydrophilic polymers are capable of steric stabilization but also of cross-linking the surfaces of complexes, preventing their desegregation by components of the plasma. Finally, in new fields that are just being probed, hydrophil-

lic polymers are clearly capable of enshrouding biological agents such as viruses, preventing antibody recognition and permitting the introduction of new targeting tropisms. Each of these approaches holds important clinical advances, often in different and sometimes complementary therapeutic fields, and each is presently under active development in widespread parts of the global research community.

## Anticancer Drug Conjugates with Macromolecular Carriers

F. Kratz, A. Warnecke, K. Riebeseel, and P. C. A. Rodrigues

*Tumor Biology Center, Freiburg, Germany*

### I. INTRODUCTION: DRUG TARGETING IN ANTICANCER CHEMOTHERAPY USING MACROMOLECULAR CARRIERS

The therapeutic concept of drug targeting is founded on Paul Ehrlich's vision of "the magic bullet," which he proclaimed at the beginning of the last century (1). Ehrlich's notion was based on a concept of affinity between a drug acting as a ligand and a molecular target, e.g., a receptor (see Fig. 1). Even if the precise molecular targets for all of today's drugs are not known, Ehrlich's concept appears to be valid in principle.

With the advances in protein crystallography and molecular modeling, the number of tailor-made drugs will certainly increase. However, even when the drug and its molecular target interact ideally according to a "key and lock principle," the issue of site-specific and optimal drug delivery, especially for drugs with a narrow therapeutic index, has not been satisfactorily solved for a great number of medical indications. Indeed, tailor-made drugs that fit neatly into their target cannot always be developed clinically due to poor water-solubility or rapid elimination from the body after systemic administration of the respective drug candidate. In this respect, fundamental goals of drug conjugation with suitable carriers are to circumvent such inherent disadvantages and to achieve a higher concentration of the drug at its site of action.

In the field of cancer research, coupling of anticancer drugs to macromolecular carriers received an important

impetus from 1975 onwards with the development of monoclonal antibodies by Milstein and Köhler (2). In addition, research efforts have recently concentrated on conjugating anticancer agents with a wide spectrum of macromolecules including polysaccharides, lectins, serum proteins, peptides, growth factors, and synthetic polymers. Some typical examples are summarized in Table 1.

The rationale for simply using high molecular weight molecules as efficient carriers for the delivery of antitumor agents, even if they are not targeted towards an antigen or receptor on the surface of the tumor cell, has been strengthened by recent studies concerning the enhanced vascular permeability of circulating macromolecules for tumor tissue and their subsequent accumulation in solid tumors (3–9). This phenomenon has been termed "enhanced permeability and retention" in relation to passive tumor targeting (EPR effect) (3) and is depicted schematically in Fig. 2. Blood vessels in most normal tissues have an intact endothelial layer that allows the diffusion of small molecules but not the entry of macromolecules into the tissue. In contrast, the endothelial layer of blood vessels in tumor tissue is often leaky, so that small as well as large molecules have access to malignant tissue. Because tumor tissue does not generally have a lymphatic drainage system, macromolecules are thus retained and can accumulate in solid tumors.

The pathophysiology of tumor tissue, characterized by angiogenesis, hypervascularity, a defective vascular architecture, and an impaired lymphatic drainage, seems to be a universal feature of solid tumors that can be exploited

**Figure 32.1** Hand drawing by Paul Ehrlich (1854–1915) illustrating his concept of receptor–ligand interaction. (We thank Professor Gerd Folkers of the ETH, Zürich, Switzerland, for supplying this figure.)

**Figure 32.2** Schematic representation of the anatomical and physiological differences between normal and tumor tissue with respect to vascular permeability of small and large molecules.

for tumor-selective drug delivery. A detailed description of the EPR effect is given in the article by L. Seymour in this book.

This article focuses on the design of drug polymer conjugates, on drug conjugation techniques, and on drug polymer conjugates that have reached the clinical setting or an advanced stage of preclinical development. Monoclonal antibodies, serum proteins, growth factors, cytokines, and polysaccharides are discussed as macromolecular carriers. Drug conjugates with synthetic polymers are presented in detail in the contribution by L. Seymour.

**Table 32.1** Examples of Macromolecular Carriers for Anticancer Agents

Macromolecular carrier	Examples
<b>Biological macromolecules</b>	
Proteins	Antibodies, serum proteins
Polysaccharides	Dextran, hyaluronic acid
Lectins	Concanavalin A
Peptides	Growth factors, cytokines
Nucleic acids	Deoxyribonucleic acid (DNA)
<b>Synthetic macromolecules</b>	
Poly(amino acids)	Polylysine, polyaspartic acid
Copolymers	Styrene–maleic acid anhydride copolymer (SMA) Divinylether–maleic acid anhydride copolymer (DIVEMA) N-(2-hydroxypropyl)methacrylamide copolymer (HPMA)
Polymers	Polyethylene glycol (PEG) Polyvinylalcohol (PVA)

Primarily, the review describes conjugates with organic anticancer agents of clinical relevance. Immunotoxins are only discussed with growth factors and cytokines because anticancer drugs have rarely been coupled to these carriers. It is beyond the scope of this article to review the vast amount of work that has been carried out with immunotoxins using antibodies, and the reader is referred to several review articles covering this topic (10–12).

In our discussion, we make no attempt to include every conjugate that has been developed and investigated *in vitro*; rather, examples are described that illustrate the characteristics of a particular drug delivery system. When covering the different macromolecular carriers that have been used for drug conjugation, we have taken care to refer to pertinent review articles that have appeared throughout the past 30 years.

## II. DESIGN OF ANTICANCER DRUG CONJUGATES

### A. Macromolecular Prodrugs with Anticancer Agents—Similarities and Differences in Their Design and Implications for Their Preparation

In 1975, Ringsdorf proposed a general model for a drug delivery system using synthetic polymers (see Fig. 3) (13). A definite number of drug molecules are bound to a macromolecule through a spacer molecule that incorporates a predetermined breaking point to ensure release of the drug after cellular uptake of the conjugate (the significance of incorporating predetermined breaking points will be discussed in Section D). The system can also contain targeting moieties, e.g., tumor-specific antibodies (14), antibody fragments (15), or saccharides (14), which render the conjugate biorecognizable and enhance cellular uptake by receptor-mediated endocytosis.

Macromolecules chosen for the preparation of drug conjugates should ideally be water soluble, nontoxic, and

nonimmunogenic. Furthermore, after fulfilling their function, they should be degraded and/or eliminated from the organism (16). A final, and from the chemical point of view most important, feature of the carrier is the existence of drug attachment sites or at least the possibility of their creation through chemical modification of the polymer. The number of accessible attachment sites depends on the type of polymer. The majority of relevant synthetic polymers are homopolyfunctional: classical examples for mono- or bifunctional polymers are poly(ethylene glycols) (PEGs), which have the advantage that the drug loading rate is well-defined (17).

In contrast to synthetic polymers, biomolecules (e.g., serum proteins, antibodies, or polysaccharides) are classified as heteropolyfunctional due to the abundance of different functional groups that can compete with each other in coupling reactions. Treatment of biomolecules with unspecific coupling agents can yield mixtures, and conjugation methods that allow group-specific coupling of the drug to the biopolymer are therefore preferred. Furthermore, coupling of low molecular weight drugs to proteins or antibodies should yield stable products preserving their native state and activity (e.g., drug–antibody conjugates have to retain their affinity for corresponding antigens). Hence coupling reactions are carried out in aqueous solution under mild conditions (temperature range 5–37°C, pH range 6–8, low concentration of organic solvents) in order to prevent the biopolymer from denaturation and/or degradation.

In the following section, the description of coupling methods will be restricted to *bioconjugation* methods for developing drug–polymer conjugates. Examples including synthetic polymers as carriers will be additionally mentioned if the applied coupling method can be classified as a typical bioconjugation technique. This article will not cover special methods that are only applicable to the preparation of drug conjugates with synthetic polymers (e.g., copolymerization of drug derivatives with suitable monomers), and we refer the reader to excellent reviews covering this topic (16,18).

### B. Bioconjugation Methods Used for the Preparation of Drug–Carrier Conjugates

Bioconjugate chemistry plays an important role in today's life sciences; applications range from basic protein chemistry to applied biotechnology and from immunology to medicine; relevant methods have been reviewed extensively (19–21). In the field of bioconjugation, the two terms cross-linking and conjugation are often used synonymously although there is a fine distinction in connotation between them. Cross-linking usually refers to the joining of two molecular species that have some sort of affinity

**Figure 32.3** Ringsdorf's model for drug delivery systems based on synthetic polymers.

between them. Covalent coupling of a ligand to its receptor is an example of cross-linking as well as the formation of chemical bonds between subunits of enzymes. Conjugation, however, refers to the coupling of two unrelated species. Thus coupling low molecular weight anticancer drugs to macromolecules belongs to this category. Nevertheless, coupling reagents for conjugation purposes are denoted as cross-linking agents, and we also use this expression in our article.

Cross-linking agents with two attachment sites are classified as homobifunctional and heterobifunctional, respectively. Glutaraldehyde is a popular member of the first group, forming Schiff bases with amines. However, homobifunctional cross-linkers are not always appropriate for the preparation of well-defined drug-polymer conjugates, and even from a theoretical point of view quantitative coupling is impossible (22). In contrast, heterobifunctional cross-linking agents have the advantage that different functional groups of the polymer as well as of the drug can be chemically exploited. Typically, the drug is first reacted with the heterobifunctional cross-linker and then coupled to another functional group of the polymer without prior purification of the derivatized drug. Although a number of heterobifunctional cross-linking agents are commercially available, most of them were designed for the conjugation of proteins. Several groups have therefore developed tailor-made heterobifunctional cross-linkers that allow an improved derivatization of the respective functional group of the drug. Furthermore, it has proved advantageous to isolate and characterize the polymer-binding drug derivative, which is subsequently coupled to the surface of the macromolecular carrier. In this way, the drug loading ratio, the purity of the conjugate, as well as the nature of the chemical bond between the drug and the carrier are better defined.

In the next two sections, the main functional targets of biopolymers and their reactivity in coupling reactions will be discussed (Section II.B.1), and a short overview of methods for the chemical modification of functional groups will be given (Section II.B.2). Section II.C deals with specific coupling reactions with respect to the functional groups discussed in Section II.B.1.

## 1. Functional Targets for Bioconjugation

### a. Polypeptides (Proteins)

The twenty amino acids that constitute proteins can be divided into three classes according to the polarity of their side chains (Fig. 4).

The degree of hydrophilicity and hydrophobicity is one of the major determinants of the three-dimensional structure of proteins. In contrast to hydrophobic amino acids

that are generally found in the interior of proteins, hydrophilic groups are located on the surface of the protein, where they can interact strongly with the aqueous environment. Eight of the hydrophilic side chains are chemically active. These are the guanidinyll group of arginine, the  $\beta$ - and  $\gamma$ -carboxyl groups of aspartic and glutamic acid, respectively, the sulfhydryl (thiol) group of cysteine, the imidazolyl group of histidine, the  $\epsilon$ -amino group of lysine, the thioether moiety of methionine, and the phenolic hydroxyl group of tyrosine. However, the frequency with which they are incorporated in proteins differs substantially, and some of them are rarely found (Table 2) (23).

Important functional targets are the sulfhydryl group of cysteine, the amino group of lysine, and the carboxylic groups of aspartic and glutamic acid.

The nucleophilicity of functional groups as well as the electrophilic properties of the attacking polymer-binding group are fundamental parameters in coupling reactions. Nucleophilicity is influenced by various factors, such as charge (which again depends on the pH value), basicity, size, and polarizability. Furthermore, the influence of the solvent cannot be neglected, since the order of nucleophilicity can be reversed by changing from a protic solvent to an aprotic polar one (e.g., DMF or DMSO). Pearson and coworkers measured the rate constants of the reaction between methyl iodide and various nucleophilic compounds in methanol to formulate the following order of nucleophilicity (24,25):

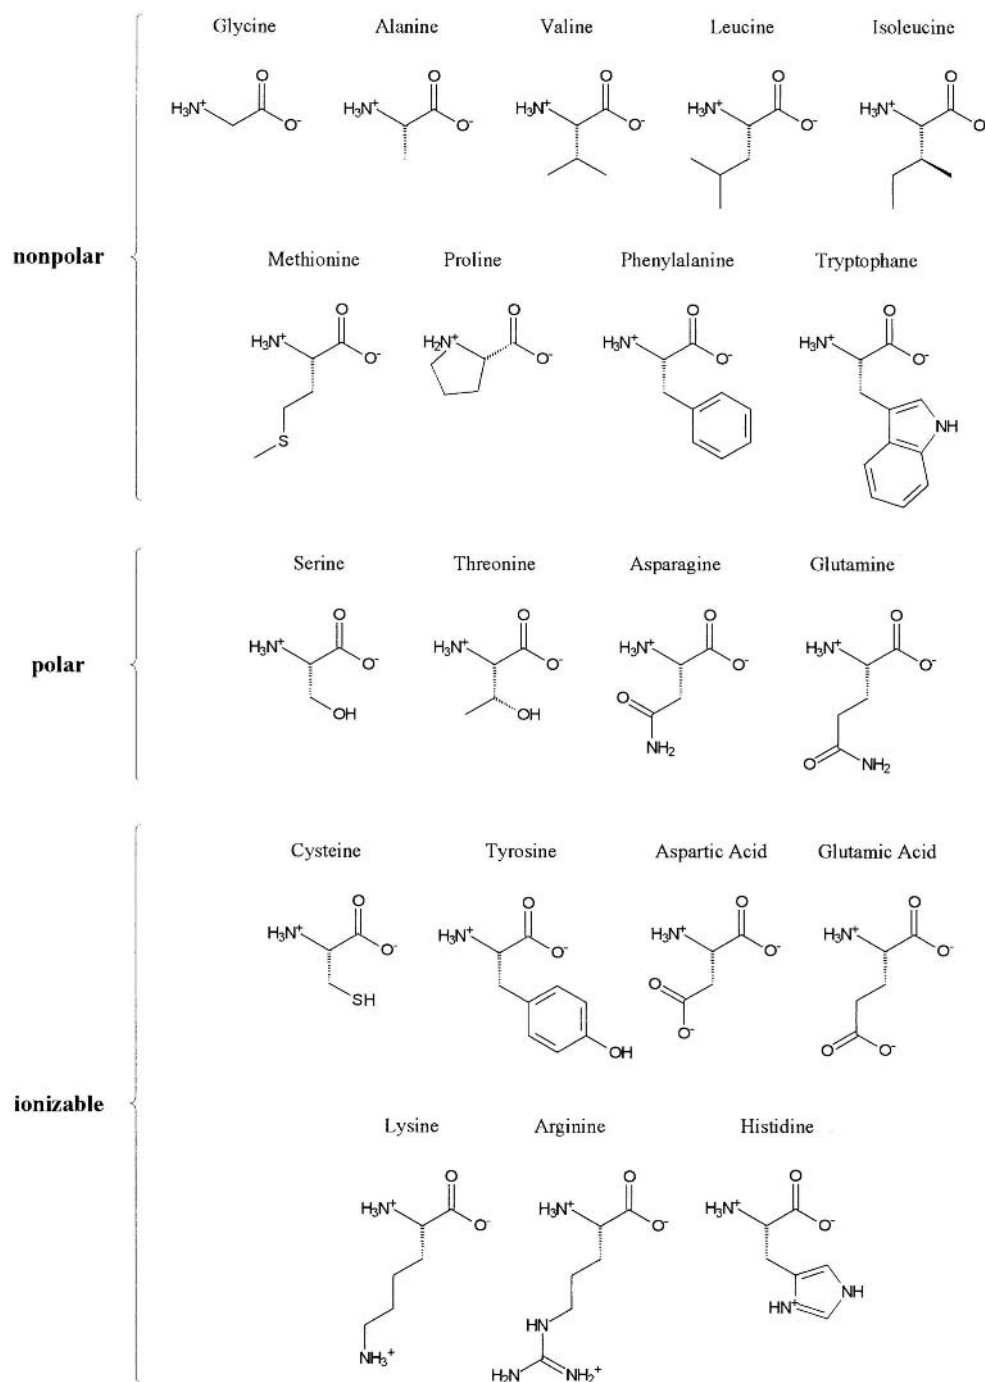

The strongest nucleophile is the thiol group in its ionized, thiolate form, followed by the amino group. Thioethers and carboxylic acids are less potent nucleophiles. Applying this order of nucleophilicity to amino acid residues, we obtain the following general order:

The aliphatic hydroxyl groups of serine and threonine, having about the same nucleophilicity as water, are generally unreactive in aqueous solutions. A reactive reagent will preferably undergo hydrolysis before it reacts with amino acids containing hydroxyl group.

