Experimentally, ADEPT has been extraordinarily successful and has caused regression of many different types of human tumor xenografts, many of which are resistant to standard therapy (20,29–34). An example is shown in Fig. 4. These experimental studies have been followed by a limited clinical study of ADEPT in patients being treated for advanced metastatic colon or rectal cancer, who all had previously received extensive chemotherapy (35,36). The trial used a conjugate of an antibody directed to the human carcinoembryonic (CEA) antigen linked chemically to a bacterial enzyme, carboxypeptidase G2, which can hydrolyze folates and glutamate prodrugs. The prodrug used was 4-[N-(2-chloroethyl)-N-(2-mesyloxyethyl)amino]-benzoyl-L-glutamic acid, and this was well tolerated by patients (doses 200–2500 mg/m<sup>2</sup> given as either 6 or 12 doses divided over 3 days). Four patients received 20,000 units/m<sup>2</sup> of an anti-CEA F(ab')<sub>2</sub>-carboxypeptidase G2 conjugate. After 2 days, a clearing antibody was administered and the prodrug given when serum carboxypeptidase G2 levels were <0.02 units/mL. Circulating levels of CEA and another tumor marker (19-9) fell in all four patients by 10–15 days after therapy. In two cases, there was a measurable decrease in the size of liver metastases, and in another case the patient became free of jaundice but with no decrease in the size of the metastases. There were also subjective responses, such as weight gain, lessening of pain, and generally improved health. However, adverse effects were also reported. After 10 to 12 days an antibody response was raised against both antibody and enzyme components of the conjugate (35,36). Thus the treatment was effectively limited to a single round of therapy, although it was proposed to prevent this antibody response by use of cyclosporin A to immunosuppress the patient. The two patients who received conjugate and the highest dose of prodrug developed myelosuppression. Presumably, this was due to the active drug being released into the circulation and being able to migrate to the bone marrow. The active drug could be detected (35–37) in serum samples, and this suggests that the release of a more reactive drug would be beneficial. With the demonstration that carbamates were also reasonable substrates for CPG2, it was possible to make a series of derivatives that would be converted by the enzyme to highly toxic and reactive chemicals that would probably hydrolyze before reaching sensitive host tissues (38) (Fig. 2). It is planned that chemicals of this structure will be used in a Phase I clinical trial of ADEPT (39).

Problems associated with ADEPT include the immunogenicity of the conjugate, activation of the prodrug by un-

**Figure 33.4** The effect of ADEPT therapy on the growth of a xenograft in vivo. Groups of mice bearing the CC3 choriocarcinoma xenograft were treated (A) intravenously with a W14 F(ab')<sub>2</sub>:carboxypeptidase G2 conjugate followed 56, 72 and 80 h later with either 5 mg/kg (▲) or 10 mg/kg (■) of p-N-bis(2-chloroethyl)aminobenzoyl glutamic acid prodrug. This can be compared with conventional therapy with either 5 mg/kg methotrexate (▽), 50 mg/kg hydroxyurea (◆), 7.5 µg/mL actinomycin D (●), 20 mg/kg cyclophosphamide (★), or 20 mg/kg ara-C (○). (B) the mice were treated with saline (△), conjugate alone (○), prodrug alone (□), or active drug alone (▽) (both at their maximum tolerated doses). (Data from Refs. 20 and 180.)

bound circulating conjugate, conjugate heterogeneity, and optimization of the pharmacology of the active drug (24–26), and these were apparent in the initial ADEPT clinical trial. These issues need to be addressed. First is the need for the release of a more reactive drug as discussed above. Second, patients rapidly developed an antibody response against both enzyme and antibody components of the conjugate. These antibody responses developed within 10 to 12 days and effectively limited the treatment to a single cycle (35,36). These preliminary clinical experiments used a murine antibody. Techniques such as complementarity-determining region (CDR) grafting now exist to humanize such antibodies, reducing the likelihood of developing antibodies against them. The enzyme is more of a problem. It is possible to use immune-suppressive drugs such as cyclosporin (40–42). This may provide a partial remedy, but a less aggressive solution is desirable. It would also be possible to use a different activating enzyme for each cycle of treatment to circumvent the antibody response. However, this is complicated and would require a different clearance system for each cycle. Alternatively, a human enzyme could be employed. The use of a human enzyme has been best exemplified by  $\beta$ -glucuronidase, and this enzyme forms part of a fusion protein with a humanized antibody that has been tested in vivo (43,44) but only in nude mice. The fundamental problem of using a human enzyme is activation of the prodrug by endogenous enzyme. This can be overcome by design of the prodrug. For example, glucuronides are charged at physiological pH. Therefore they do not readily enter cells, and prodrugs exploiting this principle will not be activated by endogenous enzymes

that are intracellular. A more elegant approach is to modify a human enzyme to have new substrate specificity, but this approach carries the risk that the “new” enzyme will be recognized as foreign by the immune system. A mutated version of human ribonuclease has been reported (45). Human ribonuclease A is a low molecular weight (14 kDa) monomer with pH optimum of 6.5 that cleaves RNA into ribonucleotides. Ribonucleases are renowned for their robustness. In the mutated enzyme, the substrate specificity has been altered so that a prodrug is converted to an active drug by the mutant enzyme but is a relatively poor substrate for the native form. This was accomplished by mutating the positively charged lysine to a negatively charged glutamate at residue 66 of the enzyme. A basic substituent was incorporated into the prodrug so that it could interact with this mutated residue and hydrolyze to realize an active mustard that is 30-fold more cytotoxic. The mutant enzyme has both a greater affinity ( $K_m = 4.2$  mM) and turns over the prodrug faster ( $k_{cat} = 15$  s<sup>-1</sup>) than the native enzyme ( $K_m = 17$  mM,  $k_{cat} = 3.4$  s<sup>-1</sup>). A similar approach has been taken with a mutant of human carboxypeptidase A1 (46). Based upon a computer model of the human enzyme (built from the known crystal structure of bovine carboxypeptidase A), bulky phenylalanine- and tyrosine-based prodrugs of methotrexate that were metabolically stable in vivo and were not substrates for wild-type human carboxypeptidase A were designed and synthesized. In addition, the model was used to design a mutant of human carboxypeptidase A1, changed at position 268 from the wild-type threonine to a glycine. This novel enzyme is, unlike the wild type, capable of activating the synthesized prodrugs. The mutant

enzyme could use these new prodrugs as efficiently as the wild type used its best substrates such as methotrexate- $\alpha$ -phenylalanine. The  $k_{cat}/K_m$  value for the wild-type enzyme with methotrexate- $\alpha$ -phenylalanine was  $0.44 \mu\text{M}^{-1} \text{s}^{-1}$ , and  $k_{cat}/K_m$  values for mutant enzyme with methotrexate- $\alpha$ -3-cyclobutylphenylalanine and methotrexate- $\alpha$ -3-cyclopentyltyrosine were 1.8 and  $0.16 \mu\text{M}^{-1} \text{s}^{-1}$ , respectively. In vitro, a conjugate of the mutant enzyme with ING-1 (an antibody that binds to the tumor antigen Ep-Cam) could kill human HT-29 colon adenocarcinoma cells (which express Ep-Cam) in the presence of either methotrexate- $\alpha$ -3-cyclobutylphenylalanine or methotrexate- $\alpha$ -3-cyclopentyltyrosine as efficiently as the active drug, methotrexate. This effect was not seen when the conjugate was made with an irrelevant antibody (46).

It is already possible to obtain highly specific tumor associated antibodies using filamentous phage display (47,48). Fusion proteins can now be constructed between enzymes and such antibodies (that have been engineered to be nonantigenic), allowing several cycles of ADEPT therapy to be given. The first fusion protein developed specifically for an ADEPT application consisted of human  $\beta$ -glucuronidase fused to the CH domain of BW431, a high-avidity anti-CEA antibody, humanized by complementarity determining region (CDR) grafting. The protein thus produced has antigen affinity very similar to that of the parent antibody and retains enzymatic activity (43,44). It is interesting that human  $\beta$ -glucuronidase is a tetramer but in this situation appears to be active as a monomer. In addition, a *B. cereus*  $\beta$ -lactamase II–single-chain antibody fusion protein has been constructed. The antibody used, L6, recognizes an antigen expressed on breast, colon, lung, and ovarian carcinomas. The fusion protein is produced by *E. coli* in an active form that does not require refolding and retains similar immunological and enzymatic properties to an equivalent chemically linked conjugate (49). The ultimate refinement, which is now possible by protein engineering techniques, is to make a bifunctional antibody in which one arm possesses an enzyme-mimicking catalytic function. Indeed, a catalytic antibody (termed an “abzyme”) has been made which, in vitro, can produce cytotoxicity (50). The abzyme can hydrolyze the carbamate prodrug 4-[N, N-bis(2-chloroethyl)aminophenyl-N-[(1S)-(1,3-dicarboxy)propyl]carbamate to generate the corresponding nitrogen mustard.

Such studies demonstrate the potential for making non-immunogenic systems that can activate prodrugs that are not substrates for native enzymes. With so many prodrugs already shown to be effective, one might also envisage combination therapy using different enzyme, antibody, and prodrug combinations that might overcome any problems arising from tumor heterogeneity. Thus there is optimism

that ADEPT, in some form or another, will eventually be used to treat the common solid cancers that are now refractory to chemotherapy.

## B. Gene-Directed Enzyme–Prodrug Therapy (GDEPT)

A gene-therapy-based approach for targeting cancer cells and making them sensitive to prodrugs has been proposed for human gene therapy trials (51–54). Prodrug gene therapy, commonly referred to as GDEPT (gene-directed enzyme–prodrug therapy) or virus-directed enzyme–prodrug therapy (VDEPT) is based on the premise that a large therapeutic benefit can be gained by transferring into tumor cells a drug susceptibility gene. The gene encodes an enzyme that can catalyze the activation of a prodrug to its cytotoxic form (Fig. 5) and has also been termed a “suicide gene” (55–58). However, in contrast to cytotoxic gene therapy approaches that involve expression of a toxic

**Figure 33.5** The generation of a cytotoxic drug by GDEPT. In the first phase, the cell is transduced with gene coding for a prodrug-activating enzyme. This enzyme is expressed, and a prodrug is administered that is converted to an active drug (D) by the bound enzyme. Importantly, the active drug can migrate and have cytotoxic effects on cells that have not been transduced.

product [for example, diphtheria toxin (59–62)], the enzyme itself is not toxic. Thus, in GDEPT, cytotoxicity only results after administration of the prodrug. There is also a bystander effect as the active drug can migrate into non-transduced cells.

GDEPT is obviously related to antibody-directed enzyme–prodrug therapy (ADEPT) in that both use a non-endogenous enzyme to activate a prodrug. However, there are fundamental differences between the two techniques, and this means that the enzyme/prodrug combinations used for ADEPT may not be suitable for GDEPT. In GDEPT the prodrug activating enzyme is expressed inside the cell, while in ADEPT it is extracellular. Thus for GDEPT the prodrug must be able to enter the cell. Therefore enzyme–prodrug systems developed for ADEPT that rely on a charged prodrug (such as a glucuronide) being excluded from the cell while the active drug is not are not directly applicable to GDEPT. However, it should be noted that a GDEPT system that allows for extracellular expression of the activating enzyme has now been described (63). As with ADEPT, a number of different enzyme/prodrug combinations have been proposed for GDEPT. Again, as in ADEPT, an enzyme is required for which there is no endogenous activity. Bacterial or viral enzymes are particularly suited to GDEPT (64). First, many of these enzymes have no corresponding activity in humans. Second, as expression is intracellular, there should be no problems with an immune response against a “foreign” protein. Third, bacterial enzymes tend to have few requirements for post-translational modification, and proteins that are more complex may not fold correctly in different species. Because activation takes place intracellularly, the prodrug should be freely diffusible and thus, ideally, a neutral species with an appropriate partition coefficient. As not all of the tumor cells will be transduced by the vector, a bystander effect is required. Thus the active drug should be able to diffuse away from the site of activation. However, its half-life needs to be such that it cannot migrate far enough to affect normal tissue. The active drug should also not be phase specific or proliferation dependent since many tumors have a low mitotic index (65), and all malignant cells need to be killed, not just those that are proliferating.

Success for this technique requires not only a choice of an enzyme/prodrug system but also a delivery system by which the gene encoding for the enzyme can be delivered efficiently and accurately to a human tumor. This requirement is common to all types of gene therapy. At present, targeting is achieved by altering the surface components of viruses and liposomes so as to achieve a level of target cell recognition while transcriptional elements can be incorporated so that the incorporated gene is expressed only in the target cells. Retroviral-based vectors can only infect

replicating target cells; but integration occurs leading to stable expression of the transduced gene. Adenoviral vectors are more efficient at transduction and do not require cell division but do not integrate, so it is very difficult to regulate gene expression. However, for the long term success of GDEPT (and any gene therapy procedure) there needs to be advances in these systems particularly to improve their targeting. It has been proposed that future gene therapy vectors will be not based on any single virus but will be synthetic vehicles, custom designed to incorporate specific targeting features relevant to the target disease and tissue (Fig. 6) (66). Nonviral gene transfer into the central nervous system (CNS) of the mouse has been achieved using the cationic polymer polyethyleneimine (PEI) (67). Three different preparations of PEI (25, 50, and 800 kD) were compared for their transfection efficiencies in the brains of adult mice. The highest levels of transfection were obtained with the 25 kD polymer (67). Further work has shown this polymer to be a promising gene-delivery vehicle [reviewed in (68)]. Such compounds may form the basis of the future gene therapy vectors discussed above.

Why GDEPT? Cancer gene therapy strategies have been divided into two categories. One, correction of the genetic defect in tumor cells or, two, killing them. This cell killing can be mediated either by the host immune system or by direct cytotoxic effects. Each of these approaches imposes different requirements on the delivery

**Figure 33.6** An ideal synthetic gene therapy vector as proposed by Miller and Vile (66). Its features include (A) a stable nonimmunogenic envelope, (B) ligands to confer a particular affinity on the vector, (C) moieties to encourage fusion with the target cell membrane, (D) site-specific recombinase for direct integration of the vector DNA, (E) sequences to enable homologous recombination of the vector DNA and a specific target loci of the genome, (F) tissue-specific promoter region to confer restricted expression on the therapeutic gene, and (G) the therapeutic DNA. Certain features of the vector such as homologous recombination are not required for GDEPT. (From Ref. 66.)

**Table 33.2** The Requirements Needed by the Delivery System for the Various Types of Gene Therapy

	Gene correction	Cytotoxic	Immunotherapy	GDEPT
Accuracy	+	+++	+	++
Efficiency	+++	+++	+	++
Stability	+++	+	+	+

system. These are summarized in Table 2. Corrective gene therapy may not be a feasible approach to curing cancer because most tumor cells contain multiple genetic mutations. However, if for example a mutant oncogene was a realistic target for corrective therapy, what is required from the delivery system? First, it will need to deliver a correct copy to every tumor cell. Therefore it must be very efficient. This is because gene correction will only work in cells that receive the gene and will have no effect on those that do not. Second, expression of the corrective gene will need to be stable, as the mutant phenotype will reappear once the corrective gene ceases to be expressed. However, third, delivery need not be accurate and specific to tumor cells. This is because, in theory, delivery of a therapeutic gene (such as a functional tumor suppresser gene) should not be deleterious to a normal cell. Opposite demands are made when a cytotoxic gene (coding for, e.g., diphtheria toxin) is delivered. Stable expression is not required, but delivery must be accurate, as expression would be deleterious to a normal cell. Immunotherapy puts the fewest constraints on the delivery system. In theory, immunotherapy attempts to activate an immune response by stimulating the immune system to recognise tumor-specific antigens as nonself by expression of immunomodulatory genes such as IL-2. These antigens are not present on normal cells. Thus expression of immunomodulatory genes should not be deleterious to them, so there is less of a requirement for accuracy. Expression and stability are also lesser requirements because, once activated, the immune system will amplify the antitumor response and kill any nontransduced tumor cells anywhere in the body. This represents an ideal situation, but in reality it may be limited autoimmunity. Further, human tumors have been extensively selected against immune recognition. It is possible to transduce genes coding for antigens, but in this case systemic protection is lost, and delivery would have to be accurate. However, the bystander effect mediated by the immune system can still be substantial.

GDEPT is a recognition of the limitations of the present delivery systems. In comparison to cytotoxic gene therapy, less accuracy is required, because the pharmacology of the

prodrug and its route of administration can confer some tumor specificity. Efficiency is improved, because there is a bystander effect that can kill nontransduced tumor cells. Long-term stability is not required, as transduced cells will be killed after prodrug administration. Further, in contrast to all other types of gene therapy, GDEPT is controllable. The expressed enzyme is nontoxic, and cytotoxicity can only occur after administration of the prodrug. Therefore unexpected toxicity can be countered by lowering the dose of the prodrug.