One of the most important considerations for planning coupling reactions is the choice of the pH value. For example, the protonated form of amino groups is unreactive towards electrophilic agents. According to the equation of Henderson and Hasselbalch (1), an ionizable group is 50% protonated at its  $\text{pK}_a$  value.

$$\text{pH} = \text{pK}_a + \log \left( \frac{[\text{base}]}{[\text{acid}]} \right) \quad 1$$

**Figure 32.4** Structures of the twenty common amino acids.

Further implications of this equation are that at one or two pH units above the  $\text{pK}_a$ , an acidic group will be 91% and 99% deprotonated, respectively.  $\text{pK}_a$  ranges of the major functional targets of proteins are given in Table 3 (20). Notably,  $\text{pK}_a$  values can vary up to three  $\text{pK}_a$  units in ex-

treme cases depending on the influence of the microenvironment.

Generally, coupling reactions are carried out by adjusting the pH value close to the  $\text{pK}_a$  value of the protonated form of the respective functional group.

**Table 32.2** Average Frequency with which Amino Acids Are Incorporated in Proteins. Values were Determined by Comparing the Structures of 207 Nonrelated Proteins

Amino acid	Average frequency of incorporation (%)
Arginine	4.7
Aspartic acid	5.5
Glutamic acid	6.2
Histidine	2.1
Lysine	7.0
Tyrosine	3.5
Cysteine	2.8
Methionine	1.7

Source: Ref. 23.

Fortunately, the reaction profile of amino acid residues with coupling agents does not depend only on their nucleophilic properties (otherwise, it would be difficult to achieve group specific coupling) but also on the nature of the attacking electrophile. In some cases, the HSAB (hard and soft acids and bases) principle propagated by Pearson can serve as a tool for predicting preferences of a nucleophile towards an electrophilic group of a coupling agent (26,27).

Finally, it should be mentioned that, apart from nucleophilic reactions, group specific properties can be exploited for conjugation purpose. Cysteine, for example, is susceptible to oxidation forming disulfide bonds. Tyrosine residues represent activated aromatic systems that can undergo electrophilic reactions, e.g., addition of iodine or diazonium salts (labeling reactions), and Mannich condensation reactions. To our knowledge, the latter reaction has not been applied in the field of drug-carrier conjugation.

#### b. Polysaccharides

Polysaccharides are polymers in which monosaccharide units are covalently linked via acetale (ketale) bonds.

**Table 32.3** pK<sub>a</sub> Ranges of Amino Acid Side Chains in Proteins

Amino acid residue	pK <sub>a</sub> range
Lysine	9.3–9.5
Histidine	6.7–7.1
Arginine	> 12
Tyrosine	9.7–10.1
Aspartic acid	3.7–4.0
Glutamic acid	4.2–4.5
Cysteine	8.8–9.1

Popular polysaccharide carriers for drugs are dextran, chitosan, and hyaluronic acid consisting of D-glucose, D-glucosamine, and N-acetyl-D-neuraminic acid, respectively. With the exception of hyaluronic acid and chitosan, polysaccharides merely contain hydroxyl groups as primary targeting moieties. Thus for performing coupling reactions in aqueous solutions, the biopolymer has to be modified by introducing functional groups of higher reactivity. However, coupling reactions using polysaccharides can also be carried out in organic solvents that allow the drug to be coupled to hydroxyl groups.

#### c. Antibodies

Most tumor-targeted monoclonal antibodies belong to the immunoglobulin- $\gamma$  (IgG) class. IgGs are symmetric glycoproteins composed of heavy and light chains. At the ends of these two chains are hypervariable regions containing antigen-binding domains. A variable sized branched carbohydrate domain is attached to the complement-activating Fc region, and the so-called “hinge region” contains especially accessible interchain disulfides.

For attaching cytotoxic drugs to antibodies three different methods have been used (28):

1. Coupling to lysine moieties that are distributed over the entire antibody surface
2. Generation of aldehyde groups by oxidizing the carbohydrate region and subsequent reaction with amino-containing drugs or drug derivatives
3. Coupling to sulfhydryl groups that are obtained by selectively reducing the interchain disulfides at the “hinge region”

Various problems are encountered with the first method. Binding to lysine residues results in a relatively nonselective distribution of drugs on the antibody surface, often including the antigen-binding domains. The latter will cause significant loss of antigen specificity (29). Furthermore, aggregation and precipitation of the conjugate can occur due to a reduced number of solubilizing amino groups (30).

Preparing conjugates using the second method should circumvent the first of the above mentioned problems, since the carbohydrate region is far away from the antigen-binding domain. However, the resulting immunoconjugates will have a distribution of drug loading ratios, and therefore the product will not be truly homogenous. A given glycosylation pattern may also be necessary for retaining the protein structure (31), and severe changes in the carbohydrate region can alter protein topology with consequences for antigen specificity, immunogenicity, and aggregation.

The great advantage of the third method is that four disulfides can be reduced to generate eight sulfhydryl groups selectively at the “hinge region” of an IgG under mild conditions and without significant perturbation of the protein structure (32). Hence, sulfhydryl groups obtained by reduction of interchain disulfides are the most important functional targets for conjugation of anticancer drugs to antibodies.

## 2. Methods for Modification of Functional Groups

In many cases, the native structure of a biopolymer is modified by introducing functional targets for conjugation because the carrier does not provide appropriate or sufficiently reactive groups. Chemical modifications are described in the following paragraphs including examples for applications in drug-carrier conjugation.

### a. Introduction of Sulfhydryl Groups

**Reduction of Disulfide Bonds with DTT (Cleland's Reagent).** Dithiothreitol (DTT) is the *trans* isomer of 1,4-dimercapto-2,3-butanediol. The reducing potential of this versatile reagent was first described by Cleland in 1964. Due to its low redox potential, it cleaves all accessible biological disulfides and maintains free sulfhydryl groups, even in the presence of oxygen (Fig. 5). In contrast to other disulfide reductants, such as 2-mercaptoethanol, 2-mercaptoethylamine or thioglycolate, which are added in large excess, DTT forms an entropically favored cyclic product, and reduction succeeds with a slight excess of DTT.

For example, this method has been used for selectively reducing the four interchain disulfides of monoclonal antibodies (32,33).

**Modification of Amines with 2-Iminothiolane (Traut's Reagent).** 2-Iminothiolane (Traut's Reagent) is a water-soluble hydrochloride of a cyclic thioimidoester that reacts with amines in a ring-opening reaction forming stable amidine bonds while generating sulfhydryl groups (Fig. 6). This reaction offers the advantage of maintaining the net charge of the protein, since amidine bonds are positively charged under physiological conditions.

**Figure 32.5** Reduction of disulfides with dithiothreitol.

**Figure 32.6** Thiolation of amines with 2-iminothiolane.

This reaction has mainly been applied for modifying lysine residues of antibodies (32,34) and of serum proteins, such as human serum albumin (35) or transferrin (36).

**Modification of Amines with *N*-Succinimidyl 3-(2-Pyridyldithio)propionate (SPDP).** *N*-succinimidyl-3-(2-pyridyldithio)propionate (SPDP) is one of the most popular heterobifunctional cross-linking agents that forms a stable amide bond with amines of proteins. Free sulfhydryl groups are generated after straightforward DTT-reduction of the pyridyldithio moieties (Fig. 7) (37).

Using this technique, a number of drug conjugates have been prepared with antibodies (32,38,39) and with the iron transport protein transferrin (40). HPLC methods determining the degree of derivatization (ratio of pyridyl disulfide moieties to macromolecule) have recently been developed (41).

Furthermore, SPDP can be employed as a sulfhydryl-binding heterobifunctional cross-linking agent by first reacting the linker with an amino-containing drug and subsequently binding it to cysteine moieties (34).

### b. Introduction of Aldehyde Groups

Carbohydrates and other biological molecules that contain polysaccharides, such as antibodies, can be specifically modified at their sugar residues to yield reactive aldehyde groups. The most commonly used method is the oxidation with sodium periodate that cleaves the carbon-carbon bond between vicinal hydroxyl groups (Fig. 8).

Although this method alters the polysaccharide structure substantially, it has been frequently used for the preparation of drug-polysaccharide conjugates with dextran (42-44) and antibodies (30).

### c. Introduction of Carboxylic Groups

A commonly used method for introducing carboxylic groups is the reaction of amino groups with cyclic anhydrides, such as succinic, glutaric, or maleic anhydride (Fig. 9).

The sulfhydryl group of cysteine, the phenolate group of tyrosine, and the imidazole ring of histidine can also react, but the acylated products are sensitive to hydrolysis,

**Figure 32.7** Reaction of SPDP with amino-containing polymers forming an amide bond and subsequent reduction with DTT yielding the thiolated macromolecule.

**Figure 32.8** Periodate oxidation of vicinal dihydroxyl compounds.

thus regenerating the original group of the respective amino acid at physiological pH.

Only a few examples for preparing drug-carrier conjugates with succinylated macromolecules have been reported (45). For instance, bovine serum albumin was treated with succinic anhydride yielding 88–95% conver-

sion of the lysine residues. Subsequently, peptide spacer containing daunorubicin derivatives were coupled to the introduced carboxylic groups (46).

It should be noted that converting positively charged amino groups into negatively charged carboxylic groups is often accompanied by a dramatic change in the three-dimensional structure of the protein (47) that results in an irreversible loss of biological activity (48).

### C. Group-Specific Coupling Reactions

This chapter deals with the final step in the preparation of drug-carrier conjugates: the coupling of the polymer-

**Figure 32.9** Introduction of carboxylic groups into amino-containing polymers.

**Figure 32.10** Michael addition of a sulfhydryl group to the double bond of a maleimide group.

binding drug to the (modified) macromolecular carrier. Although a number of water-soluble spacer molecules have been developed (49), most polymer-binding drug derivatives have the disadvantage of being hydrophobic. In these cases, it has proved useful to add small amounts of organic solvents, such as dimethylformamide or dimethylsulfoxide, up to a concentration of approximately 10%. It is important that under these coupling conditions no denaturing and/or irreversible precipitation of the biopolymer takes place. Due to the poor water-solubility of many drugs, precipitation can also take place if the carrier is overloaded with hydrophobic drugs. Therefore the drug loading ratio needs to be carefully controlled (30).

In the following sections, the most commonly used group-specific coupling methods are described, including examples for their application in drug-carrier conjugation.

### 1. Sulfhydryl-Reactive Methods

#### a. Maleimides

Maleimides are the most important sulfhydryl specific coupling agents. The sulfhydryl group adds to the double bond of the heterocycle's Michael system, forming a stable thioether bond (Fig. 10).

Maleimide reactions are specific for sulfhydryl groups when carried out in a pH range of 6.5–7.5 and can be followed spectrophotometrically by the decrease in absorbance at 300 nm as the double bond reacts and disappears. At pH 7, the reaction of the maleimide with sulfhydryl groups is approximately 1000 times faster than with amino groups. At higher pH values, cross-reactivity with amino groups can take place (20), whereas tyrosine, histidine, or methionine residues do not react (21). A possible side reaction of the maleimide itself is a hydrolytic ring-opening reaction forming maleamic acids (Fig. 11) that typically occurs at higher pH values.

For preparing tailor-made spacer molecules containing maleimide groups, three methods are commonly used:

1. Acylation of amines with maleic anhydride followed by dehydration of the intermediate maleamic acid (Fig. 12) (50).

**Figure 32.11** Hydrolysis of maleimide derivatives at alkaline pH.

**Figure 32.12** Synthetic route for maleimide derivatives by treating primary amines with maleic anhydride in a first step and forming the maleimide ring by dehydration in a second step (method 1).

Although this approach proved to be suitable for the preparation of a number of heterobifunctional cross-linking agents containing maleimide groups (51), it was not applicable to acid-sensitive compounds. A variation of this method carried out as a microwave-induced one-pot reaction has been reported recently (52).

2. Conversion of amino acids under mild conditions by treatment with *N*-alkoxycarbonylmaleimides in aqueous solution (Fig. 13) (53).

This method was chosen for synthesizing water-soluble oligoxyethylene-based heterobifunctional cross-linkers (49).

3. Alkylation of maleimide by alcohols using Mitsunobu reaction conditions (Fig. 14) (54,55).

Since alcohols as starting materials are generally easier to prepare than the analogous amino compounds, the importance of this reaction for the synthesis of heterobifunctional cross-linkers will probably increase in future.

Due to their excellent sulfhydryl binding properties, maleimide groups have been extensively used for coupling drug derivatives to thiol-group-containing macromolecules (28,32,33,56–63). For instance, the commercially

**Figure 32.13** Synthetic route for maleimide derivatives by reacting amines with *N*-alkoxycarbonylmaleimides (method 2).

**Figure 32.14** Mitsunobu alkylation of maleimide with alcohols (method 3).

available heterobifunctional cross-linker 6-maleimidocaproic acid hydrazide has been employed in the preparation of the immunoconjugate BR96-Dox (32,33), which has undergone clinical trials (57). In more recent work, the synthesis of branched-maleimide-bearing linkers that are capable of binding two or more molecules of doxorubicin and attaching them to BR96 antibodies has been reported (58). Maleimide derivatives of doxorubicin were coupled to a number of thiolated poly(ethylene glycols) employing maleimide-containing heterobifunctional cross-linkers (59). Maleimide chemistry has also been used for coupling anticancer drugs to thiolated serum proteins (60,61). Recently, it could be shown that the selectivity of the maleimide group towards the cysteine 34 position of circulating albumin is sufficient for forming doxorubicin–albumin conjugates *in vivo* after intravenous application of the maleimide-containing drug derivative shown in Fig. 15 (62).

#### b. Haloacetyl Derivatives

Sulfhydryl groups can be alkylated by haloacetyl derivatives, e.g., bromoacetyl or iodoacetyl compounds, in a nucleophilic substitution reaction (Fig. 16).

**Figure 32.15** Albumin-binding doxorubicin prodrug incorporating an acid-cleavable hydrazone bond and a thiol-binding maleimide moiety.

**Figure 32.16** Alkylation of sulfhydryl groups by haloacetyl compounds forming a thioether bond.

In contrast to the reaction with maleimides, coupling of bromoacetamides to sulfhydryl groups takes place only at higher pH values (pH 9) with a desirable reaction rate (63) whereby surprisingly no cross-reactivity towards amino or imidazole groups could be observed in the investigated examples. According to Hermanson, the relative reactivity of haloacetates toward protein functionalities is sulfhydryl > imidazolyl > thioether > amine (32). Among halo derivatives, the relative reactivity is I > Br > Cl > F, with fluorine being almost unreactive. Haloacetyl drug derivatives can be conveniently prepared by esterification or by forming amides of a haloacetic acid with hydroxyl- or amino-containing drugs using carbodiimides for activation.

Although haloacetyl derivatives are generally appropriate for group-specific coupling, their use in the field of drug–carrier conjugation is limited due to the basic pH values needed for achieving effective coupling.

#### c. Pyridyl Disulfides

Pyridyl disulfides are perhaps the most popular type of sulfhydryl-disulfide-exchange reagents that ensure effective group specific coupling. Treatment of thiols with these compounds yields mixed disulfides and releases pyridine-2-thione as a nonreactive by-product (Fig. 17).