GDEPT has been pioneered by the use of the enzymes viral thymidine kinase (tk) (Fig. 7) and cytosine deaminase, which can activate ganciclovir and 5-fluorocytidine, respectively. Herpes simplex virus (HSV)-tk/ganciclovir

**Figure 33.7** The activation of ganciclovir by herpes simplex virus thymidine kinase (HSV-tk). Cellular kinase can convert the monophosphate into the cytotoxic triphosphate.

is the most described GDEPT system, and delivery of the gene coding for HSV-tk to animal tumors *in vivo* has been achieved using retroviruses, adenoviruses, and naked DNA. Retroviral vectors are being used to deliver the gene to intracranial and leptomeningeal tumors in rats, and the system was proposed for the first clinical trials of GDEPT (51,52). Transfer of HSV-tk in tumor cells confers sensitivity to ganciclovir and its analogues both *in vitro* and *in vivo* (Fig. 8). *In vitro*, cells expressing HSV-tk are generally inhibited by 1–50  $\mu\text{M}$  ganciclovir, and these levels can be achieved by patients treated with the drug (69–78). In the absence of prodrug, expression of HSV-tk is not detrimental, and expressing cells grow normally *in vivo* and *in vitro*. Recently a mutant of HSV-tk has been made with improved kinetics with respect to ganciclovir (79). In theory, this should allow effective therapy at lower prodrug concentrations. A bystander effect has been demonstrated for the HSV-tk system. As the active metabolite of ganciclovir, the triphosphate, is highly charged, it should not diffuse out of expressing cells, and thus it would not be predicted that the bystander effect is mediated by a diffusible metabolite. *In vitro*, a mixed population containing only 10% of HSV-tk expressing cells was totally killed by a dose of ganciclovir that is not cytotoxic to non-HSV-tk expressing cells (80). Metabolic cooperation is involved,

**Figure 33.8** The antitumor effect of ganciclovir on HSV-tk expressing tumor cells. Mice were inoculated *s.c.* with KBALD tumor cells ( $2 \times 10^5$ ) either stably transduced with the HSV-tk gene (open symbols) or not (closed symbols). The mice were then treated with ganciclovir (150 mg/kg twice a day for 3.5 days) commencing on day 0 (□) or day 5 (△), or left untreated (○). (Data from Ref. 80.)

and a ganciclovir metabolic product, presumably a phosphorylated form, can pass from HSV-tk expressing cells to nonexpressing cells and mediate cytotoxicity, but only as a consequence of direct contact (81,82). The uptake of apoptotic vesicles by the nonexpressing tumor cells has also been demonstrated (80). *In vivo*, there is also a cell-mediated immune component to the bystander effect (83).

Cytosine deaminase is found in many fungi and bacteria and catalyzes the deamination of cytosine to uracil. It is not found in mammalian cells. Cytosine deaminase can also convert the clinically used antifungal agent 5-fluorocytosine (5-FC) into the known antitumor drug 5-fluorouracil (5-FU). The yeast enzyme is superior to the bacterial enzyme in this respect (84). 5-FU is further metabolized to 5-fluorouridine-5'-triphosphate, 5-fluoro-2'-deoxyuridine-5'-triphosphate, and 5-fluoro-2'-deoxyuridine-5'-monophosphate. The first two compounds inhibit RNA and DNA synthesis, respectively, and the monophosphate is a potent inhibitor of thymidylate synthase, which is an important enzyme in DNA biosynthesis. Mouse 3T3 cells were shown to be sensitive to 5-FC when transfected with the gene encoding cytosine deaminase (85). When injected into syngeneic mice, the cytosine deaminase expressing tumors could be eliminated *in vivo* by systemic treatment with 5-fluorocytosine without significant toxicity to the host, although delaying the prodrug treatment reduced its effectiveness (Fig. 9). Interestingly, animals whose tumors

**Figure 33.9** The effect of 5-fluorocytidine (5-FC) on the growth of a cytosine deaminase expressing mouse adenocarcinoma. Mice received 5-FC (37.5 mg) twice daily for 10 days 4 (●), 11 (▲), or 18 (□) days after tumor inoculation. Untreated controls (■). (Data from Ref. 57.)

had been eliminated by prodrug treatment resisted subsequent rechallenge with unmodified wild type tumor. This posttreatment immunity appeared to be tumor specific (57). It was postulated that cell death led to a more effective antigen presentation or that the cytosine deaminase protein itself was immunogenic (57). Human colorectal tumors were also shown to be sensitive to 5-FU when they expressed cytosine deaminase (86). The sensitivity of these cells was retained in vivo when grown in nude mice (86). Importantly, a large bystander effect was observed both in vitro and in vivo (86). 5-FU was liberated into the surrounding environment when cytosine deaminase-expressing tumor cells were treated with 5FC. This liberated 5FU is able to kill neighboring, noncytosine-deaminase-expressing tumor cells in vitro and in vivo (87). When only 2% of the tumor mass contained cytosine deaminase-expressing cells (98% noncytosine-deaminase-expressing cells), significant regressions in tumors were observed when the host mouse was dosed with nontoxic levels of 5FC (87).

In a direct comparison of cytosine deaminase with HSV-tk, both transduced into human lung adenocarcinoma cell lines and driven by the CMV promoter, cytosine deaminase was superior in its ability to achieve high levels of specific enzyme activity, to induce growth inhibition, and to affect neighboring cell growth (88).

Other enzymes considered for GDEPT include thymidine phosphorylase, deoxycytidine kinase, carboxylesterase, cytochrome-P450, carboxypeptidase G2, and nitroreductase (Table 1). All demonstrate that selective killing of tumor cells can be achieved by GDEPT. Perhaps unfortunately, many of the active drugs formed are antimetabolites. These are only cytotoxic to dividing cells and tend to require long exposure times for optimum effect. Alkylating agents do not suffer from these disadvantages and are less prone to induce drug resistance (89). In this respect, the enzymes cytochrome-P450, carboxypeptidase G2, and nitroreductase are of particular interest because they can activate prodrugs of alkylating agents.

An example is the activation of the prodrug CB 1954 by *E. coli* nitroreductase (Fig. 10). This enzyme requires a cosubstrate to act as an electron donor. This is not a problem, because the enzyme is expressed intracellularly and thus can use the endogenous cofactors NADH or NADPH [of which nitroreductase can use either (90)]. In fact, the cofactor requirement may be an advantage, because any enzyme that escapes into the circulation (for example, from dying cells) will be incapable of activating circulating prodrug because of the lack of a cofactor. This is because NAD(P)H is very rapidly metabolized by serum components (91).

A recombinant retrovirus encoding NR was used to in-

**Figure 33.10** The activation of the prodrug CB 1954 (5-(aziridin-1-yl)-2,4-dinitrobenzamide) by the enzyme *E. coli* nitroreductase.

fect mammalian cells. NIH3T3 cells expressing NR were killed by CB1954. The bulk infected, unselected, cell population was about 100-fold more sensitive to CB 1954 than the parental cells (92). A selected clone was even more sensitive and, using a cell count assay, was over 1000-fold more sensitive to CB 1954 than parental NIH3T3 cells (Fig. 11) (92). Similar results were seen in human melanoma, ovarian carcinoma, and mesothelioma cells (93). The rapid action of CB 1954 (94) and the resulting need for a shorter exposure time may facilitate the use of this prodrug clinically. A significant bystander effect was observed, and admixed, unmodified NIH3T3 cells could also be killed by a normally nontoxic dose of prodrug (92). The bystander effect is mitigated by diffusible metabolites, and both the 2- and 4-hydroxylamino derivatives of CB 1954 are released into the medium of CB 1954 treated nitroreductase-expressing NIH3T3 cells (95). Importantly, and in contrast to the HSV-tk/ganciclovir enzyme/prodrug system, NR/CB1954 cell killing was cytotoxic towards non-

**Figure 33.11** The cytotoxicity of CB 1954 against a nitroreductase (NR) expressing cell line. NIH3T3 cells were infected with a recombinant retrovirus containing NR and a cell clone (NIH3T3-NR) derived by limiting dilution. Parental NIH3T3 cells (■) or NIH3T3-NR cells (□) were treated with CB 1954 for 24 h prior to assay. (Data from Ref. 92.)

cycling cells (Fig. 12) (92). In an initial investigation of NTR/CB1954 for the treatment of tumors *in vivo*, a regression of tumors expressing NTR following administration of CB1954 resulted in significantly increased median survival (Fig. 13) (96).

In addition, other potential prodrugs for use with the nitroreductase have been proposed. Chinese hamster V79 cells transfected with a nitroreductase expression vector were 770-fold more sensitive to CB1954 than control non-expressing cells. Other prodrugs, such as nitrofurazone (97-fold) and the nitroimidazole compounds, misonidazole (21-fold), and metronidazole (50-fold), also exhibited increased cytotoxicity against the nitroreductase-expressing cells and were found by HPLC to act as substrates for the purified NR enzyme (97). However, this correlation was not absolute. In particular, the quinone EO9 [3-hydroxy-methyl-5-aziridinyl-1-methyl-2-(H-indole-4, 7-indione)-propenol] showed only a very small differential (< 3-fold). This is probably because this compound can undergo activation by endogenous enzymes such as NADPH: cytochrome P450 reductase (97). When misonidazole or metronidazole were activated by NR extracellularly there was little increase in cytotoxicity (98). This would suggest that the active species has a very short half-life and probably would not exhibit a large bystander effect. A series of 2,4-

dinitrobenzamide mustard analogues of CB 1954 have also been evaluated as potential prodrugs (98). Other potential prodrugs that could be used in GDEPT are those activated by a self-immolative mechanism (99) that can potentially form active drugs such as mustards, actinomycins, mitomycin C (99), enediynes, (100), seco-CI alkylating agents (101), or tallimustine (102). The prodrugs are all 4-nitrobenzyloxycarbonyl derivatives of these drugs, which upon enzymatic reduction generated the drug through self-immolation of the 4-(hydroxylamino)benzyloxycarbonyl group.

The generation of an alkylating agent probably offers the most potent means of killing targeted cell types. However, given the different modes of action of, for example, nitroreductase/CB 1954 and HSV-tk/ganciclovir, a combination of these approaches offers a way of obtaining potentially synergistic effects. Cooperative killing was observed when cells expressing both NR and HSV-tk were treated with a combination of CB1954 and ganciclovir (92).

Thus CB 1954 is a good example of the requirements of an ideal prodrug for use in GDEPT when activated by nitroreductase, and this enzyme can also be used in combination with other prodrugs. However, systemic administration of the present generation of gene therapy vectors is not possible, and GDEPT, unlike ADEPT, is thus limited to isolable tumor deposits, such as intracerebral tumors (53) or prostate cancers (54), surrounded by largely nondividing normal tissue. In such cases, GDEPT is feasible using retroviral-based vectors. Improved vectors have been proposed and are certainly under development. On the other hand, it should be remembered that GDEPT is an answer to some of the limitations of the present gene therapy vectors, and a perfect tumor-specific gene delivery system would make GDEPT obsolete.

### C. Targeting by Means of Polymers

The use of polymer drug conjugates as prodrugs is a relatively new concept for the treatment of cancer (103,104). N-(2-Hydroxypropyl)methacrylamide (HPMA) copolymer-drug conjugates containing either anthracycline antibiotics or alkylating agents bound to polymer through peptide linkers designed for cleavage by endogenous thiol dependent enzymes have been described (103,104). HPMA copolymer conjugates, like other molecules with prolonged plasma residence times, can accumulate preferentially in a tumor because of the phenomenon of the enhanced permeability and retention effect (EPR) (Fig. 14) (105). This effect occurs because the physiology of solid tumors differs from that of normal tissues in a number of important aspects, the majority of which stem from differences between the two types of vasculature. Compared

**Figure 33.12** The effect of (A) ganciclovir (GCV) or (B) CB 1954 on NIH3T3 cells either expressing (■) or not expressing (●) either (A) herpes simplex virus thymidine kinase or (B) nitroreductase. Cells were treated during either normal growth (solid symbols) or following growth arrest in the  $G_0$  phase of the cell cycle (open symbols). (Data from Ref. 92.)

with the regular, ordered vasculature of normal tissues, blood vessels in tumors are often highly abnormal, distended capillaries with leaky walls and sluggish flow (106). Tumor growth also requires continuous new vessel growth, or angiogenesis. The physiology of solid tumors at the mi-

**Figure 33.13** The therapy of a human, *E. coli* B nitroreductase-expressing, pancreatic xenograft (SUI2-NR) using CB 1954. This is compared to the treated parental line (SUI2). CB 1954 (80 mg/kg I.P.) was given on day 1 and 10 as indicated. (Data from Ref. 96.)

croenvironmental level is thus sufficiently different from that of the normal tissues from which they arise to provide a unique and selective target for cancer treatment (107,108). The EPR effect results from enhanced permeability of macromolecules or small particles within the tumor neovasculature due to leakiness of its discontinuous endothelium, and this mechanism of tumor targeting of polymeric systems was first described by Matsumura and Maeda (105). In addition to the tumor angiogenesis (hypervascularity) and irregular and incompleteness of vascular networks, the attendant lack of lymphatic drainage promotes accumulation of macromolecules once they extravasate (105). This phenomenon of passive diffusion and localization in the tumor interstitium is observed in many solid tumors for macromolecular agents and lipids (109,110). Unless specifically addressed for tumor cell uptake by receptor-mediated endocytosis, macromolecules entering the intratumoral environment are taken up relatively slowly by fluid-phase pinocytosis and then transferred from endosomes to lysosomes (111). Modified pathways of fluid extravasation and tissue drainage in tumors are thought to be the physiological cause for the passive tumor tropism of macromolecules. Ineffective or absent pathways of lymphatic drainage results in poor convection and elevated interstitial hydrostatic pressures [reviewed by (112)]. This leads to poor oxygenation of the tumor mass and induces the release of angiogenic and capillary-permeabilizing factors such as vascular endothelial growth factor (VEGF) in order to improve the supply of oxygen

Figure 33.14 Enhanced permeability and retention (EPR) of tumor cells.

and nutrients [reviewed by (113)]. The enhanced vascular permeability will support the great demand of nutrients and oxygen for the rapid growth of the tumor. To realize this demand, tumor tissues recruit blood vessels from the pre-existing network as well as inducing extensive angiogenesis by releasing VEGF (114–116). Without angiogenesis, the tumors could not increase in size to more than a few millimetres (117–119). When using polymeric drugs, the EPR effect is a great advantage as a means for targeting. Low molecular weight analogues readily leave the bloodstream, as they quickly pass into the tissue or are excreted. In contrast, polymeric drugs can often achieve a prolonged half-life in the bloodstream because of decreased glomerular excretion. Extended circulation is a requisite for optimal targeting by the EPR effect. However, an optimum molecular weight exists in terms of achieving the most efficient accumulation by the EPR effect. For example, with N-(2-hydroxypropyl)methacrylamide (HPMA) copolymers (fractions of molecular weight 22–778 kDa), at 10 min after administration in vivo, all fractions were already detectable in the tumor, and those of molecular weight greater than the renal threshold showed progressive tumor accumulation up to 20% of dose administered per gram after 72 h in Sarcoma 180 model (120). HPMA copolymer fractions showed profiles of blood clearance that were strongly dependent on molecular size. For this reason, although the initial tumor levels of all HPMA copolymer fractions were virtually independent of substrate size, their progressive accumulation was different (120). Further, macromolecular carriers in the bloodstream may be recog-

nized by scavenger cells, namely the RES (reticuloendothelial system). These cells are located within such organs as liver, spleen, and lung. RES recognition is particularly serious for colloidal and vesicular carrier systems, including microparticles and liposomes (121). Thus it is essential to develop appropriate carrier systems that achieve long circulation in the bloodstream, avoiding glomerular excretion and RES recognition [like HPMA copolymer (122)], allowing for a significant EPR effect. When using a polymer it is therefore important to choose an adequate carrier for both the drug and the enzyme, bearing in mind the possibility of immunogenicity in addition to the above-mentioned RES capture.

A polymer-based system for targeting enzymes to tumors that is directly analogous to ADEPT is called MDEPT (macromolecular-directed enzyme-prodrug therapy). This utilizes EPR to localize an enzyme polymer conjugate but uses a nonpolymer prodrug and an inhibitor such as a clearing antibody to reduce conversion of the prodrug in the circulation (123). MDEPT would therefore appear to be the same as ADEPT except that the antibody-targeting component is replaced by a polymer and in theory could be used with any of the ADEPT enzyme/prodrug systems previously described. It was found that the enzyme CPG2 conjugated to methoxypolyethyleneglycol (MPEG) localized in nude mice bearing human xenografts of LS174T (colon), PC3 (prostate), COR L23 (lung), and MDA (breast). Different chain lengths of polyethylene glycol (PEG) and ratios of PEG to protein affect the level of uptake by tumors (124). In a therapy study using CPG2 con-

jugated to methoxypolyethyleneglycol and a phenol mustard prodrug, MDEPT was shown to be effective in treating the LS174T tumor (Fig. 15) (123).

Polymers are interesting also for their effect on the immunogenicity of foreign proteins (125,126). This is generally attributed to their ability to mask epitopes. There is also evidence that they can induce immune tolerance to challenge with bacterial enzymes. The substitution of a polymer for an antibody vector therefore reduces the immunogenicity associated with an antibody vector and has the potential to allow the repeated use of bacterial enzymes in man without the necessity for immunosuppression (124).

Recently, polymer-directed enzyme prodrug therapy (PDEPT) has been described. PDEPT is a novel two-step antitumor approach in which both the prodrug and the enzyme components are targeted (Fig. 16). Because of the relatively short plasma residence time of the polymeric prodrug, a dosing schedule can be used that avoids the need for a clearing antibody used in ADEPT, and the unwanted activation of the prodrug in the circulation can be controlled. As PDEPT relies on two components, a polymer–enzyme and a polymer–drug conjugate, the design of both components must be optimized. There are dif-

**Figure 33.15** The effect of MDEPT therapy on the growth of a xenograft in vivo. (■) Nude mice bearing LS174T tumors were given 25 enzyme units of CPG2–PEG (22 PEG molecules, PEG 5000) followed at 20 h, 23 h, 26 h by galactosylated SB43. At 48 h post-CPG2–PEG they received 25 mg/kg of a phenol prodrug (4-[N,N- bis(2chloroethyl)amino]-phenoxy carbonyl-L-glutamic acid) intraperitoneally, repeated to a total of 3 doses at 1 h intervals. (●) Untreated controls. (Data from Ref. 123.)