For the preparation of tailor-made heterobifunctional cross-linkers, pyridyl disulfides can be generated by activating thiols with methoxycarbonylsulfonylchloride and subsequent reaction with 2-mercaptopyridine (Fig. 18) (39).

Pyridyl disulfide containing drug derivatives have been conjugated with antibodies. For instance, doxorubicin was reacted with pyridyl disulfide containing carboxylic hydrazides to form respective hydrazone derivatives. The

**Figure 32.17** Disulfide exchange reaction of sulfhydryl compounds with pyridyl disulfide derivatives.

**Figure 32.18** Pyridyl disulfides formed by reaction of sulfhydryl compounds with methoxycarbonylsulfonylchloride and 2-mercaptopyridine.

drug derivatives were then coupled to a thiolated monoclonal antibody (39). In another work, the hydrazone of doxorubicin and hydrazine was treated with SPDP to form a thiol-binding drug derivative, which was coupled to a SPDP-thiolated antibody (38).

## 2. Amino Groups

In most cases, drugs are coupled to amino-containing polymers by acylation. Other functional groups, e.g., sulfhydryl, imidazolyl, or phenolate groups, can also be acylated, but the products are sensitive to hydrolysis, thus regenerating the original group. Acylation can be achieved by *in situ* activation of carboxyl-group-containing drugs with carbodiimides (compare with Section II.C.3) or by the use of drug derivatives containing isothiocyanates, imidoesters, or active esters, especially (NHS) esters. NHS esters react readily with amines, forming a stable amide bond while releasing *N*-hydroxysuccinimide as a by-product (Fig. 19).

NHS esters are usually prepared by esterification of the carboxyl-containing drug with *N*-hydroxysuccinimide and DCC (*N,N'*-dicyclohexyl carbodiimide) (Fig. 20). *In situ* activation using this method is also possible.

In some cases, the NHS ester derivatives exhibit poor water solubility. This problem can be circumvented by the use of sulfo-NHS (*N*-hydroxysulfosuccinimide), a highly hydrophilic NHS derivative. Sulfo-NHS-esters reacts with amines on target molecules with the same specificity and reactivity as NHS-esters (64).

The use of NHS- or sulfo-NHS esters in the field of drug-carrier conjugation is widespread. For example, the

**Figure 32.20** Synthesis of NHS esters using DCC activation.

sulfo-NHS or NHS esters of a succinylated derivative of the anticancer drug paclitaxel was coupled to human serum albumin (65) and hyaluronic acid, respectively (66).

## 3. Carboxylic Acid Groups

In contrast to other functional targets of polymers, carboxyl groups need to be activated by so-called *zero-length* cross-linking agents in order to react with amino-bearing drugs. Carbodiimides are popular members of this class of cross-linkers. In a first step, they react with carboxylic acids forming a reactive *O*-acylisourea intermediate that is capable of acylating amines (Fig. 21). In nonaqueous solutions, reaction with alcohols takes place, forming respective esters.

Due to the poor water-solubility of most carbodiimides, such as DCC or DIPC (*N,N'*-diisopropyl carbodiimide), water-soluble derivatives have been developed. EDC (1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride) (Fig. 22), a hydrophilic tertiary amine containing reagent, is the most popular *zero-length* cross-linker used for bioconjugation purposes. The urea by-product formed after reaction with the amine compound is also water-solu-

**Figure 32.19** Reaction of amines with NHS esters forming stable amide bonds.

**Figure 32.21** Activation of carboxylic acids with carbodiimides forms a reactive *O*-acylisourea intermediate that readily reacts with amines forming a stable amide bond.

ble, so it can be removed using standard methods such as dialysis or gel filtration.

A general problem that can occur when working with carboxyl group activating agents is cross-linking of the protein due to the presence of reactive groups on the protein surface, such as amino groups. This method has therefore been mainly used with homopolyfunctional polymers (67–69).

#### 4. Aldehyde Groups

Amino-containing drugs can be coupled to aldehyde groups of the macromolecular carrier that are typically generated by periodate oxidation. The resulting imine bonds of the Schiff base are sensitive towards hydrolysis and are therefore converted into respective stable secondary amines by treatment with the mild reducing agent sodium cyanoborohydride (Fig. 23).

This method is named reductive amination, wherein the first step (the formation of the Schiff base) is pH dependent, and best results are obtained when it is carried out at a pH of  $\sim 9$  (19). Instead of using sodium cyanoborohydride in the second step, sodium borohydride can be selected if other reducible groups are absent.

**Figure 32.22** Structure of EDC (1-ethyl-3-(3-dimethylamino)propyl) carbodiimide hydrochloride).

Primarily, doxorubicin has been coupled to oxidized dextran (42–44) or to the carbohydrate region of antibodies using this method (30).

#### D. Incorporation of a Predetermined Breaking Point Between Drug and Carrier

One of the key issues that has been addressed in recent years regarding the pharmacological activity of polymer drug conjugates is the significance of the chemical bond between the drug and the polymer. For designing effective drug polymer conjugates, spacers can be incorporated between the anticancer agent and the macromolecule, which allow the drug to be released either extra- or intracellularly. Over the past ten years two types of bonds have been investigated in some detail: (a) acid-cleavable bonds [reviewed in (70)] and (b) peptide bonds, which can be cleaved by lysosomal enzymes [reviewed in (71)].

Essentially, both types of bonds exploit the cellular uptake mechanism for macromolecules, i.e., endocytosis, which allows the macromolecular bound drug to be released in intracellular compartments. In general, macromolecules are taken up by the cell through receptor-mediated endocytosis, adsorptive endocytosis, or fluid-phase endocytosis.

Endocytosis is a complex process that is shown as a simplified scheme in Fig. 24 [for a review see (72)].

At the cell surface, invaginations occur and endosomes are formed that migrate into the cytoplasm. Depending on the macromolecule and the kind of endocytosis process involved, a series of sorting steps takes place in which the

Figure 32.23 Reductive amination of aldehydes.

endosome is transported to certain cell organelles (e.g., the Golgi apparatus), returns to the cell surface (recycling), or forms primary and secondary lysosomes, respectively.

During endocytosis a significant drop in the pH value takes place from the physiological pH (7.2–7.4) in the extracellular space to pH 6.5–5.0 in the endosomes and to around pH 4 in primary and secondary lysosomes. A great number of lysosomal enzymes become active in the acidic environment of these vesicles.

Both the low pH values in endosomes and lysosomes and the presence of lysosomal enzymes are therefore intracellular properties that can be exploited for developing drug–polymer conjugates that release the polymer-bound drug specifically in tumor cells.

Classical examples for acid-cleavable bonds are carboxylic hydrazone and *cis*-aconityl bonds (70). Peptide spacers that are enzymatically degraded by lysosomal enzymes, such as cathepsin B, have been studied in great detail, and tailor-made sequences, e.g., Gly-Phe-Leu-Gly, have been identified (71).

### III. DRUG CONJUGATES WITH MONOCLONAL ANTIBODIES

#### A. Introduction

Targeted tumor therapy is based on the presumption that characteristic differences exist between normal and cancer cells, which can be exploited for the selective delivery of antineoplastic agents to the tumor site (73–79). The initial discovery that tumor cells expressed certain determinants (tumor-associated antigens) on their cell surface that were not found on normal cells and the subsequent advent of hybridoma technology (2,80) led to the development of a large number of monoclonal antibodies (mAbs), each with its own binding specificity for certain tumor-specific antigens. Monoclonal antibodies are very attractive as drug carriers due to the high binding affinity for their respective antigens. This should allow the accumulation of lethal drug concentrations in the tumor tissue. In addition, the long circulation time of antibodies in the blood stream

provides a greater probability that the drug will reach the tumor site.

In the past twenty-five years, a great number of immunoconjugates with cytotoxic agents, such as bacterial or plant toxins, radioisotopes, and anticancer drugs, have been synthesized, and their biological activity has been investigated intensively (see Table 4) (28,82–84).

*Radioimmunoconjugates* are widely used in the diagnosis of malignant diseases. Additionally, they are currently being evaluated as therapeutic agents in radioimmunotherapy with encouraging results in the treatment of advanced hematological malignancies. The concept for radioimmunotherapy as well as preclinical and clinical investigations have been reviewed elsewhere (85–87). *Immunotoxins*, conjugates comprising toxins and antibodies, have recently been tested clinically and have demonstrated promising efficacy in some patients with malignant diseases refractory to surgery, radiation therapy, and conventional chemotherapy (10).

This chapter does not address the latter two topics but focuses on recent progress that has been made in the area of antibody-targeted delivery of conventional chemothera-

peutic drugs, summarizing the results of clinical trials with these chemoimmunoconjugates.

## B. Design of Chemoimmunoconjugates

As a result of their transformed state, cancer cells overexpress various membrane-associated proteins in comparison to normal tissue, a property that is exploited in targeted cancer chemotherapy.

To achieve optimal targeting, the antigen (Ag) on the tumor cell surface should (a) be a well-defined molecule expressed exclusively on tumor tissue, (b) not be expressed on normal tissues, (c) be bound by the targeting molecule with high affinity, (d) be expressed homogeneously on all the tumor cells, (e) be present on the tumors of all patients with the same type of cancer and (f) not be shed into the circulation.

### 1. Antigenic Targets

A variety of cell surface proteins have been exploited as targets for monoclonal antibodies (88,89). Notable classes of tumor-associated Ags include the carcinoembryonic antigen (CEA),  $\alpha$ -fetoprotein, blood group carbohydrates such as Lewis y ( $Le^y$ ) (recognized by the mAbs BR64 and BR96), gangliosides such as the L6 Ag, the adenocarcinoma-related KS1/4 antigen, mucins, selectins, glycosphingolipids, integrins, and other adhesion molecules. These antigens are generally overexpressed on the surface of tumor cells, although they are found to some extent on normal cells as well. The only truly tumor-specific antigens appear to be those found in hematopoietic tumors, such as idiotypes present on the surface of B-cell tumors (90).

### 2. Antibodies as Targeting Moieties

Monoclonal antibodies have been used for tumor targeting in their natural, fragmented, chemically modified, or recombinant forms in a variety of experimental settings.

The majority of employed natural antibodies were murine immunoglobulins of the IgG class. A murine immunoglobulin IgG molecule is a symmetric glycoprotein (MW ca. 150,000 Da) that has a Y-shaped structure and is composed of two heavy and two light chains that are linked through disulfide bonds (91). Each chain contains a constant and a variable region (see Fig. 25). The stem region is a constant domain that is responsible for triggering effector functions that eliminate the antigen-associated cells (80). It also contains a carbohydrate moiety.

Treatment with pepsin removes the constant domains that are not required for antigen binding, generating a bivalent antibody-binding fragment  $F(ab')_2$ . In contrast, digestion of the antibody with papain produces two monovalent

**Figure 32.25** Schematic representation of an IgG.

antigen-binding fragments Fab, and one crystallizable fragment Fc (see Fig. 26). The smallest fragment that retains the full monovalent binding affinity of the intact antibody is the Fv molecule that comprises aligned and noncovalently associated  $V_H$  and  $V_L$  domains containing three hypervariable amino acid sequence regions that are responsible for antigen recognition, known as the complementary determining regions (CDR).

Most mAbs that have been evaluated in the clinical setting, were generated in mice. As a consequence, the use of these mAbs and respective conjugates is limited by the development of human antimouse antibodies (HAMA), which results in accelerated clearance of the administered immunoconjugates (92,93). The antigen-binding fragments ( $F(ab')_2$ , Fab, or Fv) are much less immunogenic than the intact antibody, because the cleavage of the Fc region generally removes the most immunogenic portion of the immunoglobulin molecule.

Recently, innovative recombinant techniques have opened the possibility of generating genetically engineered monoclonal antibodies (94,95). Chimeric antibodies are constructs containing a mouse Fab portion and a human Fc portion (see Fig. 27a). For preparing chimeric mAbs, the genes encoding the murine Fab variable regions are spliced to the genes encoding the human constant region (96,97). Humanized monoclonal antibodies contain mouse sequences in the binding site of a human mAb (see Fig. 27b). These antibodies are engineered by transferring the antigen-binding hypervariable sequences (CDR) of a murine antibody into human immunoglobulin framework re-

gions (98,99). Since CDRs form the antigen binding site, a humanized antibody preserves the murine antigen specificity. Both constructs, chimeric and humanized antibodies, are predicted to minimize the immune response, because the most immunogenic domain of the murine antibody, the constant Fc region, is substituted by a human sequence.

### 3. Coupling of Drugs to the Monoclonal Antibody

The success of drug immunoconjugate therapy depends not only on highly tumor-specific mAbs but also on the drug coupling technique used (100,101). Conjugation of cytotoxic drugs with antibody molecules aims to introduce a maximum number of residues under conditions that ensure optimal retention of both drug activity and antibody reactivity. Only a limited number of drug molecules can be introduced by conjugation with the antibody without producing protein denaturation and loss of antibody reactivity. Individual antibodies vary in their ruggedness towards substitution. Some antibodies will lose antigen-binding activity even when using mild procedures, while others permit a relatively high substitution rate without losing binding affinity (102,103).

### C. Clinical Trials with Chemoimmunoconjugates

Several chemoimmunoconjugates have been investigated in clinical trials. Although, in general, the observed thera-

**Figure 32.26** Cleavage of IgG into F(ab')<sub>2</sub> and Fab fragments by pepsin and papain, respectively.

**Figure 32.27** Schematic representation of (a) chimeric and (b) humanized antibody.

peutic efficacy must be considered disappointing, these studies provide valuable information on the fate of cytotoxic immunoconjugates in humans. The results of pertinent studies are summarized in Table 5. In the following, selected trials are described in more detail with respect to the exploited cytotoxic drug.

### 1. Doxorubicin-BR96-Immunoconjugate

One of the most promising chemoimmunoconjugates in preclinical studies has been the BR96-doxorubicin conjugate (BR96-DOX) (32,33,104–106). BR96 is a mouse/human chimeric monoclonal antibody (IgG1) that identifies a tumor-associated antigen related to Lewis Y ( $Le^y$ ), which is overexpressed on the surface of human carcinoma cells of the breast, colon, lung, and ovary (> 200,000 molecules/cell); the antibody shows high tumor selectivity and is rapidly internalized after binding (107).

BR96-DOX is prepared in a multi step reaction. First, the four interchain disulfides of the mAb are reduced with dithiothreitol to create eight thiol groups. These are then reacted with the maleimidocaproyl hydrazone derivative of doxorubicin. The caproyl hydrazone bond has acid-sensitive properties that allow the drug to be released in the acid environment of lysosomes or endosomes (see Fig. 28). The antitumor activity of the BR96-DOX-immunoconjugate has been evaluated in several clinical trials.

In a first phase I study, the immunoconjugate was ad-

**Figure 32.28** Structure of the BR96–doxorubicin immunoconjugate. (From Ref. 104.)

ministered to 62 patients as an intravenous infusion every 21 days (108,109). Doses of BR96-DOX ranged from 66 to 875 mg/m<sup>2</sup>, which is equivalent to 2 to 25 mg/m<sup>2</sup> of free doxorubicin. Two patients exhibited partial responses, one with breast and the other with gastric carcinoma. A stable disease was observed in a number of patients.

In a second phase I dose-escalation study, 34 patients with  $Le^y$ -expressing tumors were treated with BR96-DOX administered as a weekly infusion of 100–500 mg/m<sup>2</sup> of BR96-DOX (equivalent to 3–15 mg/m<sup>2</sup> doxorubicin) (110). Although antibody localization studies demon-

CR = complete response; MR = minor response; PR = partial response; SD = stable disease; MOLR = Drug/mAb mole ratio; \* = value not given.

strated binding of the immunoconjugate at the tumor site, no objective responses were observed. In both studies, BR96-DOX showed dose-limiting gastrointestinal (GI) toxicity at the highest doses. Importantly, no cardiotoxicity was observed, and no HAMA response to the chimeric Ab was induced after repeated dosing.