### Step I. Administration of polymer-drug

### Step II. Administration of polymer-enzyme when polymer-drug is no longer in the circulation

**Figure 33.16** Release of anticancer drug from its polymeric conjugate by polymer-directed enzyme–prodrug therapy (PDEPT).

ferent requirements for the polymer–drug and for the polymer–enzyme conjugates, which can be summarised as follows.

The polymer–drug conjugate should

1. Be inactive in the bloodstream
2. Accumulate selectively in the tumor by the EPR effect
3. Be excreted through the kidneys within 5 h after administration
4. Contain a linker that is degraded by the enzyme present in the polymer–enzyme conjugate with effective and favorable activation kinetics
5. Release an active drug that can induce a bystander effect
6. Ideally release a drug effective in both cycling and noncycling cells

The polymer-enzyme conjugate should

1. Display enzymatic activity in the polymer conjugate with a favorable  $K_m$  towards the polymer-drug conjugate as a substrate in vivo
2. Ideally contain a nondegradable linker in vivo
3. Accumulate selectively in the tumor by the EPR effect
4. Display a long circulation time in the body
5. Be nonimmunogenic

To test the feasibility of PDEPT, an HPMA copolymer-enzyme conjugate was synthesized containing cathepsin B as a model enzyme, and its in vitro and in vivo properties were evaluated. HPMA copolymer-Gly-Phe-Leu-Gly-doxorubicin (PK1) was used as a substrate for HPMA copolymer-cathepsin B to test the PDEPT combination in vitro and in vivo. PK1 has already shown promise in early clinical trials, and a phase II programme is currently ongoing (127). This compound was chosen following a systematic evolution of an optimum molecular weight of carrier to allow tumor-selective doxorubicin delivery, and optimization of linker design (Gly-Phe-Leu-Gly) to mediate controlled release of the drug intratumorally (intracellularly) by the lysosomal thiol-dependent proteases [reviewed in (128)]. PK1 has a molecular weight of 30 kDa and a doxorubicin content of  $\sim 8$  wt% ( $\sim 2$  mol%). The conjugate displays a longer plasma half-life than free doxorubicin ( $t_{1/2}$  approximately 1 h). Moreover, it shows significantly increased tumor deposition of doxorubicin (in comparison with free doxorubicin) due to the EPR effect (129). Covalent conjugation of doxorubicin via the peptidyl spacer ensures that no significant liberation of free drug in circulation takes place, thus leading to a marked increase in the therapeutic index compared with free doxorubicin. HPMA copolymer-protein conjugates showed little or no immunogenicity and are known to display selective accumulation in solid tumors (129,130). A recent Phase I clinical trial of PK1 showed that it is biocompatible in man and amenable to clinical development (127). PK1 is activated by endogenous proteases, mainly following internalization into the cell and then intralysosomal digestion. The compound is a suitable polymeric prodrug for PDEPT because the targeting of an additional external protease could significantly increase the rate of doxorubicin release.

The enzyme model selected to explore the PDEPT concept was cathepsin B, a mammalian lysosomal thiol-dependent enzyme that functions in the normal turnover of proteins in mammalian cells. Cathepsin B is a cysteine proteinase that plays an important role in lysosomal proteolysis (131). It is secreted as a proenzyme that requires two proteolytic events for activation. Once activated, cathepsin B degrades type IV collagen, fibronectin, and

lamin, at both acidic and neutral pH (132). This enzyme was a convenient choice, as it is the native activating enzyme for PK1. This gave the possibility to combine well with PK1 to study aspects of the PDEPT combination. The spacer chosen between the HPMA copolymer and the enzyme was a glycine-glycine linker, because it is nondegradable in the body.

Following polymer conjugation (yield of 30–35%), the enzyme retained 20–25% of its enzymatic activity. To investigate the pharmacokinetics in vivo, a  $^{125}\text{I}$ -labelled HPMA copolymer-enzyme conjugate was administered intravenously (i.v.) to B16F10 tumor-bearing mice. Due to selective tumor tissue accumulation by the enhanced permeability and retention (EPR) effect, the HPMA copolymer-enzyme conjugate showed a 2–3-fold increase in tumor accumulation compared to the native enzyme, and also exhibited a longer plasma half-life.

The ability of HPMA copolymer-cathepsin B to access and degrade the prodrug in vivo was determined by HPLC evaluation of doxorubicin release. PK1 was injected i.v. to B16F10-bearing mice and after 5 h HPMA copolymer-cathepsin B was administered. This enzyme led to a rapid increase in the rate of doxorubicin release intratumorally (3.6-fold faster than seen for PK1 alone) (Fig. 17). Moreover, when the antitumor activity (doxorubicin-equivalent dose of 10 mg/kg) was measured using this tumor model, the combination PDEPT had the highest activity ( $T/C = 168\%$ ) compared to that seen for PK1 alone ( $T/C = 152\%$ ) or free doxorubicin ( $T/C = 144\%$ ). No animal weight loss

**Figure 33.17** Free doxorubicin released in the tumors of C57 mice bearing B16F10 murine melanoma from PK1 in the absence (■) or presence (▲) of HPMA-cathepsin B.

or other toxicity was observed, indicating the possibility of dose escalation (133,134). These results demonstrate that the PDEPT concept is sound and could be applied to other enzyme polymeric prodrug systems. An HPMA conjugate of  $\beta$ -lactamase has been made and could activate polymeric prodrugs where the linker between the polymer and the drug is a cephalosporin linker, which is cleaved by  $\beta$ -lactamase (134).

#### D. Antimetabolite with Inactivation of Rescue Agent at Cancer Sites (AMIRACS)

Antimetabolite drugs have been in the forefront of anticancer therapies since the early 1950s and still remain an important and fruitful field for drug discovery. Such drugs act as competitive inhibitors for certain key enzymes involved in the process of cell growth and division, leading to arrest of the cell cycle and cell death. A number of such enzyme targets exist, particularly in the pathways associated with folic acid metabolism, as illustrated in Fig. 18. However, it has long been recognized that antimetabolite drugs do have some disadvantages. An important disadvantage is that they are not cancer specific in their activity. Although they tend to be selective for the rapidly dividing cells of tumors, they are not tumor specific because they also exert toxic effects on rapidly dividing normal cells in the body, for example the gut mucosa and hair follicles. The severity of these side effects is dose limiting, and the development of such dose-limiting toxicity necessitates cessation of treatment. A further disadvantage of antimetabolite drugs as currently used is that cancer cells can develop resistance to them, either by increased expression of the target enzyme, or by changes in the rate of drug trans-

**Figure 33.19** Folinic acid enters the folate cycle downstream of the methotrexate-induced blockade, allowing the cell cycle to restart.

port into and out of the cell, or by a combination of these. The development of resistance necessitates escalating doses to retain efficacy, and the history of antimetabolite cancer therapy is one of a drive to find safe methods of administering ever greater doses of drug while circumventing the problems of dose-limiting toxicity. One approach has been to administer high doses of drug and then follow at an appropriate juncture with the appropriate metabolite, termed a “rescue agent,” which is capable of counteracting the effect of the antimetabolite. Such agents generally work by entering the metabolic pathway downstream of the antimetabolite-induced block. For example, folinic acid can rescue cells from methotrexate toxicity (Fig. 19). The use of methotrexate therapy in conjunction with folinic acid rescue is now well established in clinical practice (135,136), and the possible use of alternative rescue agents for methotrexate, such as 5-methyltetrahydrofolate and thymidine, has also been explored (137–140). For

**Figure 33.18** The pathways of folate metabolism. Key enzymes are underlined.

most cancers, the value of rescue agents is limited because the agent “rescues” the tumor as well as the normal tissue. However, the use of folinic acid to rescue the combination of the folate antimetabolite trimetrexate and the metabolite folinic acid is licensed for the treatment of *Pneumocystis carini* in HIV patients (141). In this instance the infective organism is, like its host, sensitive to the antimetabolite but, unlike the human cells, the infective organism cannot be rescued by folinic acid. The use of the trimetrexate/folinic acid combination allows much higher doses of drug to be administered without toxic side effects than would be the case with drug alone.

AMIRACS is a technology that uses targeted enzymes to break down rescue agents at tumor sites, preventing the tumor cells from being rescued while allowing the rescue agent to carry out its beneficial function in normal cells (Fig. 20) (124,142). Normal tissues are exposed to a non-toxic combination of antimetabolite drug plus rescue agent, whilst the tumor can be exposed to amplified doses of drug, because the rescue agent is destroyed by an enzyme that is specifically targeted to the tumor. Therefore AMIRACS offers the opportunity to make antimetabolite drugs tumor specific rather than tumor selective and enables high doses of drug to be used while confining toxic effects to the tumor and thereby increasing the therapeutic ratio of the antimetabolite. It can create in human tumors the system used successfully to eradicate *Pneumocystis carini*.

Two methods of targeting enzymes to tumors can be used—antibodies or polymers. The prototype system for demonstration of enzymatic inactivation of rescue agent

uses the dihydrofolate antagonist trimetrexate as the anti-metabolite component, with folinic acid as the rescue agent and CPG2 as the rescue agent. When using folinic acid as rescue agent in conjunction with CPG2 it is necessary to use a nonclassical antifolate drug such as trimetrexate. These lack the terminal glutamate of the classical folate analogues that are degraded by CPG2. CPG2 breaks down folinic acid by cleaving off the glutamate moiety from the pterin component of the molecule. The ability of tumor-targeted enzyme selectively to break down folinic acid at a tumor site *in vivo* is illustrated in Fig. 21. In this experiment, antibody-CPG2 conjugate was used, with second antibody clearance to give high tumor-to-blood ratios, but similar results would be anticipated from a polymer-based system. In fact, the lowest tumor folinic acid levels are obtained without the use of clearance (Fig. 21), but this is probably due to the depletion of serum folinic acid by the uncleared enzyme. In a clinical experiment, two patients were treated with antibody-CPG2 conjugate (20,000 U/m<sup>2</sup>), followed by a mixture of trimetrexate and folinic acid (143). The protocol for this experiment is illustrated in Fig. 22. This experiment used a conjugate of the anti-CEA murine monoclonal antibody, A5B7, chemically linked to CPG2. Because both components of the conjugate are of xenogeneic origin and have been shown in earlier studies to be immunogenic (41,144), it was necessary to carry out the therapy under the cover of the immunosuppressive drug, cyclosporin A. Cyclosporin A was chosen because it had been shown to suppress the immune response to both antibody and enzyme for up to three weeks. This allows three cycles of therapy to be given (36,42). The dose of

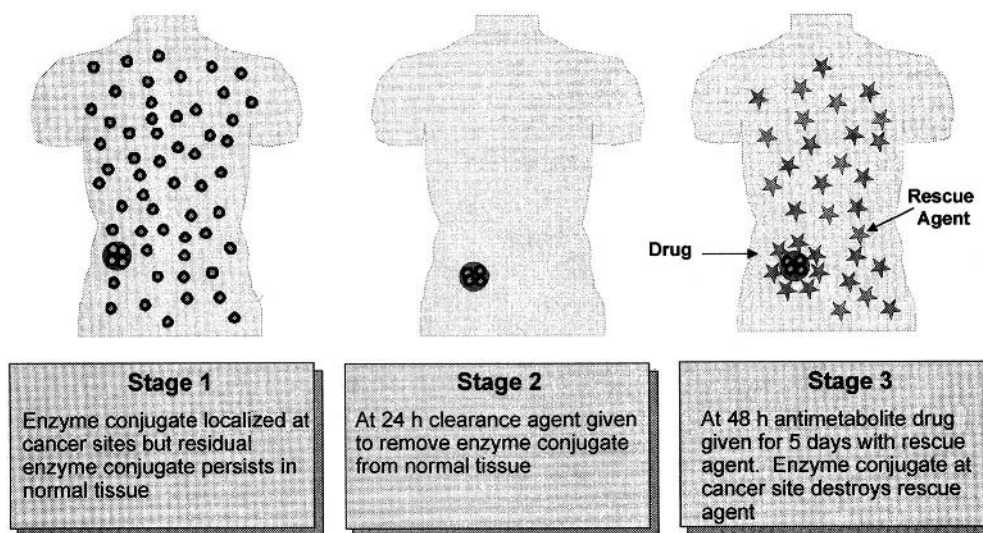

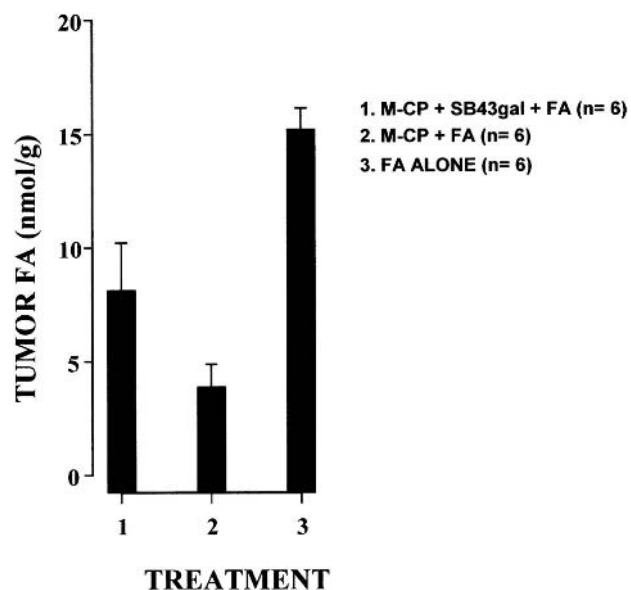

Figure 33.20 Antimetabolite with inactivation of rescue agent at cancer sites (AMIRACS).

**Figure 33.21** The ability of a tumor-targeted CPG2 conjugate selectively to break down folic acid (FA) at a tumor site in vivo. In this experiment, an antibody-CPG<sub>2</sub> conjugate was used, with second antibody clearance to give high tumor-to-blood ratios.

folic acid was 10–12-fold higher than the normal maximum tolerated dose in the absence of folic acid. This regimen resulted in minimal toxicity towards the patient's platelet count; indeed the patient's platelet count was depressed at the commencement of therapy, due to prior chemotherapy, and rose during the course of therapy with high-dose trimetrexate plus folic acid (143).

Although inhibition of dihydrofolate reductase is the longest established form of antimetabolite therapy, drugs have also been developed as inhibitors of the other key enzymes involved in folate metabolism, notably thymidylate synthase (TS) and glycinamide ribonucleotide formyl transferase (GARFT). AMIRACS can be adapted to work with both classes. Thymidine protects against the cytotoxic effects of TS inhibitors such as Tomudex (Raltitrexed) (Fig. 23a) (145). The addition of the enzyme thymidine phosphorylase abolishes the protective effect of thymidine (Fig. 23b) (145). Inhibitors of GARFT can be rescued by means of hypoxanthine, as shown in Fig. 24. This illustrates rescue of Lometrexol by hypoxanthine (146). Hypoxanthine can be destroyed by the enzyme xanthine oxidase (147).

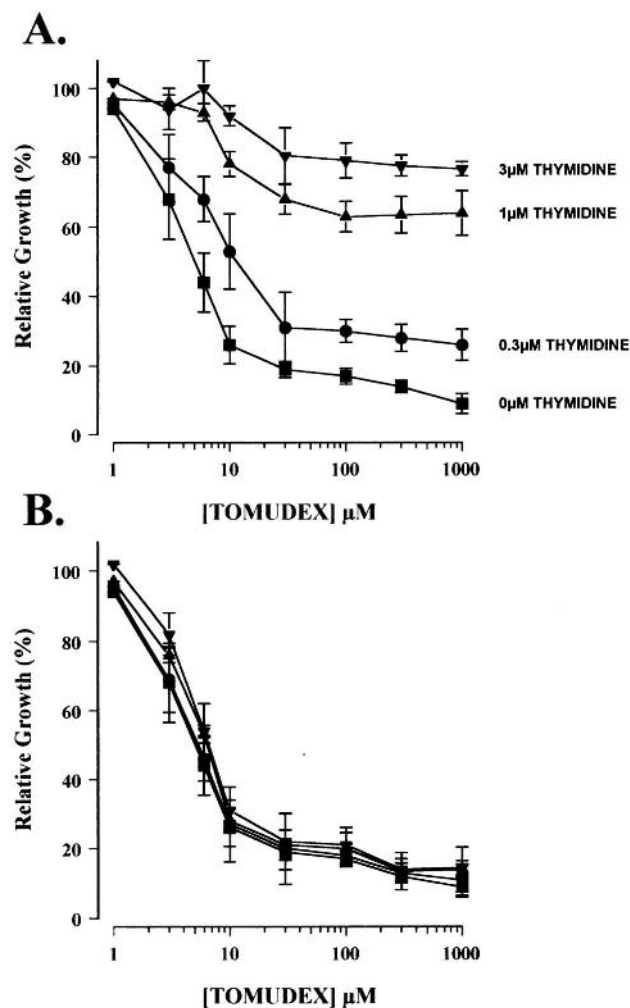

The use of targeted enzymes in AMIRACS is of particular interest because the therapy can be applied to agents that are already in everyday clinical use. Unlike the other therapies using targeted enzymes, AMIRACS does not involve activation of a prodrug to a cytotoxic species. Thus the clearance of nontargeted enzyme may not be so important. Although the systemic concentration of the rescue agent may be reduced by circulating enzyme, this can be monitored and the dosage adjusted accordingly.

### III. CONCLUSIONS

Since the concept was first described in 1987, the use of antibody-enzyme conjugates directed at tumor-associated antigens to achieve site-specific activation of prodrugs to potent cytotoxic species, termed antibody-directed

**Figure 33.22** AMIRACS clinical experiment protocol.

**Figure 33.23** The effect of 0, 0.3, 1.0, or 3  $\mu\text{M}$  thymidine on the cytotoxicity of Tomudex against human MCF-7 cancer cells in (A) the absence or (B) the presence of *E. coli* thymidine phosphorylase ( $3.5 \times 10^{-4}$  U). (Data from Ref. 145.)

enzyme-prodrug therapy (ADEPT), has attracted considerable interest. ADEPT attempts to overcome a major problem associated with the administration of cytotoxic drugs for the treatment of cancer—the intrinsic lack of tumor selectivity. Thus cancer chemotherapeutic agents have the potency to kill tumor cells *in vitro* but, because of host toxicity, the treatment of human patients has to be discontinued at dose levels that are well below that expected to kill all their tumor cells. In ADEPT, a cytotoxic agent is generated selectively at the site of a tumor by an antibody-targeted enzyme. The antibody delivery combined with the amplification provided by the enzymatic activation of prodrugs enables adequate selection to be made between tumor and normal tissue.

**Figure 33.24** The effect of 30  $\mu\text{M}$  hypoxanthine on the cytotoxicity of Lometrexol against human A549 cancer cells. (Data from Ref. 146.)

For any form of antibody-mediated targeting to be successful, it is axiomatic that there must be selective expression of the target antigen by the tumor cells. However, the only well-characterized tumor-specific antigens described to date are the idiotypic determinants on the surface immunoglobulins of B-cell lymphomas (148). Many antigens and other potential targets such as growth factor receptors are present in elevated levels in tumor tissue, but most, if not all, appear to be found to a greater or lesser extent in other tissue. Furthermore, it is well documented that tumor cells exhibit considerable antigenic heterogeneity (149,150), with some devoid of antigen expression, so a single monoclonal antibody conjugate targeted at a tumor mass will not bind to all the cells present. In ADEPT, the active drug, being of low molecular weight, can diffuse to adjacent tissues, including cells that express the target antigen but that have not bound conjugate, cells that may express alternative tumor-associated antigens not recognized by the vector, or cells that are antigen-negative, providing a bystander effect. A further advantage of ADEPT is that a single enzyme molecule has the potential to cleave many prodrug molecules—up to 800 molecules per mole of enzyme per second in the case of the benzoic acid mustard substrates of carboxypeptidase G2 (151). This provides an amplification effect, giving high levels of drug localized at the tumor which may be an important advan-

tage in the clinic in view of the typically low localization of immunoconjugate in humans (152). There is also some evidence that high levels of drug generated at the surface of tumor cells are more effective than equivalent concentrations of free drug (153). To make the use of prodrug-activating enzymes pan-tumor, polymers have been used to target the tumor. These can accumulate preferentially at a tumor because of the enhanced permeability and retention effect (EPR). Macromolecule-directed enzyme-prodrug therapy (MDEPT) is the direct equivalent of ADEPT, with the antibody-targeting component replaced by a polymer.

After administration of an enzyme conjugate, much can remain in the vascular compartment for several days. Although the concentration is much less than that bound to the tumor, the volume of plasma is much greater, and thus the actual enzyme activity may be greater in the plasma than in the tumor. In this case, administration of a prodrug may be no more selective than systemic administration of the active form. It is thus necessary to wait for plasma levels of the conjugate to fall to very low levels (during which time the enzyme activity at the tumor may also be decreasing). Alternatively, the plasma may be "cleared" of enzyme activity, and this can be achieved by use of a clearance antibody directed towards the enzyme (or antibody component in ADEPT). Many high tumor-to-blood levels of the conjugate have been reported (38:1 compared to 1.3:1 without clearance) using such an approach (154,155). Inhibition of the active site of the enzyme will enhance clearance of enzyme activity, but it is important that the clearance antibody have little effect on bound conjugate. This has been achieved by the rapid clearance of the second antibody through the carbohydrate receptors in the liver by the introduction, into the antibody, of galactose residues (154–156). Alternatively the conjugate itself can be galactosylated and the conjugate localized while the liver receptors are blocked by administration of a competitive binder such as asialobovine submaxillary gland mucin. A tumor-to-blood ratio of 45:1 for an anti-CEA-carboxypeptidase G<sub>2</sub> conjugate was achieved 24 h after injection of the conjugate using this type of approach; this increased to 100:1 at 72 h (155). Tumor-to-blood ratios of a conjugate (but not other tissue-to-blood ratios) could also be significantly increased by coadministration of tumor necrosis factor alpha, which enhances the tumor uptake of enzyme conjugates (157). Coadministration of 1.5 µg TNF with conjugate led to a twofold increase in tumor uptake with only transient increases in normal tissue localization. To avoid the need for a clearance step, polymer-directed enzyme-prodrug therapy (PDEPT) has been proposed. PDEPT uses a polymer-enzyme conjugate that accumulates by EPR to activate a polymeric prodrug that also ac-

cumulates. The polymeric prodrug is administered first, but unlocalized prodrug can be excreted through the kidneys within 5 h after administration. Thus when the enzyme conjugate is given there is no prodrug available to cause systemic activation.

An immune response was observed in patients treated with ADEPT therapy and developed against both the enzyme and antibody components of the conjugate (35, 40,144). The raising of an immune response would preclude extended therapy. Several strategies have been proposed to overcome the host immune response. The use of immunosuppressive agents such as cyclosporin can extend the time window available for therapy. This may enable multiple cycles to be given (35,40,144). Also, it may be possible to administer a second ADEPT conjugate consisting of a different antibody-enzyme combination. There is also the possibility of masking the immunogenicity of conjugates by modification with polyethylene glycol or other similar polymers (158). The immunogenicity of the antibody moiety can be reduced by using chimeric (e.g., rat antigen-binding domains coupled to human constant regions), humanized or fully human-derived antibody fragments (159). Efforts to reduce the immunogenicity of the enzyme can be attempted by reduction of the size of the active fragment; modification of the bacterial enzyme at key immunogenic residues by site-directed mutagenesis, engineering of the enzyme's active site into an antibody, or engineering a human enzyme such that its activity and specificity more closely match that of the bacterial enzyme. Model compounds consisting of a mouse Fab fused with nucleases or polymerases were reported some time ago (160). Such constructs could be produced in relatively high yield and with a greater homogeneity of conjugate by comparison with current chemical linking techniques, where yields are relatively low and the product ill defined in terms of its homogeneity (161,162). The first fusion protein developed specifically for an ADEPT application consisted of human β-glucuronidase fused to the CH domain of BW431, a high-avidity anti-CEA antibody, humanized by complementarity determining region (CDR) grafting. The protein thus produced has antigen affinity very similar to that of the parent antibody and retains enzymatic activity (163). A *B. cereus* β-lactamase II single-chain antibody fusion protein has also been constructed. The antibody used, L6, recognizes an antigen expressed on breast, colon, lung, and ovarian carcinomas. The fusion protein is produced by *E. coli* in an active form that does not require refolding and retains similar immunological and enzymatic properties to an equivalent chemically linked conjugate (49).

An important advantage of polymers is their effect on the immunogenicity of foreign proteins (125,126). This is

generally attributed to their ability to mask epitopes. There is also evidence that they can induce immune tolerance to challenge with bacterial enzymes. The substitution of a polymer for an antibody vector should therefore reduce the immunogenicity associated with an antibody conjugate and has the potential to allow the repeated use of bacterial enzymes in humans without the necessity for immunosuppression or engineering. However, polymer conjugates are still produced chemically while an antibody-enzyme fusion protein can (in theory) be produced directly in bacteria. The fusion protein is a defined product of much greater homogeneity than can be obtained with a polymer-enzyme conjugate.

An alternative enzyme-prodrug system uses methods such as viral vectors to deliver genetic material encoding the activating enzyme to the target cells. This approach is called GDEPT. Unlike ADEPT, MDEPT, or PDEPT, there is no intrinsic tumor selectivity. At present, targeting is achieved by altering the surface components of viruses and liposomes to achieve a level of target cell recognition. Transcriptional elements can also be incorporated so that the incorporated gene is expressed only in the target cells. At present, there seem to be many problems that have yet to be overcome, in particular the issue of ensuring that only the target cells are transfected with the desired gene. Systemic administration of the present generation of gene therapy vectors is not possible. Thus GDEPT, unlike the other enzyme-prodrug therapies described, is limited to isolable tumor deposits, such as intracerebral tumors, surrounded by largely nondividing normal tissue.

There is a rich diversity of potential enzyme and prodrug combinations for use in targeted enzyme prodrug applications (Table 1). In selecting an enzyme one would look for activity under physiological conditions, low immunogenicity, and little or no equivalent endogenous enzyme in humans. The enzyme must localize efficiently at the tumor when coupled. The prodrug is an integral component of systems and requires careful design in its own right. An ideal prodrug would be one with a large differential in cytotoxicity between drug and prodrug, which is a good substrate for the enzyme under physiological conditions and for which there is no mammalian homologue capable of performing the same reaction. Equal cytotoxicity of the released active drug towards proliferating and quiescent cells is also desirable if residual deposits of viable but nonproliferating cells with the potential for outgrowth are to be eradicated. Once formed, it would be desirable for the drug to have a very short half-life, limiting the possibility of escape of active drug back into the circulation and access to healthy tissue. Antimetabolite with inactivation of rescue agent at cancer sites (AMIRACS) allows the use of targeted enzymes in combination with antimetabolite

agents that are already in everyday clinical use. Unlike the other therapies using a targeted enzyme, AMIRACS does not involve the activation of a prodrug to a cytotoxic species but selectively destroys a rescue agent only at the tumor site.

In summary, the in vivo data available for the various targeted enzyme-prodrug therapies provide exciting grounds for encouragement. They offer new research ideas for the medicinal chemist, polymer chemist, enzymologist, molecular biologist, and protein engineer as well as the cancer chemotherapist. Although relatively complicated, targeted enzyme-prodrug therapies offer opportunities for the therapy of systemic cancer and may be a major advance for the treatment of solid tumors.

## New Lipid/DNA Complexes for Gene Delivery

Kenneth W. Liang and Leaf Huang

*University of Pittsburgh, Pittsburgh, Pennsylvania*

### ABBREVIATIONS

CHEMS	cholesteryl hemisuccinate
DC-Chol	3- $\beta$ -[N-(N',N'- dimethylaminoethane)carbonyl]- cholesterol
DOPE	dioleoylphosphatidylethanolamine
DOTAP	1,2-dioleoyloxypropyl-3-N,N,N- trimethylammonium chloride
DOTMA	1,2-dioleoyloxypropyl-3-N,N,N- trimethylammonium chloride
LPD	liposome-entrapped, polycation- condensed DNA
PNA	peptide nucleic acid
SAXS	small-angle x-ray scattering

### I. INTRODUCTION

Recent advances in molecular biology and the human genome project have brought about improved understanding of the genetic basis for human disease. The wealth of knowledge about genetic causes of human disease provides compelling and substantive support for the development of gene therapy. Today, many incurable diseases such as inherited genetic diseases, cancer, and AIDS are under consideration as candidates for gene therapy. In some

cases, gene therapy represents the only long-term hope of treatment for these diseases. After a decade of extensive research on gene therapy, it is now clear that the vehicle with which the therapeutic gene is introduced into the target cells of the body is the key to the success of an effective cure.

Gene delivery can be achieved with viral and nonviral vectors. Viral vectors are recombinant, replication-defective viruses with all or part of the viral coding sequences replaced by the therapeutic gene. They infect cells using the same mechanism as the parental virus and are thus highly efficient in transducing cells. For example, adenoviral vectors can efficiently transfer genes into quiescent, terminally differentiated cells such as hepatocytes and nerve cells. This is because these cells express the appropriate receptor for adenovirus, and the virus can efficiently move into the cellular nuclei by some active processes (1). Even though viral vectors are highly efficient in terms of gene transfer, they still suffer from many problems in clinical application. For example, gene expression of adenovirus vectors usually does not last for more than several weeks (2). However, high immunogenicity of the adenoviral vector makes repeat administration of the vector virtually impossible. Retroviral vectors are also very effective and are widely used for current clinical applications. However, there are serious concerns about the tumorigenic potential of retroviral vectors via the random

disruption of an oncogene and/or the generation of infectious virions through recombination with latent viral sequences (3,4). Moreover, the commonly used *ex vivo* protocol of using retroviral vectors also limits the clinical application of these types of vector. Other problems associated with viral vectors are low yield in viral preparation (5,6), a limit in the size of a therapeutic gene that can be fitted into a viral vector, and difficulty in maintaining reproducible quality and quantity. All of these problems with viral vectors have made the development of nonviral vectors more desirable for gene therapy.

Various chemical and physical methods, such as electroporation, microinjection (7), and a complex of DNA with calcium phosphate (8) or DEAE-dextran have been used for gene transfer in cultured cells. Although most of these methods are still favored in laboratories, they obviously cannot be used to transfect cells for therapeutic purposes because of efficacy and safety concerns. On the other hand, gene transfer using a cationic liposome has been successfully applied in clinical trials.

Cationic lipids are amphiphilic molecules consisting of a hydrophobic anchor, usually made up of fatty acyl, alkyl, or alkoxy chain(s), a hydrophilic head group carrying a single or multiple positive charged groups, and a linker that connects the hydrophobic portion and the hydrophilic head together. In 1987, Felgner et al. reported the first successful gene transfer using a cationic lipid (9). They showed that N-[1-(2,3-dioleoyloxy)propyl]-N,N,N-trimethyl ammonium chloride (DOTMA) and dioleoyl phosphatidylethanolamine (DOPE) formed a cationic lipid/DNA complex with plasmid DNA that successfully transfected several cell lines. Since then, hundreds of new lipids and many new formulations have been developed. Currently, cationic lipid vectors generally contain a cationic lipid, a neutral lipid such as DOPE or cholesterol, and the plasmid DNA that encodes the transgene of interest. The assembly of a cationic lipidic vector is normally achieved by mixing the positively charged cationic lipid with the negatively charged plasmid DNA. Through electrostatic interaction between a lipid head group and a phosphate group on DNA, nanoparticles composed of lipid and DNA are formed. These particles are capable of entering cells efficiently and delivering a portion of the encapsulated DNA into the nucleus. Excess in positive charge is usually required for efficient gene transfer, because the resultant positively charged vectors can bind efficiently with the negatively charged cell membranes and induce endocytosis.

In order to achieve the ultimate goal in gene therapy, one needs to develop a vector that can be administered *in vivo*, and that will deliver therapeutic genes to the target cells, release the DNA from the endosome, and import the DNA into the nucleus. In addition to these features, the

vector should also be safe, simple to use, and easy to produce on a large scale. Compared to viral vectors, cationic lipidic vectors are much less immunogenic and can be easily produced in large quantities with reproducible pharmaceutical quality. Furthermore, there is no structure and size limit on the therapeutic gene. For example, cationic lipids have been successfully used to deliver human artificial chromosomes of the order of 230 kb into cells (10). Besides that, the properties of cationic lipid vectors can easily be modified via chemical and pharmaceutical methods, such as incorporating targeting ligands or by manipulation of the formulation. All of these advantages make cationic lipids a good candidate for developing ideal synthetic vectors for gene therapy.

However, one major limitation of cationic lipid vectors is their transfection efficiency, which is much lower than that of viral vectors. When the efficiency is indicated by the number of cells transfected, the cationic lipid/DNA complex can only introduce nucleic acid into a portion of the cells, usually less than several percent of the total. Numerous attempts have been done to increase the transfection efficiency of cationic lipid vectors. These include the synthesis of new cationic lipids and the improvement of cationic lipid formulations. In this chapter, we will briefly review the current development of cationic lipids and their structure–activity relationships. Later, we will focus our discussion on several new developments in our laboratory.

## II. CATIONIC LIPOSOMAL VECTORS

Since the first cationic lipid, DOTMA, was reported in 1987 (9), several hundreds of cationic lipids have been synthesized by different laboratories and companies. Although the detailed structures of the individual lipids vary considerably, all of them share a common feature in that they all consist of a cationic headgroup attached via a linker to a hydrophobic moiety. Cationic lipids can be classified into two different categories, double-chain amphiphiles and cholesterol derivatives, according to the difference in their hydrophobic anchor.

Double-chain amphiphiles are widely used in cationic liposome formulation. This type of lipid normally contains a headgroup of quaternary ammonium salt and double acyl or alkyl chains as the hydrophobic anchor. Two representative lipids in this category are DOTMA and DOTAP (Fig. 1). Lipids of cholesterol derivatives all have cholesterol as a hydrophobic anchor. A representative lipid in this category is  $3\beta$ [N-(N',N'-dimethylaminoethane)-carbonyl]-cholesterol (DC-chol) (Fig. 1). DC-chol was first developed in our laboratory with the purpose of preparing a less toxic lipid. It contains a single tertiary amine group, which

Figure 34.1 Structure of DOTMA, DOTAP, and DC-Chol.

is considered to be less toxic than quaternary ammonium groups. In addition, DC-chol is biodegradable because of the carbamoyl bond instead of a nondegradable ether bond to connect the headgroup and the cholesterol. Due to its low toxicity, DC-chol combined with DOPE was the first lipid-based gene transfer agent to be used in a human gene therapy trial (11).