Recently, a randomized phase II study was performed to evaluate the activity of BR96-DOX against metastatic breast cancer in patients with confirmed sensitivity to single-agent doxorubicin (57). Patients received either 700 mg/m<sup>2</sup> of BR96-DOX (equivalent to 20 mg/m<sup>2</sup> DOX) or 60 mg/m<sup>2</sup> doxorubicin every 3 weeks. There was one partial response in the 14 patients receiving BR96-DOX as well as one complete and three partial responses in the nine patients treated with doxorubicin alone. Interestingly, two of the four patients who crossed over to the BR96-DOX group of the trial after persistent stable disease during treatment with doxorubicin, achieved partial regression of hepatic metastases following immunoconjugate therapy (111). The cross-reactivity of BR96 with normal gastrointestinal tissue led to prominent toxicities and probably impaired the delivery of the immunoconjugate to the tumor sites.

Localization of the antibody and the drug was seen in tumor biopsies of patients receiving BR96-DOX, indicating that the antibody successfully delivered doxorubicin to tumors. Together with the low clinical response rates, the data suggest that the dose that could be safely administered every 3 weeks was insufficient for maintaining the intratumoral concentration of doxorubicin required to achieve tumor regression.

## 2. Methotrexate-KS1/4-Conjugate

A conjugate of methotrexate (MTX) and the monoclonal antibody KS1/4 was evaluated in two phase I studies in patients with non-small-cell lung cancer. KS1/4 is a murine monoclonal IgG2a antibody that recognizes a M<sub>r</sub> 40000 antigen found on most adenocarcinomas (112,113). Its high density on the cell surface and homogeneous expression in non-small-cell lung carcinoma makes this antigen a suitable target for mAb-directed therapy. The conjugate was prepared by simple nonspecific carbodiimide coupling of MTX to the lysine moieties of the mAb (114).

In the first trial, five patients received the MTX-KS1/4 conjugate, while six other patients were treated with KS1/4 alone (115). The total dose of protein administered was 1661 mg, while the amount of methotrexate received with the preparation was 28 mg. In general, the infusions were well tolerated, and similar toxicities were observed in both groups. A majority of patients in both groups developed a HAMA response. Immunoperoxidase staining of carci-

noma samples provided evidence of posttreatment localization of antibody and conjugate, respectively. However, no significant clinical response was observed in either group.

In a second clinical study, differing schedules at higher doses were administered to evaluate the therapeutic efficacy and toxicity of the MTX immunoconjugate in more detail (116).

Eleven patients were treated with the KS1/4-MTX conjugate. The resulting MTD of the conjugate was 1750 mg/m<sup>2</sup>, equivalent to 40 mg/m<sup>2</sup> MTX.

Under therapy, two patients developed meningitis. One patient had an objective response in two lung nodules (> 50% decrease) but developed immune-complex-mediated arthritis and serum sickness upon subsequent treatment.

## 3. Immunoconjugates with Desacetylvinblastine

In various preclinical studies, the tumor-associated antigen recognized by the KS1/4 mAb (112) has been investigated as a target for site-directed therapy strategies with chemoimmunoconjugates of vinca alkaloid derivatives (30,117,118). Two of these conjugates, KS1/4-desacetylvinblastine (KS1/4-DAVLB) and KS1/4-desacetylvinblastine-3-carboxyhydrazide (KS1/4-DAVLBHYD), have been examined in phase I clinical studies in patients with epithelial malignancies (119–121).

The first conjugate, KS1/4-DAVLB, contains four to six molecules of desacetylvinblastine covalently attached to the ε-amino groups of lysine residues of the KS1/4 mAb through hemisuccinate linkers (see Fig. 29a). Twenty-two patients with lung, colon, or rectum adenocarcinomas received KS1/4-DAVLB in phase I clinical trial (120,121). Single-infusion doses in 13 patients ranged from 40 to 250 mg/m<sup>2</sup> (equivalent to 1.4–14 mg DAVLB). Nine patients were treated with multiple doses of 1.5 mg/kg every 2–3 days. Antitumor activity was not observed in any of the patients. The development of gastrointestinal toxicity was predominant and limited the amount of KS1/4-DAVLB that could be administered. Results from preclinical studies suggested that substantially higher doses than those achieved in the clinical trial would be required to observe antitumor activity.

The second conjugate, KS1/4-DAVLBHYD, was synthesized by coupling 4-desacetylvinblastine-3-carboxyhydrazide to aldehyde moieties generated by mild oxidation of the immunoglobulin's carbohydrate region (30). The resulting conjugate contains 4–6 drug molecules linked to the antibody through an acid-cleavable hydrazone bond that allows release of the free drug in the acidic environment of tumor cells and tumor tissue (see Fig. 29b).

Fourteen patients were treated with a single dose of the

**Figure 32.29** Structure of the KS1/4–DAVLB immunconjugate (a) and the KS1/4–DAVLBHYD immunconjugate (b). (From Ref. 30.)

conjugate, ranging from 5 to 178 mg KS1/4–DAVLB–HYD. Eight patients received multiple infusions with a total of 127–896 mg conjugate. 77% of the patients developed a HAMA response and 36% showed antivincin antibodies (119). No clinical responses were seen in these studies.

#### 4. Immunconjugates with Daunorubicin/Chlorambucil

Allogenic antibodies directed against neuroblastoma tumor cells were used as macromolecular carriers of daunorubicin and chlorambucil (122). Seven children bearing neuroblastoma have been treated with 1 mg daunorubicin/kg or 0.5 mg chlorambucil/kg per dose. Treatment was continued up to one year, achieving three cures and one long-term response. Two further patients showed minor responses.

#### 5. Immunconjugates with Mitomycin C

Mitomycin C immunconjugates were prepared by coupling mitomycin C through an *N*-hydroxysuccinimide ester intermediate to amino groups of the antibody (123). In a phase I clinical trial, 19 patients with refractory solid malignancies received individualized combinations of mitomycin C murine monoclonal antibody conjugates selected by immunohistochemical and flow cytometric screening of tumor specimens. These “cocktails” were composed of up to six different MMC–antibody conjugates. Doses were escalated to 60 mg of MMC conjugated to 3–5 grams of mAbs over a period of 2–3 weeks. The most frequent toxicities were rash, fever, and chills. No clinical responses were seen with these immunconjugates, although several

patients had less tumor-induced pain after treatment (124,125).

#### 6. *N*-Acetylmelfhalan-Immunoconjugates

*N*-Acetylmelfhalan, a derivative of the alkylating agent melfhalan, has been coupled to murine anticolon cancer monoclonal antibodies (126). The selected antibodies demonstrated a high specificity for colon carcinomas as shown by immunoperoxidase staining.

In a phase I clinical trial with *N*-acetylmelfhalan conjugates in nine patients with colorectal cancer, up to 1000 mg/m<sup>2</sup> of conjugate (equivalent to 20 mg/m<sup>2</sup> *N*-acetylmelfhalan) could be safely administered via the hepatic artery without causing serious side effects (127).

Interestingly, the patients did not develop myelosuppression that typically occurs with the free drug at equivalent doses. HAMA responses were observed in all patients as well as serum sickness in one patient who received two courses of treatment. Minor objective responses of disseminated disease in the liver were noted in three of nine patients.

#### 7. Neocarzinostatin-Immunoconjugate

The anticancer antibiotic neocarzinostatin (NCS) consists of a very reactive polycyclic chromophore that is noncovalently associated with an apoprotein that protects it from degradation (128,129). The proteinaceous drug (MW ≈ 11,700 Da) is obtained from the culture filtrate of *Streptomyces carzinostaticus* and inhibits DNA synthesis by direct DNA strand scission (130). In vivo, NCS is deactivated within minutes and quickly cleared from the circulation-causing renal toxicity.

A neocarzinostatin immunoconjugate containing the murine monoclonal antibody A7 (131) directed against human colorectal cancer has been evaluated in 41 patients (132). No adverse effects were reported, and immunostaining of biopsied cancerous tissue showed that the conjugate was localized in these cells.

Three of eight patients with postoperative liver metastases exhibited tumor reduction as shown by computer-aided tomography. However, patients with lung or peritoneal metastases had no benefit. A follow-up study (133) showed that, in general, the rate of 5-year survival was similar for the group treated with the conjugate in comparison with groups treated with traditional chemotherapy, while individual patients of the conjugate-treated group lived longer. In addition, patients who received higher doses of the A7–NCS conjugate had a higher survival rate. Even after 5 years, human antimouse responses against the conjugate were still detected.

#### 8. Calicheamicin $\gamma_1$ -Immunoconjugate

Calicheamicins are a family of enediyne antibiotics (129) that are probably the most toxic antitumor drugs described to date. Calicheamicin  $\gamma_1$  is the most prominent member of this class of compounds. It binds to the minor groove of DNA and causes double-strand DNA breaks that ultimately induce cell death (134–136). Antibody-directed delivery provides a potential means of exploiting the impressive potency of this compound while minimizing its systemic toxicity (137,138).

A phase I study of CMA-676, an immunoconjugate of calicheamicin  $\gamma_1$  conjugated to a humanized anti-CD33 monoclonal antibody through an acid-labile hydrazone bond (see Fig. 30), has recently been completed (139). The CD33 target antigen is expressed on blast cells in most patients with acute myeloid leukemia (AML), but not on normal hematopoietic stem cells. This feature raises the

possibility of selectively delivering the cytotoxic drug to malignant cells while sparing healthy stem cells.

Forty patients with refractory or elapsed AML were treated intravenously with 0.25–9.0 mg/m<sup>2</sup> of CMA-676. Besides fever and chills, toxicity was preliminary hematological but not considered to be a dose-limiting factor. Leukemic cells were eliminated from the blood and marrow in eight (20%) of the treated patients, while blood counts returned to normal in three (8%) of them.

A phase II study has been performed involving patients with AML in first relapse, who received 9 mg/m<sup>2</sup> CMA-676 intravenously every 14 days in three cycles. An interim analysis of 23 patients showed a response rate of 43% (86,140). In ten patients, treatment with CMA-676 resulted in elimination of blasts from peripheral blood and marrow; three patients achieved a complete response, with toxicity being lower than with standard chemotherapy.

#### D. Strategies for Enhanced Antibody Delivery to Tumors

Despite the encouraging preclinical results with distinct anticancer immunoconjugates, the antitumor efficacy of these conjugates in clinical trials has been modest. The shortcomings of the strategy may derive from different obstacles concerning the effective delivery of immunoconjugates to the tumor site (141–143). Some of these problems and their potential solutions are listed in Table 6.

The most disappointing aspect of the clinical studies using chemoimmunoconjugates is the poor mAb localization in tumors, resulting in minimal antitumor responses. Tumor imaging in patients has shown that the amount of mAb localizing to the tumors is sometimes less than 0.01% (81). The inability to translate the promising efficacy seen in animal models to patients can, in part, be rationalized

**Figure 32.30** Structure of the CMA-676 calicheamicin immunoconjugate. (From Ref. 137.)

**Table 32.6** Problems of Delivery of Monoclonal Antibodies and Some Potential Solutions

Phenomenon	Delivery problem/obstacle	Potential solutions
Low tumor uptake	Heterogeneous Ag expression	Cytokines Antibody cocktails
	Poor vascularization	Interleukin 1 + 2 TNF- $\alpha$ Vasoactive agents Antibody fragments
	Small amounts of mAb binding to the tumor cell	More potent drugs Ab cocktails Carriers Higher doses
Systemic toxicity	Cross-reactivity of mAbs with normal tissue	More selective antibodies Interleukins to enhance Ag expression
Host immune response	Murine origin of antibodies	Antibody fragments Chimeric/humanized antibodies

by a dilution effect due to the larger volume of humans compared with mice. In addition, several other reasons that prevent effective delivery of the chemoimmunoconjugates to the tumor have been discussed:

1. Monoclonal antibodies are not absolutely tumor specific, and cross-reactivity of the conjugates with normal tissue causes systemic toxicity. For instance, severe gastrointestinal toxicity was observed in clinical trials with the doxorubicin conjugate BR96–DOX due to cross-reactivity of the antibody with these tissues (109–110).
2. The inner regions of solid tumors are often poorly vascularized and exhibit a relatively low blood flow (144–146). Both factors reduce the amount of chemoimmunoconjugate reaching these parts of the tumor.
3. Heterogeneity of antigen expression by tumor cells restricts the amount of cells that can effectively be targeted by antibody conjugates. Tumor cells that express the associated antigen only at a low level or not at all will most likely escape therapy due to their failure to bind the mAbs.
4. To some extent, antigens are secreted into the circulation (147). The “shedding” of antigen from the surface of tumor cells limits the amount of immunoconjugate accumulating in the tumor because soluble antigens neutralize the chemoimmunoconjugate in the circulation.
5. Murine antibodies and respective immunoconjugates evoke a human antimouse antibody (HAMA) immune response when administered to humans (93), which leads to their rapid neutralization and clearance from the bloodstream (92).

6. Conventional anticancer drugs are only moderately cytotoxic, and a large number of drug molecules have to be internalized to cause cell death. This is difficult to achieve by antibody delivery, as only a limited number of drug molecules can be linked to the immunoglobulin without diminishing its immunoreactivity (103).

Consequently, a number of strategies for improving the delivery of chemoimmunoconjugates to the tumor have been considered.

#### 1. Increasing the Administered Dose

The rate of diffusion of chemoimmunoconjugates from the blood to the tissues is dependent on the concentration gradient between the plasma and the extravascular space (144).

Thus increasing the administered dose of the conjugate generally results in higher drug levels at the tumor site, but it also increases the concentration of conjugate in the blood and normal tissues. Furthermore, high concentrations of immunoconjugate in the blood may lead to saturation of binding sites on the tumor, resulting in decreased tumor uptake (“binding-site barrier”) (148–150).

#### 2. Regional Administration of Immunoconjugates

Administration of chemoimmunoconjugates via an inter-cavitary route provides the advantages of (1) increased concentration of the agent at the tumor site and (2) decreased systemic toxicity to normal organs, such as the bone marrow or the gastrointestinal tract.

The route of local arterial injection at the tumor site has been evaluated for the neocarzinostatin immunoconjugate

A7-NCS (151). In contrast to systemic injection, the regional administration of the A7-NCS immunoconjugate produced a significant tumor reduction and was effective in preventing tumor development with concomitant low toxicity.

### 3. Overcoming Antigenic Heterogeneity

The homogeneity of antigen expression is a critical determinant for the therapeutic efficacy of chemoimmunoconjugates (152). Several biological response modifiers, such as interferon-alpha (IFN- $\alpha$ ), interferon-gamma (IFN- $\gamma$ ) and tumor necrosis factor alpha (TNF- $\alpha$ ), are capable of modulating the expression of certain tumor antigens, both in vitro and in vivo (153–155).

Interleukin-2 in combination with antibodies and an interleukin-2 immunotoxin was shown to overcome antigen heterogeneity by inducing a cellular immune response (156,157). Furthermore, a combination of antibodies may be useful for targeting all of the cancer cells. In clinical studies with chemoimmunoconjugates that were mentioned before, the use of immunoconjugate “cocktails” has been evaluated by different groups with good clinical results (124,158).

### 4. Engineered Antibodies

The large size of the IgG molecules impairs their diffusion into extravascular tumor regions (144). A variety of chemically digested or recombinantly prepared antibody fragments of lower molecular weight have therefore been developed and evaluated in preclinical models (99). Commonly used antibody-based structures include F(ab')<sub>2</sub>, Fab, and Fv fragments (see Fig. 26). Immunoconjugates derived from these compounds usually exhibit a faster and deeper diffusion into the tumor tissue (160,161). However, renal clearance rates are also enhanced because the reduced molecular weight falls below the exclusion size of the kidney, which can lead to increased renal toxicity.

The HAMA response in humans was significantly reduced by the use of chimeric (96) and humanized (139) antibodies. However, it cannot be eliminated completely, since the mouse variable and hypervariable regions may still elicit an immune response.