The efficiency of gene transfection by a cationic lipid vector can be manipulated by changes either at the molecular level or at the formulation level. At the molecular level, it was observed that a small change in the structure of the cationic lipid could significantly affect its transfection activity. This observation has sparked an extensive interest in studying the structure–activity relationship of cationic lipids, with the goal of developing lipids with high transfection efficiency and low toxicity. To date, several general rules regarding the structure–activity relationships of cationic lipids have been established.

The three moieties of cationic lipids, the headgroup, the hydrophobic moiety, and the linker, all have an influence on the transfection activity of a cationic lipid. The headgroup has been found to play an important role, since the function of the headgroup in cationic lipids is to bind with and to condense the negatively charged plasmid DNA to form a complex, as well as to enhance the binding of the complex to the negatively charged cell surface. The headgroup can affect the activity of lipids in several ways. The type of amine (12), the number of amines (13,14), and the

orientation of the headgroup (14,15) all can affect transfection activity. The hydrophobic anchor influences the transfection activity by affecting the phase transition of lipids between the gel and the liquid crystalline phases. For example, Akao and colleagues (16) found that lipids with phase transition temperatures ( $T_m$ ) below 37°C were more efficient in gene delivery than those with a  $T_m$  above 37°C. The observation that lipids with lower  $T_m$  exhibit better transfection activity is supported by the results of other groups such as those of Solodin et al. (17), and Lee et al. (14). The linker is the moiety that connects the hydrophobic anchor and the polar headgroup. The linker can be an ether, amide, carbamate, ester, or phosphate bond. The linker group affects the biodegradability and consequently the stability of the cationic lipid. Lipids with an unhydrolyzable linker provide good chemical stability and generally exhibit higher transfection activities (9,18). However, the poor biodegradability of these lipids has generated some concerns about their safety in clinical usage. Easily degraded linkers, on the other hand, may make the lipid unstable in a biological environment (13). As a result, lipid/DNA complexes may dissociate before they reach target cells. In general, a linker is selected based on the balance between its biodegradability and its relative stability.

At the formulation level, many factors can affect the efficiency of gene expression. One important factor is the stoichiometry of lipids and DNA. The relative amounts of

lipid and DNA directly affect the surface charge of a lipid/DNA complex, which subsequently affect the size and the stability of the complex, and its interaction with various components *in vivo*. Other factors, such as the method of mixing, the elapsed time of incubation (19), and helper lipid selection (20–22), can also affect the gene delivery activity.

One important characteristic of the cationic lipid/DNA complex that is affected at the formulation level is the structure of the lipid/DNA complex. In contrast to what Felgner and Ringold (23) originally proposed, that cationic liposomes remain the same size and shape after binding to DNA, experimental data now show that cationic liposome/DNA complexes are very heterogeneous and dynamic, varying in size and shape depending on the molar ratio of cationic liposomes to DNA. Using ethidium bromide as a fluorescent probe for the exposed DNA, Gershon et al. showed that the most dramatic changes in structure appear to occur when the positive/negative charge ratio is around 1 (24). Based on these results, Gershon et al. proposed that the binding of cationic liposomes to DNA induced a cooperative collapse in the DNA structure and that the resulting condensed DNA is subsequently encapsulated by lipid (24). Using Kleinschmidt metal-shadowing electron microscopy, Gershon et al. showed that DNA was bound to liposome and formed a spherical structure at low lipid-to-DNA ratios. When the amount of lipid was increased, DNA became covered by liposomes, and a smooth rodlike structure was formed (24). A similar structure was later found by Sternberg et al., who examined the structure of DC-chol/DNA complex by freeze-fracture electron microscopy and revealed that some freshly prepared DC-chol/DNA complex contained so called “spaghetti and meatball” structures (25), indicating that in the complex the DNA molecules are not well condensed but exist in an extended conformation and covered by lipids. These observations have been supported by the recent results of cryo-EM (26) and small-angle x-ray scattering (SAXS). Gustafsson et al. have obtained cryotransmission electron microscopy images of DNA complexed with DOTAP, which revealed the presence of loosely bound DNA at a low positive/negative charge ratio and large lipid/DNA structures at a high charge ratio (26). The experimental results from SAXS further revealed the detail structure inside the DNA/lipid complex. It was found that the DNA/lipid complex formed a multilamellar structure with alternating lipid bilayers and DNA monolayers. A long periodicity of 6.5 nm was observed, which is consistent with a lipid bilayer thickness of 4 nm and a hydrated DNA helix of 2.5 nm (27). These studies further indicate that the transfection activity can be greatly influenced at the formulation level.

### III. NEW LIPID/DNA COMPLEXES FOR GENE DELIVERY

#### A. Cationic Liposome-Entrapped, Polycation-Condensed DNA (LPD-I)

Improving the transfection activity is continuously a major effort in developing nonviral vectors. Although studies on the structure–activity relationship has established some correlations between the structure of a cationic lipid and its transfection activity, the search for new lipids still largely relies on a trial-and-error approach and has achieved only limited success. On the other hand, studies on the formulations of cationic lipid/DNA complex have revealed some drawbacks that require further correction. For example, the DC-chol/DNA complexes tend to form large aggregates with sizes well beyond 500 nm in diameter. The aggregation problem is particularly severe at high concentrations of lipid and DNA. This creates difficulties for preclinical and clinical studies in which complexes of high concentrations are often required (28). Since DC-chol does not condense DNA efficiently, additional condensing agents, such as polycations, have been studied extensively (24,29). For example, human chromatin can be reduced in length by a factor of 10<sup>4</sup> or more after binding to histones. Cationic polymers such as polylysine can also condense DNA from an extended conformation to highly compact structures of about 30–100 nm in diameter. Based on all these results, Gao and Huang proposed that the introduction of polylysine into the DC-chol/DNA complexes might alter its overall physical state, thereby improving its transfection activity (30). This idea was tested by examining the transfection efficiency of DC-chol/DNA complexes alone or DC-chol/DNA complexes with the addition of different amounts of polylysine. Incorporation of polylysine into the DC-chol/DNA complexes was found to increase transfection activity of DC-chol/DNA from 2- to 28-fold, depending on the cell lines being transfected (30). This new and efficient formulation was named LPD-I. In the following we examine some characteristics of LPD-I and factors that affect its transfection activity.

##### 1. Effect of Polymers

Different cationic polymers were tested for their ability to form active LPD formulation. High molecular weight poly-L-lysine, poly-D-lysine, poly-L-ornithine, polybrene, and protamine (free base) were among the most active polymers tested. Low molecular weight poly-L-lysine, histone, and oligocations such as spermine were much less active than poly-L-lysine (MW 200,000). The reason for this low activity may be that these polymers do not have enough cation density and thus cannot form stable com-

plexes with DNA under physiological conditions. Poly-amidoamine dendrimeric polymer was completely inactive. It is unclear why this type of polymer could not enhance transfection activity, since the polymer itself can complex with DNA and mediate DNA delivery (31). Sorgi et al. later substituted the condensing agent from polylysine to protamine sulfate and found that the transfection activity of LPD-I increased about 5- to 10-fold (32). The finding is significant because protamine sulfate is approved by the FDA as an intravenous antidote for a heparin overdose. Therefore the substitution made the formulation more suitable for clinical applications. The amount of cationic polymer also affects the transfection activity. Among the three lipids tested (DC-chol/DOPE, Lipofectin, and LipofectAMINE), gene expression reached a peak level when the polylysine-to-DNA ratio (W/W) reached 1:2, and the gene expression started to decrease when the ratio exceeded 1:1 (Fig. 2). In addition, the way that cationic polymer was added to form the complex was also important for gene transfection. An active formulation could only be done when DNA was incubated with polylysine first, followed by the addition of lipid, or when DNA was mixed with polylysine and lipid simultaneously. If DNA was mixed with the lipid first, followed by the addition of polylysine, the resulting complexes had very low activity. This further indicates the importance of the formation of the polylysine/DNA core.

## 2. Effect of Lipid

The enhancing effect of polylysine on gene transfection with cationic lipids seemed to be a general phenomenon. Three different types of lipids were tested, DC-chol/DOPE, Lipofectin, and LipofectAmine. Compared to DNA/lipid complex without polylysine, DNA/lipid complex with the addition of polylysine in those three lipid formulations all resulted in different degrees of enhancement in gene transfection. The amount of lipid also affected the transfection activity of LPD formulations. When the lipid concentration was low, the enhancing effect by polylysine was not very significant. When the lipid concentration was high, the addition of polylysine actually decreased the transfection activity. The optimal amount of lipid seemed to be between 3 to 6 nmol per  $\mu\text{g}$  of DNA. Furthermore, the amount of lipid incorporated in the LPD ternary complex is very important for high activity. When LPD complex was subjected to a linear sucrose density gradient (5–30%) ultracentrifugation, a broad band was found in the middle of the gradient, due to the heterogeneity of LPD complex. Fractions located at the upper portion of the gradient were more enriched with liposome than those located at the lower portion of the gradient. LPD

**Figure 34.2** Potentiation of cationic liposome-mediated transfection by polylysine on CHO cells. CHO cells grown in a 48-well plate were lipofected for 4 h with  $1\mu\text{g}$  of pRSVL plasmid complexed with the indicated amount of DC-chol liposome (a), lipofectin (b), or lipofectamine (c) and with the indicated amount of polylysine. Thirty-six hours after the transfection, luciferase activity was measured over a period of 20 seconds using  $2\mu\text{g}$  of cellular proteins from each cell lysate. Symbols: (a) ● 3.3 nmol, ■ 6.6 nmol, ○ 10 nmol, △ 12.5 nmol, × no DC-chol/DOPE (4.5/5.5, mol/mol) liposome; (b) ● 4.5 nmol, ■ 6.0 nmol, ○ 8.5 nmol, ▲ 10 nmol Lipofectin; (c) ● 4 nmol, ■ 6 nmol, ○ 8.5 nmol, ▲ 10 nmol Lipofectamine. (From Ref. 30, used with permission.)

complex purified from the upper portion of the gradient had higher transfection activity than those purified from the lower portion of the gradient. Interestingly, the activity of LPD complex lacking a sufficient amount of lipid could be restored for high activity when additional DC-chol/DOPE liposomes were added. A possible explanation of this phenomenon is that the addition of lipid improves the stability of the polylysine/DNA complex. The attachment of lipid to the polylysine/DNA complex may provide a repulsive force and thus prevent the aggregation of polylysine/DNA complexes. In addition, excess lipid in

the LPD complex may help the release of the complex from the endosome.

### 3. Structure of LPD-I

The structure of LPD-I was analyzed by negative stain electron microscopy. The LPD-I complex appeared to be small spherical particles consisting of a dense core surrounded by a lightly stained ring-shaped structure (Fig. 3) (30). The ring-shaped structure appeared to be lipid bilayers, because they had characteristics of a typical membrane staining pattern. From the structure, it is appeared that polylysine and DNA formed a very dense core and cationic lipid formed a shell covering the polylysine/DNA core. Though somewhat heterogeneous, most LPD-I particles were under 100 nm and very stable physically. No increase in size was observed even after 3 months of storage at 4°C. Compared with the structure of DC-chol/DNA complex (Fig. 4), the structure of LPD-I is very different. The more compact structure of LPD-I as compared to DC-chol/DNA complex may be due to the complete condensation of DNA by polylysine. Recent studies using cryoEM have also revealed a similar structure of LPD-I complex containing protamine sulfate instead of polylysine (data not shown).

### 4. In Vivo gene transfer with LPD-I

Intravenous injection of LPD-I resulted in gene expression in all major organs including the lung, liver, heart,

**Figure 34.3** Electron micrographs of LPDI complexes. Purified LPDI was examined by negative stain electron microscopy. The LPDI was prepared from 20 µg of DNA, 10 µg of polylysine (MW 26,500) and 800 nmol of DC-chol/DOPE liposomes (2/3 mol ratio) and purified with sucrose gradient ultracentrifugation. The samples were stained with 1% phosphotungstic acid. Bar = 100 nm. (From Ref. 30, used with permission.)

**Figure 34.4** Freeze-fracture electron micrograph of DC-Chol liposome/DNA complex. (From Ref. 25, used with permission.)

spleen, and kidney (Fig. 5). The lung and spleen had the highest gene expression levels. The liver and heart showed modest gene expression, and the kidney had the lowest gene expression level (33). This pattern of gene expression is similar to that of cationic lipid/DNA complex. Gene expression in all organs was found to be DNA dose-dependent. However, a higher dose was always associated with higher toxicity. Gene expression was also transient. It normally lasted for 3 days to a week. The lipid-to:DNA charge ratio was important for efficient gene transfection in vivo. The activity of LPD-I increased as the charge ratio (+/-) increased. It was reported that a high charge ratio could overcome the inhibitory effect of serum (19). At low charge ratios, serum can neutralize the positive charges on LPD-I and thus block its entry into cells. As with in vitro results, LPD-I that is formed with different types of lipid resulted in different degrees of increase in activity. However, the type of lipid seems to have a more profound effect on in vivo gene transfer. For example, double-chain hydrocarbon-anchored lipids such as DOTAP were more active than cholesterol-anchored cationic lipids. Furthermore, the type of helper lipid also plays an important role in in vivo gene transfer. When DOPE was used as a helper lipid, the activity of LPD-I was significantly decreased. On the other hand, cholesterol can significantly increase the activity of LPD-I. Similar results were reported by other groups using

**Figure 34.5** In vivo gene expression of LPD as a function of time. LPD was prepared as described in the legend to Fig. 2 and injected into the mice at 50  $\mu\text{g}$  DNA per animal. At different times following the injection, mice were sacrificed and major organs were assayed for gene expression ( $n = 3$ ). (From Ref. 33, used with permission.)

cationic lipid/DNA complex (34–36). It appeared that cholesterol could reduce the interaction of LPD-I with serum. Using SDS-PAGE, Li et al. found that the amount of serum associated with LPD-I formulated with cholesterol was much less than in LPD-I formulated with DOPE as a helper lipid (37). This may explain that LPD-I formulated with cholesterol provides a higher activity. The amount of lipid is also very important for in vivo gene transfection. The activity of purified LPD-I by sucrose gradient centrifugation can be enhanced by adding free liposome. The excess of liposome is thought to prevent the release of DNA due to the interaction between LPD-I and serum. In addition, excess cationic liposomes also prolong the residence of LPD-I in the microvasculature of the lung.

### B. Anionic Liposome-Entrapped, Polycation-Condensed DNA (LPD-II)

Although cationic liposomes are the most popular delivery vectors in nonviral gene therapy, there is always a strong desire to use anionic liposomes to deliver plasmid DNA. There are several reasons that anionic liposomes are more desirable for in vivo gene delivery. First, the cationic liposome/DNA complex is highly positively charged; it can interact nonspecifically with anionic proteins in vivo such as serum proteins. This kind of interaction normally causes a decrease in gene transfection activity and an increase in undesirable side effects. Second, cationic liposomes deliver DNA by nonspecific binding to the cell membrane. Therefore it is difficult to use cationic liposomes to target DNA to a specific cell type. In contrast, it

is possible to conjugate a specific targeting ligand to the surface of an anionic liposome and deliver DNA to the target cells. Much effort has been devoted to developing an anionic liposome delivery system, but little success has been achieved. The major problem is the low encapsulation efficiency of DNA due to the large size and the high negative charge content of uncondensed DNA. Recently, in our laboratory, we have developed an anionic liposome formulation for the delivery of DNA without actually encapsulating DNA into the liposome (38). DNA was first condensed with an excessive amount of polylysine so that the resulting complex was slightly positively charged. Anionic liposomes were then added. Through electrostatic interaction, anionic liposomes could bind to the surface of the polylysine/DNA complex and form a shell on the polylysine/DNA core. The protocol and possible mechanism for the formation of this formulation is illustrated in Fig. 6. We call this type of formulation LPD-II.

To form LPD-II particles, a pH-sensitive, anionic liposome formulation composed of DOPE/cholesterol hemisuccinate (CHEMS)/folate-poly(ethylene)glycol-DOPE was added to the polylysine/DNA complexes. The resulting particles contained folate-targeting ligand. However, depending on the amount of anionic liposome used, the resulting LPD-II particles could either be positively or negatively charged. Negative-stain EM analysis revealed that the resulting LPD-II particles had a very similar morphology to the LPD-I particles. Both kinds of particle appeared to be spherical and consisted of a high-density core of polylysine/DNA complex coated with a low-density lipid layer. The LPD-II particles were used to transfect KB

**Figure 34.6** Possible mechanism for the formation of LPD-II. The targeting ligand in the current study is folate. (From Ref. 38, used with permission.)

cells, a cell line that over-expresses folate receptor. Both cationic and anionic LPDII particles could efficiently transfect KB cells. Both types of LPD-II were about 20- to 30-fold more efficient than the conventional DC-chol/DNA complex. However, anionic LPD-II particles containing folate as a targeting ligand were more efficient than the cationic LPD-II particles. Although both types of particle transfected cells efficiently, they apparently used different mechanisms. First, unlike the anionic LPD-II particle, the transfection by cationic LPD-II particles could not be blocked by excessive free folate. Second, another cell line, CHO, which does not express the folate receptor, could also be efficiently transfected by cationic LPD-II particles, but not the anionic LPD-II. This indicated that the transfection of cationic LPD-II was not through the receptor-mediated endocytosis but rather by nonspecific binding to the cell membrane. On the other hand, efficient transfection with anionic LPD-II particles depended on the presence of both the targeting ligand on the LPD-II and the receptor on the cell surface. All these results demonstrated that the anionic LPD-II particles could only transfect cells through the receptor-mediated endocytosis pathway.

### C. Advantages and Limitations

Compared to the traditional lipid/DNA complex, the addition of a polycationic condensing agent to the cationic

lipid/DNA complex offers several advantages. First, the LPD particles are much smaller than the simple lipid/DNA complex. LPD particles are more homogeneous, and most of them are about 100 nm in diameter, while the conventional lipid/DNA complexes are very heterogeneous and tend to form large aggregates around 1000 nm or larger. Since endocytosis is the major pathway responsible for the cellular uptake of DNA complexes, smaller particles such as LPD are favored for internalization. Second, LPD formulations are much more stable than cationic lipid/DNA complexes. As mentioned previously, LPD can be stored for more than three months at 4°C without any increase in size. Third, LPD formulations offer better protection to DNA from nuclease degradation. Even at the optimal ratio, DC-chol/DNA complex cannot completely protect DNA from degradation. In contrast, LPD formulations can completely protect DNA from enzymatic degradation. Thus the more functional plasmid DNA can be delivered into cells by LPD. Fourth, the addition of a condensing agent dramatically reduces the amount of cationic lipid needed for condensing, protecting, and delivering the plasmid DNA. The amount of cationic lipids needed to form the conventional lipid/DNA complex is usually too large for scaling up for clinical applications. Finally, highly positively charged polylysine and protamine may facilitate the transport of DNA from cytoplasm to nucleus, once the DNA is delivered into cells.

The advantages of LPD-II include that the preparation does not require purification and is a single-vial formulation. Unlike cationic delivery systems, LPD-II can be targeted to different organs simply by changing the ligand conjugated to the anionic lipid. For example, Transferrin (Tf) was conjugated to anionic liposomes, and LPD-II using transferrin as a targeting ligand has been developed. The LPD-II was able efficiently and selectively to deliver DNA into myoblasts and myotubes (39). Compared with the traditional anionic and neutral liposomal vectors, there is no problem with encapsulation. DNA is highly condensed and is quantitatively encapsulated without the use of excess amounts of lipid. Finally, since anionic lipids exist naturally, they are more biocompatible than cationic lipids. Taking all together, the anionic LPD-II may become the vector for tissue-specific gene delivery *in vivo*.

Although the LPD formulations increase gene expression both *in vitro* and *in vivo*, the level of gene expression is still lower than in viral vectors. Lack of targeting capacity is another limitation for LPD-I. And due to the cationic nature of LPD-I, targeting to a specific organ may not be efficient with a targeting ligand conjugated to these particles. LPD-II has the targeting capacity, but the instability of this formulation in serum greatly limits the application of the formulation *in vivo*. Improvement of the formulation is currently underway in our laboratory.

#### D. Toxicity of LPD

Recently, more and more reports suggest that cationic lipids are not so nontoxic or nonimmunogenic as previously thought (40,41). When introduced into the lung, cationic lipid/DNA complex usually causes an inflammatory response characterized by cellular infiltrates and elevated levels of several proinflammatory cytokines. In our studies, injection of a large dose of LPD-I can also cause severe toxicity that results in the deaths of animals. Injection of LPD was found to cause the secretion of several proinflammatory cytokines including  $\text{TNF}\alpha$ ,  $\text{INF}\gamma$ , IL-6, and IL-12. However, injection of DNA, polylysine, or cationic lipid alone was not able to cause the production of these cytokines (42). Recent studies suggest that the presence of unmethylated CpG motif in the plasmid DNA is responsible for the production of the cytokines (43). Methylation of the CpG motif in the plasmid significantly reduced the cytokine response.

### IV. CURRENT AND FUTURE DEVELOPMENT

#### A. Systemic delivery

Systemic delivery of therapeutic genes is the ultimate goal of gene delivery. Compared to *in vitro* gene transfer, *in vivo* gene delivery faces many more obstacles such as the size limitation of endothelial wall penetration, nonspecific interaction with components in the biological fluids and extracellular matrix, and binding to nontarget cell types. Although many studies have reported successful *in vivo* transgene expression in several organs, few studies have identified the cell type in the organ that has been transfected. Whether the transgene expression is in the parenchymal cells, which are normally the targets for gene transfer, remains unclear. Using fluorescence microscopy to track the fate of fluorescently labeled liposomes and DNA, McLean et al. found that most DNA uptake apparently was in endothelial cells of the microvasculature of the lung, lymph nodes, ovary, anterior pituitary, and adrenal medulla (44). Therefore transgene expressed mostly in endothelial cells and not in parenchymal cells. The result is not surprising, considering that most liposome/DNA complexes have diameters of about 100 to 500 nm. The endothelial barrier would normally prevent particles of this size from crossing, except in organs such as the spleen where the endothelium is discontinuous. Besides the endothelium barrier, the positive charged surface of the lipid/DNA complex also causes problems. Interaction of the lipid/DNA complex with plasma components such as serum proteins (37) and coagulation factors (45,46) may cause the growth of the particle and eventually obstruct

the lung capillaries. Other problems associated with the positively charged lipid/DNA complex, such as erythrocyte aggregation, opsonization (47), and clearance by the reticuloendothelial system (RES), have also been reported (48). The results from *in vivo* gene transfer studies suggest that the ideal vectors for systemic application should be small enough to pass through physiological barriers and be specific for binding to the target cells but inert against both body fluids and unspecific interactions with tissues and cells, such as the RES.

#### B. Naked DNA as a Vector

Naked DNA appears to be a good vector for gene transfer, since it is small in size and polyanionic, which can diminish nonspecific interactions. However, due to its polyanionic charge and high molecular weight, naked DNA is not likely to be able to enter cells by itself. A condensing agent is thought to be required to condense DNA and make the particles positive in charge so that the DNA complex can be internalized by cells via absorptive endocytosis. However, many *in vivo* gene transfer studies have demonstrated that naked DNA can enter cells efficiently by some unknown mechanisms. Many different organs including the liver (49–51), lung (52–54), heart (55), kidney (50), thyroid gland (56), and tumor (57,58) have been successfully transfected by naked DNA. It is now clear that many cell types *in vivo* can be transfected by naked DNA, as long as a sufficient amount comes in contact with the cells for a prolonged period of time (52). Compared to lipid/DNA vectors, naked DNA is much smaller in size. It was found that supercoiled DNA in pleconomic form has superhelix dimensions of approximately 10 nm (59), which allows the naked DNA to cross microvascular walls and reach target cells. Systemic administration of the naked DNA is still limited due to the rapid degradation of naked DNA in the circulation. However, in some cases, systemic administration of naked DNA resulted in significant gene expression. For example, Liu et al. injected a large volume of DNA solution through the tail veins of mice and detected very high transgene expression in the liver (60). Budker et al. injected large volumes of DNA solution through the femoral artery while blocking the blood inflow and outflow and successfully transfected a large percentage of muscle fibers in the whole legs of rats (61).

#### C. Targeted Delivery of Naked DNA

Since many cells are capable of internalizing naked DNA, targeted delivery of naked DNA via receptor-mediated endocytosis may enhance the cellular uptake of DNA and therefore increase the gene expression. However, targeted delivery of naked DNA is hindered by the difficulty in con-

**Figure 34.7** Schematic illustration of PNA/DNA/PNA triplex (A) and PNA binding to plasmid DNA (B). The PNA contains two strands that are linked through three linker units (8-amino-3, 6-dioxaoctanoic acid or O). One of the strands can hybridize with plasmid DNA in an antiparallel manner by Watson–Crick hydrogen bonding, while the other strand can bind in a parallel manner via Hoogsteen hydrogen bonding. Lysine and cystine are incorporated at the C and N terminals of PNA, respectively. Tf can be conjugated with PNA through a disulfide bond. (B) PNA can be designed to bind to a specific location in the plasmid, such as an antibiotic resistant gene, so that the binding of PNA does not affect gene activity. (From Ref. 63, used with permission.)

jugating a targeting ligand to naked DNA without affecting its activity. Current conjugation methods, whether they are chemical methods such as photolysis or enzymatic methods such as nick translation, attack DNA randomly and therefore may break the coding sequence on the plasmid. Recently, we have successfully used the peptide nucleic acid (PNA) as a linker to conjugate a targeting ligand to naked DNA without affecting the gene expression (63). PNA is an oligonucleotide analog containing normal DNA bases with a polyamide backbone (62). The bases on the PNA can bind to double-stranded DNA in a sequence-specific manner and form a stable triplex (Fig. 7). The polyamide backbone can be readily modified, which will allow conjugation of targeting ligands to PNA. We have designed a PNA sequence targeted to a unique sequence located at the antibiotic resistance region of a plasmid containing the gene luciferase, so that the binding of PNA to the plasmid will not affect the luciferase gene expression. A targeting ligand, transferrin, was conjugated to PNA via

a disulfide bond. The binding of PNA to the naked DNA was highly sequence specific. Furthermore, the binding of PNA did not change the supercoiled conformation of DNA. This is important because DNA in the supercoiled form is much smaller than that in the relaxed form. The ability of Tf-PNA/DNA to mediate the cellular uptake of the naked DNA via receptor-mediated endocytosis was tested in myogenic cells in vitro. Compared to PNA/DNA complexes, Tf-PNA/DNA enhanced gene expression in both myoblasts and myotubes, and the enhancement effect was only seen when the whole complexes were negatively charged, although a polycationic polymer, polyethylenimine (PEI), was still required. Furthermore, the enhancement of gene expression could be inhibited by the excess amount of free transferrin, indicating that the enhancement was via Tf-mediated endocytosis.

## V. SUMMARY AND CONCLUSION

Nonviral gene delivery systems have become more popular because of their favorable safety profiles, contrasting with those of viral vectors. Numerous nonviral vectors have been developed. However, cationic lipids remain the most widely used vectors in nonviral gene transfer. It is clear that the application of cationic lipid vectors for therapeutic use is limited by their low transfection efficiency. Several factors may be responsible for this drawback. First, the entry of the cationic lipid/DNA complex is inefficient. Second, the cationic lipid/DNA complex is not cell-type selective. Third, cationic lipids bind to DNA with relatively low efficiency, so that the amount of lipid required is often too large to be delivered for therapeutic purposes. Fourth, once internalized, the lipid/DNA complex remains trapped in the endosome compartment and is subsequently degraded. Substantial efforts have been devoted to overcome these hurdles by synthesizing new lipids and developing new formulations. The development of LPD represents one such effort. The LPD formulations not only increase the efficiency of gene transfer but also make the complex more stable, more homogenous, and smaller in size. LPD-II is the first formulation with an overall negative charge on the surface, while the DNA is efficiently protected. Although the development of this LPD formulation has overcome part of the problems associated with cationic lipid vectors, other problems such as the large size of the DNA/lipid complex and the lack of targeted delivery still remain. Continuous efforts are required for the development of new lipids and new formulations that may overcome these problems in the future.

The size limitation of endothelial wall penetration represents one of the major barriers for cationic lipid vectors. The small size of naked DNA offers an alternative to study gene transfection in those organs where cationic lipid vec-

tors are normally unable to reach. While cationic lipids have been extensively studied as gene delivery vectors, studies on using naked DNA for gene transfection have lagged behind. The fact that naked DNA can enter many cell types efficiently has intrigued many investigators. Successful gene therapy with naked DNA will require specific delivery of the DNA to target organs. However, the property of naked DNA makes it difficult for the site-specific conjugation of the targeting ligand. PNA appears to be an ideal linker for conjugating a targeting ligand to naked DNA, since the binding of PNA to DNA is sequence specific and does not change the conformation of the naked DNA. However, many studies aiming at understanding the mechanism by which naked DNA enters into the cell and at overcoming the degradation of naked DNA must be carried out, before naked DNA can be widely used for in vivo gene transfer. On the other hand, further developments in cationic lipids and formulations may overcome the size limitation and degradation problems. For example, we have seen the development of new lipids and formulations capable of forming DNA/lipid complexes that contain only a single molecule of DNA. This type of formulation may become an efficient gene delivery vector in the future.

### I. INTRODUCTION

During the last decade much interest has been generated in gene therapy approaches to the treatment of genetic metabolic disorders, cardiovascular diseases, cancer, immune system deficiencies, and infectious diseases (1–8). One of the major problems of gene therapy is the effective delivery and expression of therapeutic genes into target cells in vitro and in vivo (9–11). Viral vectors for gene delivery have certain advantages, including high levels of transduction in the case of adenoviruses, and efficient and stable integration of foreign DNA into a wide range of host genomes in the case of retroviruses. The usefulness of viral vectors is limited, however, by host immune and inflammatory reactions, toxicity, difficulty of large-scale production, size limit of the exogenous DNA (for adeno-associated viruses), random integration into the host genome (in the case of retroviruses), and the risk of inducing tumorigenic mutations and generating active viral particles through recombination (9,12–14). Therefore the use of non-viral gene delivery vehicles may become essential in many applications of gene therapy (15).

Cationic liposome–DNA complexes (“lipoplexes”) have been used extensively for in vitro and in vivo gene delivery and constitute a viable alternative to viral gene delivery vehicles (10,16–21). Reporter genes delivered via lipoplexes in vivo have been expressed in a number of tis-

sues, and relatively long-term expression of several months has been obtained in some cases (22–29).

Lipoplexes present numerous advantages in gene delivery (9,13,20): (a) lipoplexes can protect DNA or RNA from inactivation or degradation in biological milieu; (b) lipoplexes can carry large pieces of DNA, potentially up to chromosome size; (c) they are not immunogenic; (d) they are safe relative to viral vectors; (e) large-scale production of liposomes is easy compared to that of viruses; (f) they are highly versatile.

Lipoplexes currently have several limitations for gene therapy applications: (a) they utilize unnatural cationic lipids that can be toxic (16,30,31); (b) they incorporate suboptimal DNA concentrations; (c) their efficiency of gene delivery and expression is limited due to various cellular barriers (10,11,32); (d) many lipoplex formulations are heterogeneous and have a relatively large particle size; (e) they may have adverse interactions with negatively charged biological macromolecules in serum and on cell surfaces (33); (f) gene delivery by many types of lipoplexes is inhibited by serum (16,34–38).

### II. GENE DELIVERY BY LIPOPLEXES IN CELL CULTURE

Cationic liposome–DNA complexes have been used for gene delivery in cell culture (in vitro) and in experimental

animals (in vivo) since the landmark contribution of Felgner et al. (16) utilizing the cationic lipid N-[1-(2,3-dioleoyl)propyl]-N,N,N-trimethylammonium chloride (DOTMA) (Fig. 1). This study showed that small unilamellar liposomes composed of DOTMA and the zwitterionic lipid phosphatidylethanolamine (PE) (1:1) interact spontaneously with DNA to form lipid–DNA complexes, that the complexes mediate the expression of chloramphenicol acetyltransferase (CAT) from the pSV2cat plasmid in CV-1 or COS-7 kidney cell lines, that the level of gene expression depends on the amount of cationic liposome complexed with the DNA, and that transfection activity is much more effective than that achieved with calcium phosphate or DEAE–dextran. Felgner et al. (16) also reported that high concentrations of lipid are toxic depending on the cell type,

**Figure 35.1** Structures of some cationic lipids used for transfection. DOTMA, N-[1-(2,3-dioleoyl)propyl]-N,N,N-trimethylammonium chloride; DOGS, di-octadecylamidoglycyl-spermine; DODAC, di-octadecyldimethylammonium chloride; DMRIE, 1,2-dimyristyloxypropyl-3-dimethyl-hydroxyethylammonium bromide; DOTAP, 1,2-dioleoyloxy-3-(trimethylammonio)propane.

time of incubation with the cells, and the cell density in the culture, and that the presence of serum during incubation of the complexes with cells is inhibitory to transfection. Based on the observation of diffuse fluorescence over the plasma membrane as well as intracellular membranes following incubation of rhodamine-labeled DOTMA/PE liposome–DNA complexes with cells, it was proposed that gene delivery occurs via fusion of the complexes with the plasma membrane. When phosphatidylcholine (PC) was substituted for PE in the cationic liposomes, only punctate fluorescence was observed; this was interpreted to reflect the inhibition of fusion by the presence of PC in the liposome membrane, consistent with the fusion-inhibitory properties of PC (39,40). DOTMA/dioleoyl-PE (DOPE) liposomes are commercially available as the reagent Lipofectin (Table 1).

DNA complexed to lipopolyamine particles composed of spermine with covalently attached lipidic moieties [for example, di-octadecylamidoglycyl-spermine (DOGS)] (Fig. 1) could induce CAT activity in primary pituitary melanotrope cells (41). Efficient transfection required a net positive charge on the lipoplexes, but CAT activity could still be observed at theoretically net negative charges [e.g., lipid/DNA (+/–) charge ratio of 0.5]. In this system maximal transfection could be observed even after a 30 min incubation of the cells with complexes containing 5 μg DNA and a charge ratio (+/–) of 3. This transfection method was not cytotoxic, while complexes prepared with the cationic detergent di-octadecyldimethylammonium chloride (DODAC) (Fig. 1) at the same charge ratio were highly toxic. The DOGS lipoplexes were also reported to transfect various cell lines, including LMTK, Ras4, CHO, F9, BU4m S49, HeLa, and AtT-20 cells, as well as other primary chromaffin and neuronal cell cultures. In a later study it was shown that lipoplex formation by sequential addition of DOGS (“Transfectam”) to DNA, compared to immediate mixing of the two reagents, resulted in significant enhancement of transfection in 3T3, Hep-G2, K562, and COS-7 cells and primary fibroblasts (42). This effect was particularly pronounced when transfection was carried out in the presence of 10% serum. Preparation of the complexes in a small volume (10 μL vs. 100 μL) also resulted in significant enhancement of transfection in the presence of serum.