### 5. Enhancement of Tumor Vascularization

Several cytokines, including interferons, tumor necrosis factor  $\alpha$ , and interleukin-2 along with some novel drugs, can increase the vascular permeability and thus enhance the uptake of macromolecules in tumors (142). Several preclinical studies have demonstrated improved targeting

of radiolabeled mAbs to tumor xenografts in mice that were treated with some of these compounds (82,156).

### 6. Increasing the Cytotoxicity of Chemoimmunoconjugates

In order to increase the drug loading ratio of chemoimmunoconjugates, intermediate carrier molecules, such as dextran (103,162) or human serum albumin (163–166), have been developed, but none of these constructs have reached an advanced stage in preclinical development.

Another possibility of enhancing the cytotoxicity of a chemoimmunoconjugate is to use drugs that are much more cytotoxic than conventional anticancer agents, such as calicheamicins. The feasibility of this approach has been demonstrated in recent clinical trials with a calicheamicin-immunoconjugate CMA-676 (see Section III.C)

## IV. DRUG CONJUGATES WITH SERUM PROTEINS

During the past 40 years numerous studies have demonstrated that the blood proteins albumin and transferrin accumulate in tumor tissue (167–171). Tumor uptake has been demonstrated by labeling these proteins with <sup>67</sup>gallium, <sup>68</sup>gallium, <sup>111</sup>indium, <sup>97</sup>ruthenium, or <sup>103</sup>ruthenium, and <sup>131</sup>iodine, respectively, or with dyes such as evans blue or fluorescein compounds. Relevant diagnostic studies with albumin, transferrin and low-density lipoprotein (LDL) have been recently reviewed (171).

As an example of a fairly new technique to determine the uptake of labeled proteins, Fig. 31 shows the results of near-infrared imaging with an indotricarbocyanine albumin conjugate (structures are depicted in Fig. 32) in a tumor-bearing nude mouse model. In near-infrared imaging, suitable fluorescent dyes are administered intravenously to tumor-bearing mice, and these are then exposed to radiation in the near-infrared (> 740 nm). The resulting emission spectrum is recorded with a camera and analyzed with a software program, thus revealing the in vivo distribution pattern of the respective dye. As can be seen in Fig. 30, there is a high rate of tumor accumulation for the albumin conjugated form (MW ~ 67,500 g/mol).

Besides the diagnostic evidence for tumor uptake, albumin and transferrin are suitable as drug carriers for a number of reasons: (1) tumor cells express high amounts of specific transferrin receptors on their cell surface (172–177); (2) they accumulate in tumor tissue and are taken up by proliferating tumor cells through endocytosis, probably in order to cover nutritional needs, i.e., amino acids and iron (178–182); (3) they are biodegradable, nontoxic, and

**Figure 32.31** Near-infrared imaging in a nude mouse bearing a subcutaneously growing colon tumor 24 h after intravenous administration of an acid-sensitive indotricarbocyanine albumin conjugate (see Fig. 31). Tumor localization is indicated by an arrow. (From cooperation with the IDF of the University of Berlin, FRG.)

nonimmunogenic (4) they are readily available in a pure form exhibiting good biological stability. In the past, various transferrin and albumin conjugates have been developed with clinically established anticancer drugs and some representative examples are described in the following. Direct coupling methods employing glutaraldehyde for cross-linking doxorubicin and daunorubicin to either albumin or transferrin have resulted in active conjugates. Faulk et al. have shown that transferrin conjugates of doxorubicin show high *in vitro* activity (183). These transferrin doxorubicin conjugates have been used in the treatment of patients with acute leukemia, and the results have shown diminished numbers of leukemic cells in peripheral blood, no increase of leukemic cells in bone marrow biopsies, and

no anaphylactic reaction in the patients (184). When doxorubicin was coupled to bovine serum albumin by the same glutaraldehyde method, Ohkawa et al. demonstrated that this albumin conjugate was able to overcome multidrug resistance in a rat hepatoma model (185).

The importance of realizing a point of cleavage in the spacer between the drug and the carrier protein was established through experiments by Trouet et al. in the development of peptide spacers (46). Daunorubicin was bound to succinylated albumin through a series of peptide spacer arms, and the resulting conjugates differed significantly in their antitumor activity against L1210 leukemia depending on the cleavability of the oligopeptide by lysosomal enzymes. Albumin daunorubicin conjugates containing distinct tri- and tetrapeptide spacers have shown high antitumor activity in *in vivo* models when administered *i.p.* (46).

We have recently developed a number of transferrin and albumin conjugates with the anthracyclines doxo- and daunorubicin and the alkylating agent chlorambucil (35,36,60,61). In these protein conjugates the drug was bound to the protein through an acid-sensitive carboxylic hydrazone bond or through an amide and ester bond, respectively.

The *in vitro* and *in vivo* activity of these conjugates has been studied intensively (35,36,60,61,186–188). A common theme that emerged from these studies was that the conjugates in which the anthracycline was linked to the protein through a stable amide bond showed no or only marginal inhibitory effects, whereas the acid-sensitive anthracycline protein conjugates demonstrated cytotoxic activity that was, on the whole, comparable to that of the free anthracycline. Interestingly, a comparison of analogous transferrin and albumin anthracycline conjugates showed a very similar picture of *in vitro* activity, *i.e.*, inhibitory effects did not depend on the carrier protein but rather on the chemical link realized between the drug and the protein. This fact was confirmed with our work on chlorambucil protein conjugates (36,61).

**Figure 32.32** Structure of an acid-sensitive indotricarbocyanine albumin conjugate.

The antitumor activity of acid-sensitive doxorubicin transferrin and albumin conjugates has been evaluated in a number of xenograft mammalian carcinoma models in a direct comparison with free doxorubicin (187). The transferrin and albumin conjugates showed significantly reduced toxicity (reduced lethality and body weight loss) at low doses with a concomitantly stable and improved antitumor activity of the transferrin and albumin conjugates compared to free doxorubicin at equitoxic doses. In accordance with the *in vitro* data we did not observe a pronounced difference between the transferrin and albumin conjugates with regard to *in vivo* efficacy in the tested animal models. Additionally, an acid-sensitive doxorubicin albumin conjugate induced a complete remission of primary kidney tumors against murine renal cell carcinoma and prevented the formation of metastases in the lungs, in contrast to therapy with doxorubicin at its optimal dose (188).

The folate antagonist methotrexate (MTX) is a further anticancer drug that has been bound serum proteins such as HSA. Chu and Whiteley have shown that MTX–albumin conjugates, synthesized through direct coupling with carbodiimides, are more effective than the free drug in reducing the number of lung metastases in mice inoculated subcutaneously with Lewis lung carcinoma (189–191). However, this conjugate did not exhibit improved activity over free MTX in prolonging the life span of L1210-bearing mice (192). Research on MTX–HSA conjugates carried out a decade later focused on the required coupling techniques in more detail (193–195). Preparation methods using either the N-hydroxysuccinimide ester of MTX or the assistance of water-soluble carbodiimides were carried out. Both methods were found to have advantages and drawbacks in terms of purity, stability, efficiency, and simplicity. MTX–HSA conjugates, synthesized by direct coupling using carbodiimides, have shown a reduction in tumor size and pulmonary metastases in B16 melanoma-bearing mice compared to free MTX, but no difference in overall survival was observed (194). It should be noted that the MTX/HSA ratio in these conjugates was high, about 26 molecules of MTX being bound to one molecules of HSA.

Sinn and coworkers have very recently emphasized that the drug loading rate determines the tumor-targeting properties of MTX albumin conjugates in rats. In a systematic study, in which the tumor uptake of MTX–albumin conjugates loaded with 1, 5, 7, 10, or 20 molecules of MTX was compared in Walker-256 carcinoma-bearing rats, only loading rates of close to one equivalent of MTX per molecule of albumin offered optimal tumor-targeting properties comparable to unmodified albumin (196).

This MTX–HSA conjugate loaded with one equivalent of MTX by reacting an intermediate derivative of MTX, i.e., a reactive ester formed by reaction with N-hydroxy-

succinimide and dicyclohexylcarbodiimide, with HSA, has shown high antitumor efficacy in xenograft nude mice models, and a clinical phase I study has been performed with 17 patients in Germany (197). An interesting finding of this study was that two patients with renal cell carcinoma and one patient with mesothelioma responded to MTX–HSA therapy (one partial response, two minor responses). Phase II studies are ongoing.

A further anticancer agent that has been bound to serum albumin as well as to transferrin is mitomycin C. Coupling was performed by binding an activated ester of glutarylated mitomycin C to bovine serum albumin or human serum transferrin (198,199). The resulting imide bond at the aziridine group of the drug is relatively unstable, and mitomycin C release appears to be through hydrolysis in the extracellular space of tumor tissue. The albumin mitomycin C conjugate was shown to accumulate in tumor tissue, to suppress tumor growth, and to increase the survival rate of tumor-bearing mice.

## V. DRUG CONJUGATES WITH GROWTH FACTORS AND CYTOKINES

Another approach for delivering therapeutic agents to tumor cells that has been investigated in the past 20 years is the coupling of anticancer drugs or toxins to peptide growth factors and cytokines, which are often involved in the mitogenic signaling of tumors (200,201).

### A. Drug Conjugates with Growth Factors

Peptide growth factors bind with high affinity to their receptors on the surface of malignant cells, resulting in intracellular responses that cause differentiation, growth, and survival of these cells (202,203). The specific interaction between ligand and growth factor receptor triggers a cascade of intracellular biochemical signals, resulting in the activation or suppression of various subsets of genes that are linked to cancer and that promote cell division and cell replication (200,204). Because large numbers of growth factors are found on the surfaces of various tumor cells, growth factors are potential carriers of cytotoxic agents for selective drug delivery.

In the past, different kinds of peptide growth factors have been studied with regard to their structure, to their origin, to their site of action, and to the characterization of the respective receptor. Some of these properties are listed in Table 7.

Coupling toxins to growth factors is a relatively new method for drug delivery due to their only recent characterization and restricted availability. Nevertheless, estab-

**Table 32.7** Properties of a Selection of Polypeptide Growth Factors

Growth factor (GF)	Description	Target cells	Receptors
Epidermal GF (EGF) Transforming GF $\alpha$ (TGF- $\alpha$ )	Major forms are 6 kD with some larger species detected, EGF and TGF- $\alpha$ proteins are 40% identical; both are released by proteolysis of membrane-bound precursors	Epithelia, mesenchymal and glial cells	Protein tyrosine kinase (175 kD) Product of the c-ERB protooncogene; receptor for EGF, TGF- $\alpha$ and vaccinia virus growth factor
Transforming GF (TGF): TGF- $\beta$ 1, TGF- $\beta$ 2, and TGF- $\beta$ 3	25 kD homodimers; secreted as latent complexes	Wide variety of cells	Type 1, 50 kD; type 2, 70 kD; type 3, 280–330 kD; each type binds TGF- $\beta$ 1, $\beta$ 2, and $\beta$ 3; type 1 may be main mediator of responses
Fibroblast GF (FGF): FGF1 and FGF2	Acidic and basic FGF, respectively; 16–17 kD; occasionally larger forms; 55% homologous; also related to other FGFs and interleukin-1 family	Variety of endothelial, epithelial, mesenchymal, and neuronal cell types	(150 kD) FGF1 and (130 kD) FGF2 receptors, both protein tyrosine kinases; high cross-reactivity of FGF1 and FGF2 with respect to receptor binding
Plateted-derived GF (PDGF): PDGF AA, AB, and BB	Dimers of A (17 kD) and B (16 kD) chains; B chain is product of c- <i>SIS</i> protooncogene	Mesenchymal cells, glial cells, smooth muscle cells, placental trophoblasts	Two species of glycoproteins; both tyrosine kinases; type $\alpha$ (170 kD) binds all PDGF dimers; type $\beta$ (180 kD) binds PDGF BB and AB weakly
Vascular endothelial-GF (VEGF)	Dimers composed of two subunits of identical weight (2 $\times$ 23 kD)	Wide variety of cells	Protein tyrosine kinase; <i>fms</i> -like, (160 kD)
Insulin-GF (IGF): IGF1 and IGF2	7 kD, both growth factors are related to each other and to proinsulin	Wide variety of cells	IGF1 receptor (130 kD + 90 kD); protein tyrosine kinase that binds IGF1 and IGF2; IGF2 receptor (250 kD) is identical to mannose-6-phosphate receptor and binds solely IGF2

Source: Ref. 205.

lished methods for providing recombinant peptides in large amounts, e.g., through gene splicing DNA techniques (206), has led to an increased interest in using peptide growth factors as carrier systems. In this chapter, several important peptide growth factors and their conjugates with anticancer agents and toxins are described.

### 1. Epidermal Growth Factor and Transforming Growth Factor

The epidermal growth factor family of proteins encompasses several growth factors that are structurally and functionally related proteins, such as the epidermal growth factor (EGF) and the transforming growth factor (TGF- $\alpha$ ) (207). Both growth factors interact with the same cell sur-

face receptor which is overexpressed in several tumor types.

#### a. Epidermal Growth Factor (EGF)

Among the growth factors that have been purified to date, EGF is one of the most biologically potent and best characterized with respect to its physical, chemical, and biological properties (208). EGF is a single-chain polypeptide composed of 53 amino acids with an isoelectric point at pH 4.6 and a molecular weight of 6045 Da (208). The biological effect of EGF, which is secreted by the salivary glands and by specialized enteroendocrine cells found in the small intestine (209,210), is to promote proliferation of the basal cell layer of various epithelia of ectodermal origin.

The epidermal growth factor receptor (EGF-R) is frequently implicated in human cancer and binds EGF as well as TGF- $\alpha$ . Enhanced expression of EGF-R has been implicated in human cancers of the brain, head, neck, lung, ovary, and breast (211). Furthermore, patients with tumors that overexpress EGF-R often have a poor prognosis. Considering the high affinity between EGF-R and its ligand ( $K_d \cong 2-4 \times 10^{-10}$  M) and the fact that the receptor-ligand complex is internalized (208), exploitation of EGF as a vehicle for drug delivery is a potential strategy of achieving tumor targeting (212).

In the past years, EGF was coupled to different anticancer drugs, toxins, or radionuclides by several groups, and the antitumor activity of the respective conjugates was evaluated with respect to the amount of EGF-R on the cell membranes of different cell lines (213–219). A first example is described by Acostata and coworkers who prepared a conjugate of EGF with the anticancer drug doxorubicin using glutaraldehyde as the coupling reagent (213). Subsequent *in vitro* studies in tumor cell lines showed that the conjugate exhibited the same binding capacity to EGF-R as free EGF in breast cancer cells, and there was no loss of cytotoxicity of conjugated doxorubicin. Furthermore, the cytotoxicity of the conjugate was dependent on the amount of EGF-R on the cell membranes (214).

In another work, conjugation of EGF with ricin, a toxic glycoprotein from castor beans, is described (215). The EGF-ricin conjugate was cytotoxic at much lower concentrations than required for ricin itself.

Jinno et al. reported on human and murine EGF conjugates with mammalian pancreatic ribonuclease (RNase) (214). The EGF-RNase conjugate retained potent RNase activity and showed dose-dependent cytotoxicity against EGFR-overexpressing A431 human squamous carcinoma cells as well as against other squamous carcinoma and breast cancer cell lines. In all cases, the efficacy of the conjugates correlated positively with the level of expression of EGF-R in each cell line.

*In vitro* as well as *in vivo* experiments were performed in order to study the antitumor activity of EGF conjugates with phthalocyanines, i.e., disulfochloride cobalt phthalocyanine, against murine B16 melanoma (216). The conjugate possessed higher cytotoxic activity *in vitro* in comparison to the unbound agent. Subsequent *in vivo* results in mice treated intravenously with the conjugate showed tumor growth inhibition as well as increased mean life spans and survival of the experimental animals.