The cationic lipids 1,2-dioleoyloxy-3-(trimethylammonio)propane (DOTAP) (Fig. 1) and 1,2-dioleoyl-3-(4'-trimethylammonio)butanoyl-*sn*-glycerol (DOTB) formulated in liposomes with DOPE in a 1:3 ratio and complexed with a CAT expression plasmid (pSV2cat) could transfect CV-1 and 3T3 cells much more effectively than DEAE–dextran (43). The ability of these liposomes to undergo lipid mixing with negatively charged liposomes or

Gene Porter 1 & 2	Gene Therapy Systems	Proprietary

cellular membranes was greatly inhibited by the presence of even small amounts of DNA (0.17–0.85 mol DNA phosphate per mol cationic lipid). This observation, coupled with the lack of correlation between the ability of different cationic lipid dispersions to intermix lipids with anionic liposomes and their ability to mediate transfection, suggested that DNA transfer to cells may not be mediated simply by the fusion of the cationic liposomes with cellular membranes.

Liposomes containing the cationic amphiphile, N-t-butyl-N'-tetradecyl-3-tetradecylaminopropionamide (diC14-amidine, Vectamidine) complexed with a CAT-expressing plasmid transfected both adherent CHO cells and K562 cells in suspension (44). Maximal transfection activity was achieved within the first hour of incubation with cells.

Using the 2,3-dialkoxypentyl quaternary ammonium backbone, Felgner et al. (45) developed a series of cationic lipid molecules to understand the relationship of structure to transfection activity. Liposomes composed of these compounds and DOPE (at a 1:1 mol ratio) were tested for their ability to transfect cultured COS-7 cells. The homologous series of dioleoylalkyl (di-C18:1) lipids with hydroxyalkyl moieties with increasing chain lengths attached to the quaternary amine group showed transfection activity in the order ethyl > propyl > butyl > pentyl > DOTMA (no hydroxyalkyl group). Varying the alkyl chains attached to dimethyl hydroxyethyl ammonium bromide head groups resulted in the order of transfection activity dimyristyl (di-C14:0) > dioleoyl (di-C18:1) > dipalmitoyl (di-C16:0) > disteryl (di-C18:0). The lipid 1,2-dimyristyloxypropyl-3-dimethyl-hydroxyethylammonium bromide (DMRIE) (Fig. 1) in combination with DOPE (1:1) was more active than DOTMA/DOPE under a range of transfection conditions, and this was especially pronounced at lower lipid and DNA

levels (under which conditions the potential for toxicity would also be reduced). The role of the colipid in transfection was also established in this study, the use of 50 mol% DOPE in conjunction with cationic lipids resulting in 2–5-fold higher transfection activity than formulations containing the same mol percentage of dioleoylphosphatidylcholine (DOPC) or those without any neutral lipid. The use of DOPE analogs with increasing acyl chain saturation resulted in progressively lower activity. These investigators found that lipoplexes prepared by the complexation of DNA with multilamellar liposomes of diameter 300–700 nm mediated about 2-fold higher levels of gene expression than those prepared with small unilamellar vesicles (50–100 nm).

The optimal charge ratio of cationic lipid to anionic DNA in lipoplexes prepared from DMRIE:DOPE was found to be 1.25 for the transfection of HeLa and primary airway epithelial cells (46), indicating that positively charged complexes interact with the negatively charged cell surface. The optimal charge ratio was found to be somewhat higher in studies with COS-7 cells (45).

Replacing the alcohol group on DMRIE with a primary amine produced a cationic lipid ( $\beta$ -aminoethyl-DMRIE) with transfection activity higher than that achieved with DMRIE over a broad range of cationic lipid and DNA concentrations (47). This lipid was maximally effective in the absence of the colipid DOPE.

The role of cationic lipid acyl chains in gene delivery was investigated using analogs of N-[1-(2,3-dioleoyloxy)propyl]-N-[1-(hydroxy)ethyl]-N,N-dimethyl ammonium iodide (DORI) in liposomes containing 50 mol% DOPE (48). In NIH3T3 fibroblasts, Chinese hamster ovary (CHO) cells and human respiratory epithelial cells (16HBE14o-), optimal acyl chain length and symmetry varied with

cell type. Cationic lipids with dissymmetric acyl chains (for example, 14:0, 12:0) mediated transfection activities equivalent or superior to the best symmetric acyl chain analogs. The phase transition temperature of the cationic lipid moiety did not appear to alter appreciably the transfection activity of the lipoplexes. For certain lipids and cells investigated in this study the use of multilamellar or small unilamellar liposomes provided an advantage over the other.

Utilizing the cationic lipid  $3\beta$ [N-(n', N'-dimethylaminoethane)-carbamoyl]cholesterol (DC-chol) (49) (Fig. 2) and DOPE, Caplen et al. (50) found that optimal weight ratios of DNA/cationic lipid (at fixed DNA concentrations, or at fixed liposome concentrations) were different among the various cell lines used in their study (monkey kidney SV40-transformed COS-7, cystic fibrosis nasal polyp CFNPE-90-, and bronchial mucosal epithelial 16HBE140-

cells), but still within a fairly narrow range. Gene expression was enhanced when lipoplexes were formed at pH 9 in physiological solution, compared to pH 7 or plain water. Increased incubation time of the lipoplexes resulted in increased reporter gene expression, except at very high DNA and liposome concentrations where maximal activity was observed after 1 h.

Two guanidium derivatives of cholesterol, bis-guanidium-spermidine-cholesterol (BGSC) and bis-guanidium-tren-cholesterol (BGTC) (Fig. 2) were found to mediate transfection of a number of cell lines (human lung carcinoma A549, COS-7, canine kidney MDCK-1, rat pancreatic islet cell tumor RIB-m5F, rat osteosarcoma ROS, rat pheochromocytoma PC12, and mouse pituitary tumor AtT-20 cells), both when prepared in micellar form or formulated with DOPE as liposomes (51). The optimal charge ratio (+/-) of lipid/DNA phosphate was found to be between 6 and 8 for micellar BGTC, and about 3 for liposomal BGSC/DOPE.

The cationic lipid GS2888 (Boc-arginine dimyristylamide) (Fig. 2) was found to transfect COS-7 cells more effectively than Lipofectin, LipofectAce, Transfectam, or Lipofectamine (Table 1) in the presence of 10% serum at various charge ratios (52).

Pyridinium compounds with double hydrocarbon chains, formulated with equimolar DOPE, showed improved transfection activity and reduced toxicity over that of DOTMA/DOPE (53). The most active compound, SAINT-4, has two C18:1 chains with trans double bonds (Fig. 2). The percentage of cells transfected with liposomes composed of SAINT-2 (containing 85% cis double bonds) and DOPE was also higher than that obtained with DOTMA/DOPE.

Liposomes composed of the cationic phospholipid derivative ethylphosphatidylcholine mediated gene transfer to a number of cell lines, including BHK, CHO, and 3T3 cells (54). The advantages of this cationic lipid are that transfection is not inhibited by the presence of 10% serum during incubation with cells, that preincubation with 95% serum does not have any deleterious effect on the transfection capacity of the lipoplexes, and that the lipid is biodegradable.

Formation of lipoplexes in the presence of phosphate or calcium was found to affect their transfection activity. For example, preincubation of Lipofectin with phosphate buffer followed by complex formation with a reporter plasmid resulted in a 26-fold enhancement of luciferase gene expression (55). Optimal transfection was observed when complexes were prepared in the presence of 30–80 mM phosphate, and around pH 6. The presence of calcium in the concentration range 5–25 mM during complex preparation, using DODAC/DOPE liposomes, mediated up to 20-fold higher transfection levels in BHK cells compared

**Figure 35.2** Structures of some cationic lipids used for transfection. DC-Chol,  $3\beta$ [N-(n',N'-dimethylaminoethane)-carbamoyl]cholesterol; lipid #67, 3- $\beta$ -(sperminecarbamoyl) cholesterol; BGTC, bis-guanidium-tren-cholesterol; BGSC, bis-guanidium-spermidine-cholesterol; GS2888, Boc-arginine dimyristylamide; SAINC-4, diolelmethylpyridinium chloride.

**Figure 35.3** Structures of some cationic lipids used for transfection. DDAB, dimethyldioctadecylammonium bromide; DOTIM, 1-[2-(9(Z)-octadecenoyloxy)-ethyl]-2-(8(Z)-heptadecenyl)-3-(2-hydroxyethyl)-imidazolinium chloride; TMAG, didodecyl-N-(a-(trimethylammonio)acetyl)-D-glutamate chloride; DOSPA, 2,3 dioleyloxy-N-[2(spermine carboxaminino)ethyl]-N,N-dimethyl-1-propanaminium trifluoroacetate.

to controls (56). This result was attributable in part to the enhancement of cellular uptake of lipoplexes and to a higher level of intact intracellular plasmid. Transfection of other cell lines such as CV-1 and SK-OV3 was also enhanced by this procedure. Calcium enhancement of transfection was not limited to DODAC/DOPE liposomes and was also observed with DOTMA/DOPE and dimethyldioctadecylammonium bromide (DDAB)/DOPE liposomes (Fig. 3).

### III. DELIVERY OF PROTEINS BY CATIONIC LIPOSOMES

Cationic liposomes have also been used to deliver proteins to cells. A glucocorticoid receptor derivative, T7X556, a mammalian transcriptional regulator, was delivered to cultured cells by association with DOTMA liposomes, was

localized rapidly in the nucleus, and mediated selective expression from glucocorticoid response element–linked promoters (57). Thus cationic liposome-mediated delivery may enable the functional analysis of proteins that have been generated by recombinant DNA techniques in bacteria or other mammalian cells.

A subsequent study showed the DOTMA/DOPE liposome-mediated delivery of prostatic acid phosphatase into human prostate carcinoma cells (58).

The human immunodeficiency virus type 1 (HIV-1) transactivator protein Tat was delivered into A431 cells expressing a reporter gene (CAT) under the control of the HIV-1 promoter, using DC-Chol or DOTMA-containing liposomes coincubated with the protein (59). The presence of DOPE in the liposome membrane was essential for protein delivery; liposomes containing phosphatidylcholine were ineffective. DOTMA/DOPE liposome-mediated delivery of Tat was confirmed in a system using a luciferase reporter gene in HeLa cells (60).

The delivery of the Rep68 protein of adenoassociated virus by complexation with the polycationic liposome Lipofectamine resulted in the rescue-replication of a codelivered inverted terminal repeat-flanked plasmid, as well its site-specific integration (61).

### IV. GENE DELIVERY BY LIPOPLEXES IN VIVO

In the first demonstration of the *in vivo* activity of lipoplexes, intravenous or intratracheal injection of DOTMA/DOPE complexes with the plasmid pSV2CAT resulted in CAT expression in the lungs of mice (62). The authors speculated that the technique could be used to genetically engineer lung cells to produce intracellular or secreted proteins, with eventual “therapeutic possibilities.”

Nabel et al. (22) injected lipoplexes containing a  $\beta$ -gal expression plasmid and DOTMA/DOPE liposomes into iliofemoral arteries of pigs via a catheter and found extensive gene expression after 4 days in the arterial tissue. Gene expression persisted for at least 6 weeks in this system. It was proposed that this method of gene delivery may be useful in the inhibition of smooth muscle proliferation or thrombus formation, which are complications of coronary angioplasty.

Transgene expression in the lungs was achieved by aerosolizing DOTMA/DOPE liposome complexes with the pCIS-CAT plasmid (23). The majority of airway epithelial and alveolar lining cells were transfected, and the gene product was detectable in the lung for at least 3 weeks. Intravenous injection of the same type of lipoplexes in mice resulted in transfection of lungs, spleen, liver, heart, kidney, lymph nodes, thymus, uterus, ovary, skele-

tal muscle, pancreas, bone marrow, stomach, small intestine, and colon (63). Metastatic lung tumors were also transfected by this procedure. The CAT gene was expressed in many cells in multiple tissues for at least 9 weeks after injection of the lipoplexes. No treatment-related toxicity was noted in injected animals. These authors suggested that specific tissues and cell types could be targeted by means of tissue-specific promoter-enhancer elements, by regional administration of lipoplexes, or by the use of targeting ligands.

Intravenous injection of DNA complexes with DC-Chol/DOPE liposomes into mice resulted in the localization of the DNA primarily in the lung and heart, as detected 2 to 3 weeks following injection (64). Complexes injected directly into experimental CT26 tumors caused DNA localization in the tumors. Lipoplex injection was found not to affect tissue-specific serum enzymes, tissue histology, or electrocardiography. When mice were injected with genes encoding murine MHC class I proteins, no significant immunopathology could be detected in various tissues, although an immune response was elicited (65). The introduction of various genes did not cause any gene localization in the testes or ovary, as detected by the polymerase chain reaction. Similar experiments were performed with DMRIE/DOPE–DNA complexes, which facilitated the injection of much higher doses of DNA without causing toxicity (66). The introduction of a foreign MHC gene (H-2Kd) into an MCA 205 tumor via DMRIE/DOPE liposomes resulted in a substantial antitumor response, while DC-chol/DOPE liposomes were ineffective.

Intraperitoneal injection of a CAT-expressing plasmid complexed to DOTMA/DOPE, DDAB/DOPE, or DOTAP/DOPE liposomes mediated gene expression in the spleen, lymph nodes, and liver (67). A large percentage of T lymphocytes from the paracortical region of lymph nodes was transfected. In addition, about 20% of bone marrow cells revealed intracellular CAT antigen.

Repeated intravenous injection of DDAB/DOPE–DNA complexes was shown to produce levels of transfection at least as high as that following a single injection, demonstrating that lipoplexes are not neutralized by a host immune reaction (24). Among the different promoters tested (CMV immediate early promoter, SV40 early promoter, herpes simplex virus thymidine kinase promoter, and the adenovirus 2 major late promoter), the CMV promoter resulted in the expression of much higher levels of CAT in various tissues. The delivery of genes encoding murine granulocyte-macrophage colony stimulating factor and human granulocyte-colony stimulating factor resulted in significant levels of expression of these proteins in the circulation. The expression of  $\beta$ -gal under the CMV promoter, following aerosol delivery in DOTAP lipoplexes, was

found to be more prolonged compared to that under the SV promoter (68). The CMV promoter was also found to be more effective in luciferase gene expression *in vivo* than the RSV promoter when complexed to DOGS/DOPE liposomes (28). The use of a human papovavirus (BKV)-derived episomal vector, however, resulted in prolonged expression in various tissues, up to 3 months (28). The episomal vector was shown to replicate extrachromosomally in the lungs 2 weeks following initial administration.

A comparison of the *in vitro* and *in vivo* transfection efficiencies of different cationic liposome reagents showed that the optimal lipid-to-DNA ratio for cell culture experiments did not translate to the highest transfection efficiencies (% of transfected cells) following intratumoral injection of lipoplexes containing the plasmid pCMV $\beta$ IL-2 (69). DC-Chol was found to be the most efficacious cationic liposome in this study, which also reported that transfection efficiency was reduced as the size of 2E9 tumors increased. Interestingly, gene expression was inhibited by cationic liposomes upon injection into BL6 mouse melanoma tumors, while the size of the tumor did not affect gene expression by free DNA (70). Nevertheless, growth suppression of tumor xenografts was observed only upon injection of a therapeutic plasmid (expressing interleukin-2) complexed to DC-Chol liposomes, but not with naked DNA (71).

The role of linking polyamines to a cholesterol or other hydrophobic anchor in the transfection activity of lipoplexes in cystic fibrosis airway epithelial CFT1 cells and lungs was examined by Lee et al. (27). The orientation of the polyamine head group in relation to cholesterol was found to be highly significant, with lipids conjugated to spermine or spermidine in a T-shape configuration producing higher *in vivo* gene delivery than lipids coupled to the polyamines via a primary amine to generate a linear shape. Intranasal instillation of lipoplexes composed of 3- $\beta$ -(sperminecarbamoyl) cholesterol (Lipid #67)/DOPE (Fig. 2) and a CAT plasmid produced lung levels of the enzyme 100-fold higher than that mediated by DMRIE/DOPE or DC-Chol/DOPE lipoplexes.

The inclusion of the nonionic surfactant Tween 80 in DC-chol-containing liposomes appeared to inhibit the formation of large DNA–lipid complexes and to resist the inhibitory effects of serum on transfection activity (72). Increasing the ratio of DOTMA to DNA, or DOTMA to Tween 80, enhanced gene expression in various organs, especially the lungs (73).