Further *in vivo* experiments were described using a conjugate of EGF and the isoflavone genistein (217). The *in vivo* toxicity profile, the pharmacokinetics, and the anticancer activity of the conjugate were studied. The conjugate significantly improved tumor-free survival in a severe

combined immune deficiency (SCID) mouse model of subcutaneous human breast cancer at systemic exposure levels nontoxic to mice when administered intraperitoneally. Furthermore, plasma samples from EGF-genistein-treated monkeys exhibited potent and EGF-R-specific *in vitro* antitumor activity against EGF-R-positive human breast cancer cell lines (217).

Another example for using EGF as a carrier system is a targeted DNA delivery system developed for the possible treatment of lung cancer (218). EGF was chemically modified with poly-L-lysine (PLL), thus allowing the attachment of DNA to the conjugate. *In vitro* experiments showed that EGF/PLL complexed with DNA could efficiently deliver DNA into several lung cancer cells by receptor-mediated endocytosis.

Finally, Zhao et al. studied a mouse EGF-dextran-tyrosine conjugate *in vitro*. Murine EGF was coupled to dextran (70 kD) by reductive amination, and subsequently tyrosine residues were introduced onto the dextran surface to allow the attachment of radionuclides, such as  $^{125}\text{I}$  (219). Exposure of the conjugate to dextranase showed that iodine was primarily attached to the dextran part of the conjugate. The conjugate was effectively internalized in human glioma cells, and radioactivity was retained inside the cells for up to 50 h.

#### *b. Transforming Growth Factor $\alpha$ (TGF- $\alpha$ )*

TGF- $\alpha$  is a 50 amino acid protein that is derived from a 170 amino acid precursor protein, pro-TGF- $\alpha$ , and that acts exclusively through the EGF receptor (220). TGF- $\alpha$  expression is prevalent in tumor-derived cell lines, e.g., in non-small-cell lung cancer cell lines, and in cells transformed by cellular oncogenes, retroviruses, and tumor promoters; its biological function is to induce cell proliferation (221).

Although it is more common to conjugate drugs or toxins with the epidermal growth factor, several studies have been performed in order to investigate the potential of TGF- $\alpha$  as a drug carrier. For this purpose, recombinant toxins containing TGF- $\alpha$  and *Pseudomonas* exotoxin 40 have been developed (222). This technique has the advantage of avoiding the difficulties of chemical conjugation methods that can produce heterogeneous products that affect receptor binding (223). The former chimeric protein exhibits the receptor-binding properties of TGF- $\alpha$  and the cell-killing activity of *Pseudomonas* exotoxin 40. *Pseudomonas* exotoxin is a single-chain protein made up of three major domains: domain Ia binds to the cell surface, domain II catalyzes the translocation of the toxin into the cytosol, and domain III contains the ADP-ribosylation activity that inactivates elongation factor 2 and leads to cell

death (224). In vitro experiments showed that the conjugate is extremely cytotoxic against a variety of cancer cell lines including liver, ovarian, and colon cancer cell lines, indicating high levels of EGF receptor expression in these cells (225).

Similar results were obtained when using conjugates with derivatives of *Pseudomonas* exotoxin, which are slightly modified forms of the toxin protein (226). In vivo experiments with a modified conjugate were performed in tumor-bearing nude mice that either expressed the EGF receptor or not. The results showed that mice bearing tumors that express EGF receptors lived significantly longer when treated intraperitoneally with the conjugate compared to saline-treated controls (101 vs 47.5 days) (222). The conjugate did not prolong the survival of mice bearing tumor cells that lack EGF-R (15.5 vs. 19.5 days). When given i.p., the conjugate induced moderate hepatic necrosis.

In further studies, a recombinant toxin composed of human TGF- $\alpha$  fused to a fragment of *Pseudomonas* exotoxin (PE38), devoid of its cell-binding domain, was coupled to monomethoxy-polyethylene glycol (PEG) of different molecular weights (range 10–63 kDa), and the conjugates were tested for their in vivo activity (227). The experiments showed that PEGylated conjugates exhibited markedly enhanced antitumor activities when compared to the unmodified chimeric toxin and that they had extended lifetimes in the blood when administered intravenously to tumor-bearing mice.

## 2. Vascular Endothelial Growth Factor (VEGF)

The growth of solid tumors beyond a size of 2 mm in diameter is dependent on new blood vessel formation through angiogenesis (228). This complex process is mediated by various tumor-derived growth factors such as the vascular endothelial growth factor (VEGF) (203). VEGF was first purified by Gospodarowicz et al. and Ferrara and Henzel in the late 1980s from the conditioned medium of bovine pituitary folliculo stellate cells and shown to be an approximately 46-kDa protein that dissociates into two apparently identical 23-kDa subunits upon reduction (229–231). Binding of VEGF to its specific receptor causes a mitogenic signal resulting in cell proliferation and growth of capillary endothelial cells (232). VEGF is an angiogenic factor that simulates endothelial cell proliferation and migration and can induce local permeability changes in blood vessels that lead to capillary leak and fibrin deposition (233).

The use of VEGF as a carrier system in order to block tumor neovascularization was intensively studied by Ramakrishnan et al., who investigated whether VEGF could

be used to deliver toxin polypeptides to vascular endothelial cells (234). A conjugate was synthesized linking a recombinant isoform of VEGF to a truncated form of the diphtheria toxin. This conjugate was investigated for its ability to inhibit vascular endothelial cell proliferation and angiogenesis in human umbilical vein endothelial cells and in human microvascular endothelial cells. Treatment of the cells with the conjugate resulted in a selective, dose-dependent inhibition of growth. In an in vivo model of angiogenesis, the conjugate showed marked inhibition of neovascularization. Further in vivo experiments were performed to investigate the antitumor activity of the chemically linked conjugate (235). Athymic nude mice bearing established subcutaneous tumors were treated i.p. with VEGF toxin, which evoked an antitumor response. Histological analyses showed tumor necrosis originating from vascular injury, and the conjugate had no effect on well-vascularized, normal tissues.

However, recent in vitro investigations with similar chimeric proteins containing isoforms of VEGF and diphtheria toxin were found to be highly toxic to proliferating endothelial cells but not to vascular smooth muscle cells (236). The fusion proteins were also active in in vivo experiments with mice bearing s.c. Kaposi's sarcoma, a tumor type that expresses high levels of VEGF receptor and that is commonly seen in patients with HIV-1 (237). The in vivo results of subcutaneously administered conjugate showed that the protein substantially retarded the growth of Kaposi's sarcoma (236).

## 3. Fibroblast Growth Factor (FGF)

Several factors inducing angiogenesis have been isolated and characterized, among them the acidic and basic form of the fibroblast growth factor (229). Acidic FGF (aFGF) is a 140 amino acid protein (~ 16 kDa) that was isolated from tissue of the bovine brain and the retina (238). Basic FGF (bFGF) is a 146 amino acid protein (~ 17 kDa) isolated from several tissues, such as bovine and human brain, retina, and kidney (239). The amino acid sequence of aFGF has a 53% homology to bFGF, and both growth factors interact with the same cell surface receptor. In fact, in normal adult tissue, the expression of FGF receptors is either absent or very low. However, in diseased tissues, such as cancer, FGF receptors are overexpressed (240). Both aFGF and bFGF are potent mitogens for vascular and capillary endothelial cell types and stimulate the formation of blood capillaries (angiogenesis) in vitro and in vivo (241,242).

Conjugation of toxins with FGF to achieve selective antitumor activity has been investigated in a few cases. In the early 1990s, several scientists investigated the in vitro and in vivo antitumor activity of a chemically linked conju-

gate of bFGF and the ribosome-inactivating protein saporin (243). In vitro experiments in several human cancer cell lines expressing FGF receptors showed high cytotoxicity of the conjugate. In addition, in vivo experiments in nude mice bearing human tumor xenografts, the conjugate given intravenously demonstrated dramatic tumor growth inhibition and minimal toxicity (243,244). Later, a fusion protein containing the full-length sequences of bFGF and saporin was expressed in *Escherichia coli* that demonstrated high binding affinity to FGF receptors (245). In vivo experiments against B16-F10 melanoma, the subcutaneously administered recombinant protein proved to have the same therapeutic profile as the chemically linked conjugate (246). Recently, in vitro studies with both chemically conjugated and fusion bFGF–saporin protein in human bladder cancer cell lines showed high antiproliferative activity (247).

In other studies, chimeric proteins composed of aFGF and several forms of *Pseudomonas* exotoxin were investigated for their cytotoxic activity in a variety of tumor cell lines including hepatocellular, prostatic, colon, and breast carcinomas (248). The cytotoxic effects were FGF-receptor-specific as demonstrated by competition with excess aFGF and by showing that aFGF toxin bound to the FGF receptor with the same affinity as aFGF. Furthermore, it could be shown that cell-killing was toxin mediated.

## B. Immunotoxins with Interleukins

Among the cytokines, interleukins have been extensively studied as carriers of toxins, and we will restrict our discussion to respective immunotoxins with these cytokines.

The interactions between immune and inflammatory cells are mediated to a large part by proteins termed interleukins (IL) that are able to promote cell growth, differentiation, and functional activation. The name interleukin was chosen because it reflected the basic property of these mediators to serve as communication links between leukocytes (201). During the last two decades, the molecular structure of a number of interleukins (IL-1–IL-15) has been described in detail, and their genes have been cloned. Each interleukin has its unique biological activity, but some functions overlap. Physicochemical and biological properties of interleukin 1–8 are presented in Table 8.

The interest of synthesizing immunotoxins with interleukins is increasing due the promising results obtained in the past. Clinical phase 1 and 2 trials have been performed in some cases, e.g., with a chimeric conjugate of interleukin-2 and diphtheria toxin (250). In the following, immunotoxins with interleukins IL-2, IL-4, and IL-6 are presented as prominent examples.

### 1. Immunotoxins with Interleukin-2

Interleukin-2 (IL-2) is a 15.5 kDa glycoprotein with a slightly basic isoelectric point; its cDNA was first isolated and characterized by Taniguchi et al. (251). Among the various biological functions of IL-2, the most important are to promote the proliferation, differentiation, and recruitment of T and B cells, natural killer cells, and thymocytes (252–254). In addition, IL-2 causes cytolytic activity in a subset of lymphocytes (201). As a biological response modifier, IL-2 as well as several forms of recombinant IL-2 are in various stages of preclinical development and clinical investigation (255). Patients with renal cell cancer and melanoma, who responded poorly to conventional therapy, have responded to therapy with recombinant IL-2 (256).

The use of IL-2 as a drug carrier in drug delivery was studied mainly as a fusion protein with *Pseudomonas* exotoxin (PE) or diphtheria toxin. A chimeric immunotoxin was constructed genetically by fusing IL-2 to the amino terminus of a modified form of PE (257). Internalization of IL-2-PE40 via the p55 and p70 subunits of the IL-2 receptor, two individual polypeptide chains of the receptor complex, was studied in several mouse and human cell lines expressing either the p55 or the p70 or both IL-2 receptor subunits. The results demonstrated that internalization of IL-2-PE40 is mediated by either the p55 receptor subunit or by the p70 subunit but is much more efficient when high-affinity receptors composed of both subunits are present.

The construction of a diphtheria-toxin-related fusion protein has been described in which the native receptor-binding domain of the toxin was genetically replaced with IL-2 (258). This conjugate, DAB389IL-2, was shown to bind to the IL-2 receptor and selectively to kill lymphocytes that express a high-affinity form of the IL-2 receptor. The cytotoxic action of the conjugate was mediated by receptor-mediated endocytosis with subsequent delivery of fragment-A-associated ADP-ribosyltransferase to the cytosol of targeted cells, inducing cell death (259). A multicenter phase I/II clinical trial with DAB389-IL-2 was performed primarily including a large number of lymphoma patients (250). The results of these clinical trials are promising with partial and complete responses being observed.

### 2. Immunotoxins with Interleukin-4

Interleukin-4 (IL-4) is a 20 kDa glycoprotein produced by activated T lymphocytes. Principally, IL-4 enhances the growth and/or differentiation of T cells (260), activates macrophages, and promotes the growth of granulocytes, mast cell, and erythrocyte colonies (201).

Immunotoxins with IL-4 have primarily been developed

**Table 32.8** Properties of Interleukins

Interleukin	M <sub>w</sub> [kDa]	Principal origin(s)	Principal site(s) of activity	Major effects
Interleukin-1	13–17	Monocytes, macrophages	T cells, B cells, endothelium, fibroblasts, chondrocytes, hepacytes, osteoclasts, synovial cells	Pyrogenesis, major proinflammation, cellular proliferation, lymphokine synthesis, lymphokine receptor synthesis
Interleukin-2	15.5	T cells	T cells, natural killer cells, lymphokine-activated killer cells, tumor-infiltrating lymphocytes	Cellular proliferation and differentiation
Interleukin-3	28	T cells	Hematopoietic precursors	Hematopoiesis, cellular differentiation
Interleukin-4	20	T cells	B cells	Cellular proliferation and differentiation
Interleukin-5	4	T cells	B cells, eosinophils	Cellular proliferation and differentiation
Interleukin-6	20–30	Monocytes, macrophages	B cells, T cells	Pyrogenesis, cellular proliferation and differentiation
Interleukin-7	25	Bone marrow stromal cells	B-cell precursors	Cellular proliferation
Interleukin-8	8–11	Monocytes	Neutrophils	Chemotaxis, respiratory bursting

Source: Ref. 249.

with *Pseudomonas* exotoxin (PE) as well as with several mutated forms of this toxin. Chimeric toxins have been constructed by fusing a gene encoding human interleukin-4 with a gene encoding PE40, a noncytotoxic mutant form of PE that retains ADP-ribosylating activity, as well as with genes encoding different mutant forms of PE40 (261). The toxin with PE40 was found to be highly toxic against a murine T cell line bearing high numbers of IL-4 receptors, but had no effect on human cell lines lacking receptors for murine IL-4. In addition, the chimeric protein composed of a mutant form of PE40 with very low ADP-ribosylating activity displayed mitogenic activity similar to that of IL-4 rather than cytotoxic activity. These results demonstrated that ADP-ribosylating activity was essential for cytotoxicity and that the mutant form of the conjugate bound specifically to the IL-4 receptor (261).

A few years later, another chimeric toxin was prepared using human IL-4 and the mutant form of PE (PE4E) in which glutamate residues were substituted for basic amino acids at various positions (262). This conjugate exhibited antitumor effects against cancer cells expressing human IL-4 receptors *in vitro*. A wide range of human cancer cells express IL-4 receptors. These include hematopoietic and nonhematopoietic malignancies. Among the latter group, distinct tumor cell lines, e.g., colon, breast, stomach, liver, skin, prostate, adrenals, and cervix cell lines, were highly sensitive to the cytotoxic action of the fusion protein.

Further investigations focused on targeting IL-4 recep-

tors in human solid tumor xenografts with IL-4 toxins (263). In these studies, a mutant chimeric protein composed of human IL-4 and a mutant form of PE, named PE38QQR, was tested *in vitro* and *in vivo* together with the earlier developed conjugate IL-4-PE4E with respect to their receptor-dependent and dose-dependent antitumor activities. Neither of the chimeric toxins showed antitumor potency when the ADP-ribosylation activity of the toxin was inactivated by mutagenesis. Only the new conjugate caused a complete although transient regression of established solid tumors when administered intraperitoneally to mice (263).

Although the former studies demonstrated high antitumor activity *in vivo*, the fusion proteins bound to the IL-4 receptor with only ~ 1% of the affinity of native IL-4 (262). Several studies have indicated that the carboxyl terminus of IL-4 is important for receptor binding (264). Therefore, it is likely that the large toxin molecule attached to the carboxyl terminus impairs the binding of IL-4 to the IL-4 receptor. Thus a new strategy has been developed in which the toxin is fused to new carboxyl termini of circularly permuted forms of IL-4 (265). A circularly permuted protein is a mutant protein in which the termini have been fused and new termini are created elsewhere in the molecule. This conjugate, IL-4(38-37)-PE38KDEL, manifested improved cytotoxicity against various tumor cell lines and bound to the IL-4 receptor with a 10-fold higher affinity than an IL-4 toxin in which the toxin was fused

to the carboxyl terminus of IL-4 (265). In addition, the conjugate was 3–30 fold more cytotoxic in glioblastoma cell lines than IL-4–PE4E (266).

Further experiments were performed in order to assess the in vivo antitumor activity of the conjugate. To date, no curative therapy is available for treating malignant gliomas; recent studies have demonstrated a lack of IL-4 receptor expression on normal brain tissue compared to malignant human glioblastoma cells (267). Intratumoral administration of the IL-4 toxin into U251 glioblastoma flank tumors in nude mice produced a complete remission of small and large tumors in all animals without any evidence of toxicity (268).

Due to the positive results obtained in vivo, toxicologic experiments were performed in mice, rats, guinea pigs and monkeys. Intrathecal administration in monkeys produced high cerebrospinal fluid levels and low systemic toxicity (268). However, intravenous administration of IL-4(38-37)–PE38KDEL to monkeys resulted in reversible grade 3 or grade 4 elevations of hepatic enzymes in a dose-dependent manner. These results indicate that local administration can achieve nontoxic systemic levels of IL-4 toxin (267).

Based on these results, a phase I clinical trial evaluating the effects of an intratumoral administration of IL-4(38-37)–PE38KDEL against recurrent grade IV astrocytoma has been initiated (269).

### 3. Immunotoxins with interleukin-6

Interleukin-6 (IL-6) is a glycoprotein of 20–30 kDa that is produced by a wide variety of cells, including fibroblasts, monocytes/macrophages, endothelial cells, T and B cells, keratinocytes, and also by a number of tumor types (201). The heterogeneity in size is a function of differential glycosylation of the interleukin. IL-6 has a broad spectrum of cell targets and can thus influence an equally broad array of immune and inflammatory responses. Its varied designations—hybridoma growth factor, plasmacytoma growth factor, hepatocyte-stimulating factor, B-cell-stimulating factor 2, and  $\beta_2$ -interferon—attest to the wide range of activities associated with this interleukin (201,270,271). IL-6 receptors have been identified in large numbers on the surface of malignant bone marrow cells and on tumor cell lines derived from patients with multiple myeloma (272). IL-6 receptors have also been identified on the surface of hepatocellular carcinoma and prostate carcinoma cell lines.

In analogy to the development of immunotoxins with IL-2 and IL-4 (273,274), several fusion proteins containing different mutant forms of *Pseudomonas* exotoxin (PE40, PE66<sup>4Glu</sup>) and IL-6 were prepared and tested for their cytotoxic activity (275). The conjugates were cytotoxic against

IL-6 receptor expressing tumor cell types in culture, such as human myeloma or hepatoma cell lines. In vivo studies showed that two selected chimeric conjugates had antitumor activity against subcutaneously growing hepatocellular carcinoma (PLC/PRF/5). This tumor contained about 2300 IL-6 receptors per tumor cell (275).

## VI. DRUG CONJUGATES WITH POLYSACCHARIDES

Besides the already-mentioned natural polymers, which have been discussed as carrier systems, e.g., growth factors and the serum proteins albumin and transferrin, several other naturally occurring macromolecules have been investigated as drug carriers of anticancer agents. These biopolymers serve as carriers of information (nucleic acids), catalysts (enzymes), structural elements (fiber-forming proteins, cellulose), food reservoirs (glycogen, polyesters) or transporting molecules (hemoglobin) (276). The most important classes of homologous biopolymers are nucleic acids, proteins, polysaccharides, polyprenes, lignins, and aliphatic polyesters.

In this chapter we focus on the polysaccharides dextran and hyaluronic acid as carriers of anticancer agents. Drug conjugates with other natural substances, such as lectins, nucleic acids, and the polysaccharide alginates, chitins, or chitosans (277–280), will not be addressed in this review.

Polysaccharides are homopolymers or copolymers of various sugars that are almost exclusively hexoses and pentoses. Polysaccharides are usually subdivided into fibrin-forming linear structural polysaccharides (e.g., cellulose, chitin), moderately to strongly branched reserve polysaccharides (e.g., amylose, pectin), and physically cross-linked, gel-forming polysaccharides (e.g., gums, mucopolysaccharides).

Several techniques for coupling anticancer agents to polysaccharides have been developed, the most frequent being periodate oxidation, cyanogen bromide activation, and diazotization (28).

### A. Dextrans

Dextrans are natural macromolecules consisting of repeated linear units of covalently linked (1 → 6') glycopyranose which are branched at the  $\alpha$ -(1 → 4') position. As a consequence, only one hydroxyl group of the respective dextran chain can be reduced yielding an aldehyde group at the C1 end (276).

At least three forms of dextran have been used in drug delivery: the native hydroxyl form (Dex-OH), the aldehyde form (Dex-CHO), obtained by mild periodate treatment,

and the amino form (Dex-NH<sub>2</sub>), derived from treatment of Dex-CHO with a diamine followed by mild borohydride reduction (28). Dextrans of different molecular weight (they range generally between 40 and 70 kDa) have been suggested as drug carrier because they have

- Well-defined and repetitive chemical structure
- Good water-solubility
- High stability, because glucosidic bonds are hydrolyzed only under strong acidic or alkaline conditions
- Presence of numerous reactive hydroxyl groups that allow derivatization
- Availability of different molecular weights
- Low pharmacological activity and toxicity
- Protection of conjugated drugs from biodegradation (281)

In the past, various anticancer agents, such as the anthracyclines doxorubicin and daunorubicin, methotrexate, and mitomycin C or 5-fluorouracil, have been coupled to dextrans (282–284). The development of dextran conjugates with the anticancer agents daunorubicin, doxorubicin, and mitomycin C is described below.

#### 1. Dextran Conjugates with Anthracyclines and Mitomycin C

In a series of investigations, daunorubicin and doxorubicin were coupled to dextrans. Dextran–daunorubicin conjugates of molecular weight 40 kDa and 70 kDa were prepared by Schiff base formation followed by reduction with sodium borohydride (285). In vitro studies with these conjugates revealed a cytotoxic activity similar to that of the free drug. Later, Levi-Schaffer et al. showed that the subacute toxicity of the dextran–daunorubicin conjugates was lower than that of free daunorubicin (286).

In related work, doxorubicin linked to oxidized dextran (70 kDa) via Schiff base formation without any further reduction of the conjugate was compared to free doxorubicin with regard to antitumor activity, acute toxicity, and plasma pharmacokinetics in rats following i.v. administration. Extensive in vivo studies in a number of animal tumor models demonstrated that the conjugate had both higher antitumor activity and less toxicity than free doxorubicin. In studies with tumor-bearing mice, growth inhibition was observed in various tumor models including Lewis lung and Walker carcinosarcoma 256 (44). In mouse leukemia models, treatment with the conjugate resulted in an increase of life span. The antitumor effect of the dextran–doxorubicin conjugate was also higher than that of doxorubicin in human tumor xenografts (gastric, colorectal, breast), including tumors resistant to doxorubicin.

Toxicological evaluations of the conjugate have been

performed in mice, rats, and dogs (287) demonstrating that the LD<sub>10</sub> was about five times higher for the conjugate than for doxorubicin. Furthermore, the biodistribution profile of the dextran–doxorubicin conjugate in animals differed from that of doxorubicin. In mice and rats, plasma and tumor levels of the conjugate were higher than those of the free drug (44,288,289).

Based on the preclinical activity of the dextran–doxorubicin conjugate, a clinical phase I trial was performed. The conjugate was administered i.v. as a single dose every 21–28 days. However, significant clinical toxicity (profound but reversible thrombocytopenia and hepatotoxicity) was noted presumably due to uptake of the conjugate by the reticuloendothelial system (287).

The antitumor antibiotic mitomycin C has been coupled to dextrans and the respective conjugates evaluated as chemotherapeutic agents (281). For synthesizing the conjugates, dextrans of various molecular weights (10, 70, 500 kDa) were activated with cyanogen bromide at pH 7.0, and  $\epsilon$ -aminocaproic acid, acting as spacer, was subsequently coupled to the glucose moiety. Mitomycin C was attached to the spacer-introduced dextran by means of a carbodiimide-catalyzed reaction (290).

In a series of investigations, the physicochemical properties and the antitumor activity of dextran–mitomycin C conjugates were studied with regard to molecular weight, electric charge, and drug release rates (69). The conjugates liberated active mitomycin C in vitro by simple base-catalyzed hydrolysis, and the release rate was controlled by changing the length of the spacer (291). In addition, the conjugates showed significant antitumor activities in mice bearing P388 leukemia or B16 melanoma in an i.p.–i.p. system, and antitumor efficacy correlated positively with increasing molecular weights (69,291).

In further studies, the relationships between the physicochemical characteristics, the pharmacokinetic properties, and the therapeutic efficacy of the conjugates were investigated. Anionic dextran–mitomycin C conjugates were prepared and compared to the already presented conjugates, which are cationic conjugates due to the positive structure of the dextran chain. Anionic dextran conjugates were synthesized by derivatizing dextran with a spacer molecule, i.e., 6-bromohexanoic acid. Since not all of the spacer arms were conjugated with mitomycin C, the resulting dextran–mitomycin C conjugates are anionic. Only these conjugates demonstrated a prolonged retention in the blood circulation, marked accumulation in subcutaneously growing mouse tumors, and tumor growth inhibition (292,293).

In addition, the therapeutic effect of an intratumoral injection of cationic and anionic dextran–mitomycin C conjugates was evaluated in vivo (294). Usually, the clinical

application of regional chemotherapy using antitumor drugs of low molecular weight is limited due to the rapid clearance of the drugs from the injection site while causing severe local damage to normal tissues. Macromolecular prodrugs may offer a therapeutic benefit in this respect (295,296).

Saikawa et al. established an experimental system for assessing drug disposition in the tumor after intratumoral injection using a tissue-isolated tumor preparation of Walker 256 carcinosarcoma (297). In contrast to free mitomycin C, cationic and anionic dextran-mitomycin C conjugates were retained in the tumor for longer periods, demonstrating that the intratumoral clearance of mitomycin C can be greatly retarded by dextran conjugation. The effect was more pronounced in the case of the cationic conjugate, and a certain level of active free drug was achieved in the tumor tissue.

This study was expanded by carrying out perfusion experiments using the same tumor model in order to determine the pharmacokinetics of mitomycin C and dextran-mitomycin C conjugates after intratumoral injection. While mitomycin C disappeared rapidly from the tumor preparation following direct intratumoral injection, cationic and anionic dextran-mitomycin C were retained in the tumor. Drug accumulation was more pronounced for the cationic conjugates of high molecular weight (500 kD). In addition, pharmacokinetic studies and whole autoradiography in rats bearing subcutaneous Walker 256 carcinosarcoma confirmed the significant retention of cationic dextran-mitomycin C in the tumor after intratumoral injection (298).

## **B. Hyaluronic Acid and Anticancer Drug Conjugates**

Hyaluronic acid (HA) is a linear polysaccharide of alternating D-glucuronic and N-acetyl-D-glucosamine units and adopts a three-dimensional structure in solution showing extensive intramolecular hydrogen binding. This restricts the conformational flexibility of the polymer chains and induces distinctive secondary (helical) and tertiary (coiled coil) interactions. HA is one of several glycosaminoglycan components of the extracellular matrix and the synovial fluid of joints. The remarkable viscoelastic properties of HA and commercial cross-linked derivatives account for their usefulness in joint lubrication (299). Protein interactions with HA play crucial roles in cell adhesion, cell motility, inflammation, wound healing, and cancer metastasis (300,301). Due to its immunoneutrality, HA is an excellent building block for developing novel biocompatible and biodegradable biomaterials with potential application in tissue engineering and drug delivery systems (66).

HA is overexpressed at sites of tumor attachment to the mesentery and provides a matrix that facilitates invasion. HA is an important signal for activating kinase pathways (302) and regulating angiogenesis in tumors (303). Moreover, several types of cellular HA receptors respond to HA as a signal (304). Since HA receptors are overexpressed in transformed human breast epithelial cells and other cancers, HA drug conjugates might be able to deliver the drug selectively to these cells.

In a series of investigations, HA has been coupled to doxorubicin and daunorubicin and very recently to paclitaxel (34,305,66). Doxorubicin and daunorubicin were bound to HA (~ 140 kDa) via condensation or a cyanogen bromide technique (34). In vitro studies showed that the conjugates were less active than the free drug and that they were bound at the cell surface with only small amounts entering tumor cells (305).

The conjugation of the powerful antimetabolic agent paclitaxel with HA has been described in a recent study (66) HA-paclitaxel conjugates were synthesized by coupling the 2'-OH paclitaxel-hydroxysuccinimide ester to adipic dihydrazide (ADH) modified HA of molecular weight 1500 kDa (HA-ADH). A fluorescent dye conjugate with HA was also synthesized in order to demonstrate cell targeting and uptake of chemically modified HA using confocal microscopy. HA-paclitaxel conjugates showed selective in vitro toxicity against human cancer cell lines (breast, colon, and ovarian) that are known to overexpress HA receptors, while no toxicity was observed in mouse fibroblast cell lines at comparable concentrations. The modified HA drug carrier was nontoxic. The selective cytotoxicity was consistent with results from confocal microscopy studies, which demonstrated that the fluorescent dye conjugate was taken up by cancer cells (66).

## **VII. SUMMARY**

Coupling anticancer drugs to suitable macromolecular carriers is a promising approach of circumventing the toxic side effects of these agents to normal cells and of improving their efficacy towards malignant cells. In the 1980s, research efforts focused on the development of monoclonal antibodies directed against tumor-associated antigens or receptors as site-directed delivery systems in cancer therapy. Despite the encouraging preclinical results with distinct anticancer drug-antibody conjugates, the antitumor efficacy of these conjugates in clinical trials has been disappointing (for a discussion see Section III).

In the past ten years, tumor-targeting strategies have shifted from active targeting strategies to passive ones due to a more detailed understanding of the anatomy and physi-

ology of solid tumors (see Introduction, EPR effect). Indeed, recent studies comparing the tumor uptake of a monoclonal antibody directed against a tumor-specific antigen and a long-circulating polymer in a human small lung carcinoma model suggests that delivery to the tumor can be equally effective (306).

Seen in this light, the decisive criteria for tumor accumulation in vivo would be the molecular size of the macromolecular carrier and not its specificity and selectivity for an antigen or a receptor on the surface of tumor cells. After tumor uptake, the release of a polymer-bound anticancer drug is then dictated by conditions prevailing in the extracellular space of tumor tissue or in the intracellular compartments after cellular uptake of the conjugate by receptor-mediated, fluid-phase, or adsorptive endocytosis.

A number of anticancer drug conjugates with synthetic polymers [N-(2-hydroxypropyl)methacrylamide (HPMA) doxorubicin conjugates PK1 and PK2; PEG-camptothecin conjugate—see the article by L. Seymour for details] and biopolymers such as albumin (methotrexate albumin conjugate—see Section IV) are currently undergoing phase I and II studies. Together with further preclinical assessment, these studies should lead to a better understanding of the therapeutic potential of competing drug carriers for the treatment of cancer.

### I. INTRODUCTION

Since the early twentieth century, many researchers have sought Ehrlich's elusive magic bullet for treating the ills of mankind. The principle of chemotherapy has depended on a compound exhibiting selective toxicity towards a foreign organism. With respect to cancer chemotherapy, it was envisaged that compounds would be identified or synthesized that would be able to distinguish between normal and neoplastic cells and selectively correct or eradicate the abnormal cells with minimal toxic side effects on normal cells and tissue. Cancer chemotherapy has rarely achieved this.

The first documented use of cancer chemotherapy was in 1942 when the alkylating agent nitrogen mustard was used to obtain brief clinical remission in a patient with lymphoma. Since then, a large number of clinical drugs have been tested for their potential antitumor activity. Of the 300,000 or so compounds that have been evaluated as possible anticancer agents, about forty are considered useful. Most anticancer drugs can be grouped into families based on their biochemical activity or on their origins. These major families are

1. The alkylating agents, which include nitrogen mustard, chlorambucil, melphalan, busulphan, and the nitrosoureas. All of these compounds react so that an alkyl or substituted alkyl group becomes covalently linked to cellular constituents. Although reactions with proteins and other

cellular components occur, the important site of mustard action is almost certainly DNA (1).

2. The platinating agents, which include cisplatin and carboplatin. The important site of action of these compounds is also DNA (2,3).

3. The antimetabolites, which include methotrexate, 5-fluorouracil, cytosine arabinoside, and 6-thioguanine, are principally inhibitors of critical biochemical pathways usually leading to inhibition of DNA or RNA synthesis.

4. A number of natural anticancer compounds exist that are either plant or bacterial products and include mitotic inhibitors such as the vinca alkaloids, or the antibiotics such as mitomycin C or bleomycin.

Chemotherapy is used predominantly in the treatment of metastatic or disseminated malignant neoplastic disease. However, cytotoxic chemotherapy is an imperfect modality due to the systemic nature of its cytotoxicity. This is because the agents lack any intrinsic antitumor selectivity. They mostly act by an antiproliferative mechanism, and their action is on cells that are in cycle, or in some cases, on a specific phase of the cell cycle, rather than by a specific toxicity directed towards a particular type of cancer cell. Thus the limiting toxicity of the majority of anticancer agents is a result of a toxic effect on the normal host tissues that are the most rapidly dividing, such as bone marrow, gut mucosa, and the lymphatic system. Further, most human solid cancers do not have a high proportion of cells that are rapidly proliferating, and they are therefore not

particularly sensitive to this class of agent. Thus, because of host toxicity, treatment has to be discontinued at dose levels that are well below the dose that would be required to kill all viable tumor stem cells. This intrinsic poor selectivity of anticancer agents has been recognized for a long time, and attempts to improve selectivity and allow greater doses to be administered have been numerous. For example, different classes of chemicals with antiproliferative activity (but that differed in their normal tissue toxicity) were put together in drug combinations, thus improving the total dose of cytotoxic agent administered (4). There have been clinical trials of chemicals that either sensitize the cancer to the administered chemotherapy or protect the sensitive host tissues (4). Local application of drugs, such as by injection into the hepatic artery for the treatment of liver metastases or limb perfusion for melanoma, also allows higher doses of cytotoxic drugs to be given. However, even using these techniques, the dose escalation obtained is still not great enough for the complete regression of resistant solid cancers.

A sufficiently high degree of selectivity might be obtained by the use of prodrugs. Prodrugs are chemicals that are toxicologically and pharmacodynamically inert but may be converted *in vivo* to active products. Conversion of the prodrug to the active form can take place by a number of mechanisms such as changes of pH, oxygen tension, temperature, or salt concentration, or by spontaneous decomposition of the drug, internal ring opening, or cyclization (5,6). However, the major approach in prodrug design for cancer chemotherapy is the synthesis of inert compounds that are converted to an active drug by enzyme action (5,6). Thus, in cancer chemotherapy, the prodrug would be inert but converted *in vivo* into a highly toxic metabolite by an enzyme present in the cancer cells but not in other cells (Table 1). A classic example of the high degree of selectivity that can be attained with prodrugs is the dinitro compound CB 1954 [5-(aziridin-1-yl)-2,4-dinitrobenzamide]. CB 1954 is only a weak monofunctional alkylating agent (by virtue of the aziridine function) and is not highly cytotoxic. However, in the presence of the enzyme DT diaphorase, the 4-nitro group is reduced to the hydroxylamino that is then rapidly acylated to a bifunctional alkylating agent (7–9). There is a least a 10,000-fold difference in cytotoxicity between the Walker cell line that has a high level of the activating enzyme and Chinese hamster V79 cells, which lack the enzyme (10,11), and CB 1954 can actually cure the Walker tumor when implanted into either rats or mice (12,13). The enzyme  $\beta$ -glucuronidase can also activate a relatively nontoxic alkylating agent to an extremely reactive and toxic metabolite that can cure cancers in experimental models (14). Other examples are given in Table 1. The appropriate use of prodrugs can de-

liver much higher doses of drug than normal and might therefore be effective against common solid cancers. However, clinical studies have been disappointing. For example, in the case of CB 1954 it has been shown that this prodrug is a much poorer substrate for the human form of the enzyme DT diaphorase than it is for the rat form (15). Thus it does not show the marked antitumor effect against human tumors that were demonstrated in rat tumors (11). An aniline mustard prodrug activated by  $\beta$ -glucuronidase was also subject to a preliminary clinical trial. Although a correlation was shown between glucuronidase activity and patient response, the occurrence of high  $\beta$ -glucuronidase activity was rare and not predictable by tumor type, and it was not considered a feasible therapy (16). However, comparison of biochemical, molecular biological, and chemosensitivity data obtained from screening a large number of cell lines (e.g., the NCI tumor cell line panel) may facilitate investigation of factors influencing drug antitumor activity (17). The knowledge gained may be of value in determining the distribution of prodrug activating enzymes, the development of new anticancer prodrugs, and the selection of patients to receive specific therapies. This approach may make prodrug therapy more feasible and has stimulated further work. Thus recently a new prodrug activated by  $\beta$ -glucuronidase has been proposed for prodrug therapy (18). A new prodrug-activating enzyme has also been described. This human enzyme called NQO2 can efficiently activate the prodrug CB 1954 (19). NQO2 activity was not previously seen because its activity is normally latent and it requires a nonbiogenic cosubstrate such as NRH [nicotinamide riboside (reduced)] for enzymatic activity (19). These developments suggest that prodrug therapy is still viable but is probably applicable only to specific cancers.

Another approach to overcome the intrinsic problems associated with the administration of cytotoxic drugs was drug targeting. This came with the advent of monoclonal antibody technology in the 1970s. It involves the conjugation of a cytotoxic agent to an antibody or other molecule that can specifically bind to antigen or receptor sites that are overexpressed on the target tumor cell. However, the goal has proved to be elusive, and a number of limitations are apparent. These include poor penetration of the tumor, lack of intertumor accumulation of the cytotoxic component, and heterogeneity of tumor-associated antigens.

Therefore there are major limitations to the use of both prodrugs and drug targeting for the treatment of human cancers. However, the disappointing clinical results might be overcome by combining these two approaches. Prodrug activating enzymes, not drugs, could be targeted to human tumors using tumor-associated monoclonal antibodies prior to administration of a prodrug (20,21). This approach

**Table 33.1** Enzymes and Prodrugs That Have Been Proposed for Cancer Therapy. The Enzymes May Have Been Targets for Prodrug Therapy or Targeted Using ADEPT, MDEPT, GDEPT, or PDEPT

Enzyme	Prodrug	Drug	Application	Reference	
Alkaline phosphatase	Phenol mustard phosphate	Phenol mustard	ADEPT	165

Table 33.1 Continued

Enzyme	Prodrug	Drug	Application	Reference
$\gamma$ -Glutamyl transferase	$\gamma$ -Glutamyl p-phenylenediamine mustard	Phenylenediamine mustard	Prodrug therapy	224
$\beta$ -Lactamase	Vinca-cephalosporin	4-Desacetylvinblastine-3-carboxyhydrazide	ADEPT	225–228
Nitroreductase	Nitrogen-mustard-cephalosporin	Nitrogen mustards (various)	ADEPT	34, 229–231
	Doxorubicin-cephalosporin	Doxorubicin	ADEPT	232
	5-(Aziridine-1-yl)-2,4-dinitrobenzamide (CB 1954)	5-(Aziridine-1-yl)-4-hydroxylamino-2-nitrobenzamide	ADEPT GDEPT	11, 90, 233 92, 93, 95, 97
	2,4-dinitrobenzamide mustards	Activated mustards	ADEPT & GDEPT	98, 234
	4-Nitrobenzyloxycarbonyl derivatives	e.g. Actinomycin D, mitomycin C, enediyne, tallimustine	ADEPT & GDEPT	99, 102, 235, 236
NQO2	2-Nitroimidazole carbamate derivative	Amino-seco-CBI TMI	ADEPT & GDEPT	237
	CB 1954	5-(Aziridine-1-yl)-4-hydroxylamino-2-nitrobenzamide	Prodrug therapy	19
Penicillin amidase	Palytoxin-4-hydroxyphenylacetamide	Palytoxin	ADEPT	238
	Doxorubicin-phenoxyacetamide	Doxorubicin	ADEPT	239, 240
	Melphalan-phenoxyacetamide	Melphalan	ADEPT	240
Plasmin	Peptidyl-p-phenylenediamine-mustard	Phenylenediamine mustard	Prodrug therapy	241
	Peptidyl-p-doxorubicin	Doxorubicin	Prodrug therapy	242
Purine nucleoside phosphorylase	6-Methylpurine-2'-deoxyriboside	6-Methylpurine	GDEPT	243–245
	Arabinofuranosyl-2-fluoroadenine monophosphate (F-araAMP),	F-araA	GDEPT	243
	Ribotide prodrug	Aniline mustard	ADEPT	45
Ribonuclease A (mutant) Thymidine kinase (viral)	Ganciclovir	Ganciclovir triphosphate	GDEPT	69–78, 246, 247
	Adenine arabinonucleoside (araM)	Adenine arabinonucleoside triphosphate (araATP)	GDEPT	248
	5'-Deoxy-5-fluorouridine (5'-DFUR)	5-FU	GDEPT	249
Thymidine phosphorylase	Thymidine	Thymine	AMIRACS	124, 142
	[2'-(3'',4''-Dihydroxyphenyl)-ethyl] carbonic acid p-(bis-2-chloroethylamino)phenyl ester	Phenol mustard	Prodrug therapy	250
Xanthine guanine phosphoribosyltransferase	6-Thioxanthine	6-Thioxanthine monophosphate	GDEPT	251
Xanthine oxidase	Hypoxanthine	Superoxide, hydrogen peroxide	Radical generating system AMIRACS	147 124, 142

Source: Modified from Ref. 164.

has been termed ADEPT (antibody-directed enzyme–prodrug therapy). A related approach is gene-directed enzyme–prodrug therapy (GDEPT) or VDEPT (virus-directed enzyme–prodrug therapy) where the DNA encoding for a prodrug activating enzyme is selectively expressed and translated within a tumor cell. Biocompatible

polymers can also localize tumors at a tumor site and has led to the development of PDEPT and MDEPT. As well as activating prodrugs, targeted enzymes can also be used to destroy a rescue agent at the tumor site. Thus, while normal tissues continue to be rescued, the tumor is subject to the effect of the therapy. This approach is particularly

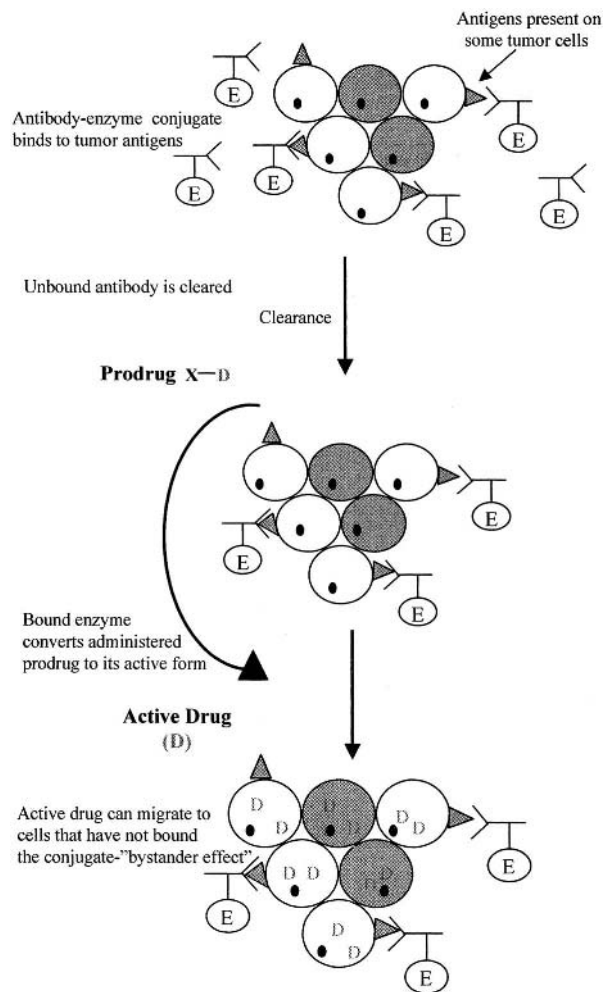

relevant to antimetabolites and has been termed AMIRACS.

## II. ENZYME-PRODRUG THERAPIES OF CANCER

### A. Antibody-Directed Enzyme-Prodrug Therapy (ADEPT)

In ADEPT, an enzyme of nonhuman or nonmammalian origin that can metabolize substrates not normally activated in humans, is linked to a tumor-associated antibody. This can be done either chemically or by using recombinant DNA techniques, and the conjugate is allowed to localize to the tumor (20–23). Thus ADEPT creates a tumor environment with a high concentration of an enzyme that would convert a normally inert substrate to a highly reactive metabolite (Fig. 1). The unlocalized conjugate is either given time to be eliminated from the body or is hastened on its way by a “clearance” antibody. A nontoxic prodrug is then administered and activated at the site of the tumor by the bound conjugate (Fig. 1). The active drug can be of low molecular weight and can therefore rapidly diffuse and reach tumor regions not accessible to the antibody-enzyme conjugate, producing a bystander effect (20–23) (Fig. 1). The targeted antibody-enzyme conjugate is designed to remain extracellular, as internalized conjugate would be expected to be rapidly degraded in the lysosomal compartment. Further, the prodrugs can exploit the external enzyme by being charged and thus excluded from the cell until activated. Secreted antigen, if it accumulates within the interstitial spaces of the tumor, can also be exploited to achieve higher levels of the conjugate at the tumor. A major advantage of the ADEPT approach (over, for example, antibody-drug conjugates or immunotoxins) is that it is catalytic, and a single enzyme molecule can, in theory, generate many hundreds of active molecules per second from the prodrug. Further, because the enzyme-conjugate is by itself inactive, it can be allowed to clear before administration of the prodrug. Not all tumor cells would be required to bind the antibody, since the drug released by the enzyme could diffuse to neighbouring cells not expressing the antigen.

It is fundamental to the concept of ADEPT that the prodrug cannot be activated by normal human enzymes. Therefore the enzyme must have little equivalent activity in humans, particularly in serum, as the prodrug may be designed to be excluded from entering cells. Further, the enzyme must be active under physiological conditions and remain active when conjugated to an antibody. A number of enzymes and prodrugs have been considered for AD-

**Figure 33.1** The generation of a cytotoxic drug by ADEPT. In the first phase, the antibody-enzyme conjugate is allowed to bind to the target cell population. After unbound conjugate is allowed to clear, a prodrug is administered, which is converted to an active drug (D) by the bound enzyme. Importantly the active drug can migrate and have cytotoxic effects on cells that have not bound the conjugate.

EPT. They have been reviewed in detail elsewhere (24–27) and are summarized in Table 1. They will therefore not be discussed in full. The enzymes include carboxypeptidase G2 (Fig. 2),  $\beta$ -glucuronidase (Fig. 3), alkaline phosphatase,  $\beta$ -lactamase, penicillin amidase, and cytosine deaminase, which can activate a wide range of prodrugs (Table 1). Mention should also be made of glucose oxidase, which was the first example of an antibody-targeted enzyme (28) and was made before the advent of monoclonal antibody technology. The enzyme generates hydro-

**Figure 33.2** The activation of a glutamate prodrug to an active mustard by the enzyme carboxypeptidase G2 (CPG2). M =  $N(\text{CH}_2\text{CH}_2\text{Cl})_2$  (25).

**Figure 33.3** The activation of a glucuronide prodrug to an active mustard by the enzyme  $\beta$ -glucuronidase. (From Ref. 25.)

gen peroxide upon oxidation of glucose. However, this system was not very cytotoxic, and glucose is a poor choice of prodrug for ADEPT because it is normally present in serum.