The use of DOTAP/cholesterol liposomes resulted in much higher levels of gene expression in the lungs after intravenous injection compared to DOTAP/DOPE, DDAB/cholesterol and DDAB/DOPE liposomes (29). Cryoelectron microscopy indicated that condensed DNA

is sequestered inside invaginated DOTAP/cholesterol liposomes. Similarly, preparation of lipoplexes from multilamellar liposomes containing cholesterol and the cationic lipid 1-[2-(9(Z)-octadecenoyloxy)-ethyl]-2-(8(Z)-heptadecenyl)-3-(2-hydroxyethyl)-imidazolium chloride (DOTIM) (Fig. 3) (74) resulted in much higher levels of gene expression in various tissues than that obtained with small unilamellar vesicles of the same composition, or with multilamellar liposomes containing DOPE (25). The uptake and retention of the delivered plasmid, as well as the circulation time, were much higher with the use of DOTIM/cholesterol multilamellar liposomes than that obtained with DOTIM/DOPE small unilamellar liposomes. The most commonly transfected cells were found to be vascular endothelial cells, monocytes, and macrophages, and the level of gene expression normalized to the amount of DNA taken up per tissue was three orders of magnitude higher in the lung than in the liver, suggesting that host tissue factors influence the efficiency of transgene expression.

## V. GENE DELIVERY IN HUMANS

A gene encoding a foreign major histocompatibility complex protein (HLA-B7) was introduced into melanoma nodules in patients with advanced disease, using DC-Chol/DOPE liposomes (18). Immunohistochemistry showed that HLA-B7 was expressed in tumors. One patient even demonstrated regression of injected nodules. This study indicated the feasibility, safety, and therapeutic potential of direct gene transfer in humans. A subsequent study employing DMRIE/DOPE lipoplexes demonstrated the presence of RNA encoding HLA-B7 or HLA-B7 protein in tumor nodules in nine of ten patients with stage IV melanoma (75). T cells migrated into treated tumors in six of seven patients, and tumor-infiltrating lymphocyte reactivity was enhanced in two of two patients analyzed. Local inhibition of tumor growth was noted in two patients.

DNA encoding the cystic fibrosis transmembrane conductance regulator (CFTR), complexed with DC-Chol/DOPE liposomes, was delivered to the nasal epithelium (76). Plasmid DNA and transgene-derived RNA were detected in the majority of treated patients. A modest restoration of function was achieved, with optimal activity being detected 3 days following transfection. Nevertheless, the function reverted to pretreatment levels by day 7. The authors suggested that transfection efficiency and the duration of expression need to be increased to achieve a therapeutic effect. Lipoplexes containing DOTAP were administered in a later clinical trial, and transgene DNA was detected by the polymerase chain reaction in 7 of 8

treated patients, while vector-derived CFTR mRNA was observed in 2 of the 7 patients (77). In 2 treated patients partial and sustained CFTR-related functional changes toward normal values were noted.

Delivery of the gene for  $\alpha_1$ -antitrypsin to the respiratory epithelium of patients with  $\alpha_1$ -antitrypsin deficiency resulted in the expression of the mRNA and the protein (78). The expression of the  $\alpha_1$ -antitrypsin via this gene therapy approach, but not the delivery of the protein, had an anti-inflammatory effect. It is believed that this therapeutic effect is due to the localization of the transgene-generated  $\alpha_1$ -antitrypsin within cells and intercellular spaces.

## VI. MECHANISMS OF AND BARRIERS TO LIPOPLEX-MEDIATED GENE DELIVERY

A series of criteria have to be met and barriers to be overcome for lipoplexes to be able to deliver functional DNA to the nucleus (10,11). The cationic lipid component of lipoplexes must be able to condense DNA to enable its protection from nuclease degradation. Lipoplexes with any associated serum components must be able to bind to cell surfaces. Cell surface heparin/heparan sulfate-containing proteoglycans are thought to mediate the uptake of lipoplexes (79,80). In contrast, proteoglycan-deficient cells were found to internalize lipoplexes containing Lipofectamine as efficiently as wild-type cells (81). At low  $+/-$  charge ratios, proteoglycan-deficient cells took up DNA and exhibited reporter gene expression to even higher levels than the wild-type cells. At higher charge ratios, however, gene expression in the mutant cells was inhibited, most likely because of the cytotoxic effect of the highly positively charged lipoplexes. Accordingly, addition of exogenous polyanionic glycosaminoglycans neutralized the cytotoxic effects of cationic liposomes in proteoglycan-deficient cells. Pretreatment of cells with enzymes that remove glycosaminoglycans or neuraminic acid did not affect the binding of liposomes containing the cationic lipid didodecyl-N-(a-(trimethylammonio)acetyl)-D-glutamate chloride (TMAG) (Fig. 3) to a macrophagelike cell line, while pretreatment of cells with trypsin reduced binding, indicating that trypsin-sensitive proteins are involved in the attachment of these liposomes to the cell surface (82).

Lipoplexes are thought to be internalized via endocytosis involving coated or uncoated endocytotic vesicles (32,83–87). Alternatively, the lipoplexes may undergo fusion with the plasma membrane with the appropriate topology to facilitate the intracytoplasmic delivery of DNA (10,16,87). Several studies have concluded that fusion (assessed by lipid mixing between lipoplexes and cellular

membranes) is not correlated sufficiently with transfection (87,88). An alternative mechanism of DNA entry has been suggested to involve pore formation in the plasma membrane (89).

The endosome membrane has to be destabilized so that the lipoplex or DNA can gain access into the cytoplasm and avoid degradation in lysosomes. The destabilization of the endosomal membrane by the internalized lipoplexes has been proposed to induce the transbilayer movement of anionic lipids from the cytoplasmic monolayer to the luminal monolayer (83). The interaction of these lipids with the cationic lipids in the lipoplex was proposed to result in the displacement of the DNA from its complex with the cationic lipid and its release into the cytoplasm. Fusion of DOPE-containing cationic lipid/oligonucleotide complexes with endosomal membranes under acidic conditions following endocytosis was observed by fluorescence microscopy (90), and this supports the hypothesis that DNA is released into the cytoplasm following endocytosis. Electron microscopic evidence for the destabilization of endosomes by various lipoplexes has also been presented (91). Pore formation at the endosomal membrane may be an alternative mechanism of escape of the complexes or of free DNA into the cytoplasm (10).

For successful transfection, the delivered DNA has to be transported to the nucleus and pass through the nuclear membrane. Since free DNA in the cytoplasm is degraded within a short period (92), it is essential for DNA to rapidly access the nucleus or continue to be protected from nucleases via complexation with the cationic lipid. The relative ease with which proliferating cell lines are transfected compared to nondividing primary cells can be attributed to enhanced nuclear permeability during mitosis (93). Whether DNA penetrates the nuclear membrane through pores via passive diffusion or active transport following nonspecific association with receptors for nuclear localization signal (NLS) peptides is not known. It is also not known if DNA in the cytoplasm is indeed plain or still associated with cationic lipid. Experiments utilizing lipoplexes or free plasmid microinjected into oocyte nuclei indicated that gene expression was inhibited completely when DNA was complexed with cationic lipids at a 5:1 lipid:DNA (w/w) ratio (approx. 1:1 +/- charge ratio), while at a lower ratio (1:1) (w/w) it was not (32). Clearly, most of the DNA has to be freed of its associated cationic lipids to be transcribed.

The presence of serum usually inhibits lipoplex-mediated gene delivery (16,34–38,94,95), although lipids can vary in their sensitivity to serum (96–99). The inhibition is most likely mediated by negatively charged components in serum (100). This inhibition is of major concern regard-

ing the *in vivo* use of lipoplexes for gene delivery by intravenous injection. Lipoplexes interacting with mouse serum aggregated and disintegrated, accompanied by the release of DNA (101). Complexes containing DOPE disintegrated rapidly and were also ineffective in gene delivery *in vivo*.

Another physiologically relevant inhibitor of lipoplex-mediated transfection in the airways is pulmonary surfactant. Transfection of murine respiratory epithelial MLE-15 and human bronchial adenocarcinoma H441 cells by lipoplexes containing DMRIE/cholesterol or DOTAP/DOPE decreased as the concentration of natural pulmonary surfactant was increased (102). Incorporation of surfactant proteins SP-B or SP-C or the phospholipids dioleoylphosphatidylcholine and dioleoylphosphatidylglycerol in the cationic lipid formulation also inhibited transfection. These observations suggest that lung surfactant may be one of the barriers to gene transfer in the lung (102). Tsan et al. (103) found that transfection of rat fetal lung fibroblast RFL-6 and calf pulmonary artery endothelial CPAE cell lines, and rat primary type II alveolar epithelial cells by lipoplexes of DDAB, DOTAP, or DOTMA/DOPE, was inhibited by a naturally derived surfactant preparation (Survanta) and a synthetic surfactant (Exosurf). This finding was proposed as a partial explanation for the observation that the efficiency of gene delivery to the lungs by plain plasmid DNA was equivalent to that by lipoplexes (103).

Sulfated glycosaminoglycans, including heparan sulfate and chondroitin sulfate, completely inhibited transfection mediated by cationic liposomes such as DOTAP and DOTAP/cholesterol, while hyaluronic acid was not inhibitory (104). Nevertheless, it is interesting to note that DOPE-containing lipoplexes were not inhibited as much as those containing only cationic lipids by the sulfated glycosaminoglycans (104).

## VII. STRATEGIES FOR THE ENHANCEMENT OF LIPOPLEX-MEDIATED GENE DELIVERY

Several strategies have been employed and are being developed to enhance the ability of lipoplexes to mediate transgene expression in mammalian cells. These include the attachment of a targeting ligand with the lipoplexes to promote cell binding and receptor-mediated endocytosis, the association of synthetic fusogenic peptides with the complexes to facilitate the destabilization of endosomes and release of the genetic material into the cytoplasm, the employment of cationic polypeptides to condense DNA, the association of albumin with cationic liposomes to con-

fer serum resistance and enhanced gene transfer, and the use of nuclear localization signal (NLS) peptides to mediate the nuclear localization of the plasmid.

### A. Lipoplex Targeting

Neutral plasmid–lipospermine complexes containing a trigalactolipid could transfect HepG2 hepatoma cells bearing the asialoglycoprotein receptor more efficiently than lipoplexes lacking the ligand (33). Galactosylated cholesterol derivatives also mediated higher levels of transfection of HepG2 cells when included in DC-Chol/DOPE liposomes (105). The association of monoclonal antibodies or ligands (asialofetuin) with lipoplexes increased both the selectivity and the efficiency of DNA delivery into cancer cells (106,107). Addition of succinylated asialofetuin to the surface of preformed DOTAP:Chol–DNA complexes resulted in high levels of transfection in the liver upon *in vivo* administration (29). Association of Lipofectin (DOTMA/DOPE) with complexes of integrin-targeting peptide and DNA resulted in a 100-fold enhancement of transfection activity and a substantial increase in transfection efficiency in a variety of cell lines (108). A further advantage of this type of complex was its tendency to form particles, unlike the fibrous network usually reported for Lipofectin/DNA complexes. The association of various lectins with Lipofectin followed by complexation with DNA resulted in the enhancement of transfection in a number of cell lines and could be inhibited by a competing sugar (109).

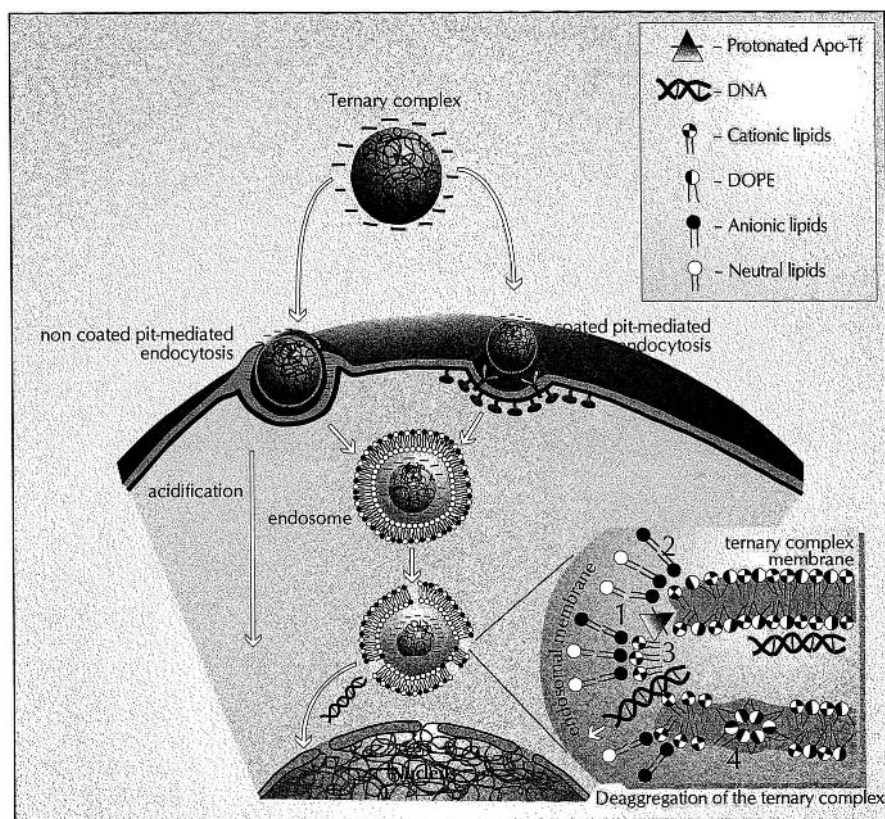

Association of transferrin with cationic liposomes followed by complexation with DNA resulted in ternary complexes with enhanced transfection in a variety of cells, including dividing and nondividing cells (110–113) (Fig. 4). Transfection was most effective with the use of optimized lipid/DNA (+/–) charge ratios at which the complexes presented a net negative charge. Studies on the mechanisms of gene delivery by such transferrin lipoplexes have suggested, however, that internalization of these ternary complexes is mediated by a nonspecific process (86) (Fig. 4). Transferrin was proposed also to facilitate endosome destabilization following acidification of the endosome lumen. Furthermore, triggering internalization of the lipoplexes through a nonspecific endocytotic process could be achieved by associating human serum albumin with cationic liposomes (38). It should be noted, however, that enhancement of the extent of binding and internalization of the lipoplexes did not necessarily result in the enhancement of transgene expression (11), indicating the importance of additional factors that facilitate the entry and expression of the transgene.

Initial complexation of DNA with poly(L-lysine) re-

duced the particle size of ternary complexes with DC-Chol/DOPE liposomes, conferred nuclease resistance to the DNA, and enhanced the transfection of different cell lines (114). The association of the polycationic peptide, protamine sulfate, with DNA followed by the addition of DC-Chol/DOPE, DOTAP/DOPE, or DOTMA/DOPE liposomes greatly increased gene expression in CHO cells compared to the plain lipoplexes (115). This effect was attributed to the ability of protamine to condense DNA efficiently, as well as to the presence of NLS peptides in its sequence. The cationic lipid–protamine–DNA formulation also mediated higher gene expression in mice than did DOTAP/DNA complexes (116). In an alternative protocol, the ternary complexes formed by the addition of protamine sulfate to DOTAP liposomes followed by the addition of DNA were shown to be small, condensed particles (diameter  $\sim 135$  nm), which exhibited even higher levels of *in vivo* gene expression (117). It was also shown that the use of cholesterol instead of DOPE as a helper lipid in cationic liposomes enhanced the *in vivo* transfection efficacy of cationic lipid–protamine–DNA complexes.

### B. Use of Nuclear Localization Signal (NLS) Peptides

The studies of Zabner et al. (32) and Labat-Moleur et al. (118) have indicated that the nuclear membrane is a major barrier to lipoplex-mediated gene delivery to the nucleus. NLS peptides generally consist of a short stretch of basic amino acids in certain proteins and direct them to the nucleus through nuclear pore complexes. Several laboratories have investigated the potential of these peptides to facilitate DNA entry into the nucleus. DNA–NLS peptide complexes associated with DC-Chol/DOPE liposomes exhibited an eightfold enhancement at the optimal peptide concentration compared to plain lipoplexes (119). Aronsohn and Hughes (120) showed that the association of a NLS peptide with DOTAP/DOPE–DNA complexes enhanced transfection in SKNSH cells by about threefold. Zanta et al. (121) covalently coupled a single NLS sequence to capped DNA containing a hairpin oligonucleotide enriched with amino groups and showed a dramatic enhancement in the transfection of a variety of cell types, including nondividing cells, even with small amounts of DNA. This represents an important progress in the use of lipid-based vectors, taking into account the putative cytotoxic effects of cationic lipids at higher concentrations. An alternative technique to attach NLS peptides was described by Brandén et al. (122) and involved the use of a bifunctional peptide nucleic acid (PNA)–NLS peptide conjugate that could both hybridize with certain sites in the plasmid

**Figure 35.4** Proposed mechanism of cellular uptake and cytoplasmic delivery of DNA via transferrin lipoplexes. Lipoplexes are internalized either by receptor-mediated endocytosis via clathrin-coated pits or by phagocytosis via uncoated pits. Efficient delivery of DNA into the cytoplasm appears to be dependent on the acidification of the endosome. Acidification may trigger a series of reactions leading to the dissociation of DNA from the transferrin lipoplexes and to the destabilization of the endosome membrane. The protonation of apotransferrin causes a structural change that facilitates deaggregation of the complex. Protonated apotransferrin becomes membrane-active and destabilizes the endosomal membrane, thereby facilitating the transbilayer movement of anionic lipids from the cytoplasmic monolayer of the endosome membrane. Electrostatic interactions between these anionic lipids and cationic lipids induce the dissociation of the DNA from the lipoplexes and transformation of the DOPE into a nonbilayer phase, which further facilitates the intermixing of lipids between the lipoplex and endosome membranes. These events lead to the cytoplasmic delivery of dissociated or partially dissociated DNA, which then has to be transported into the nucleus for gene expression. (Adapted from Simões et al. (86).)

and transport DNA into the nucleus. Cell-specific nuclear translocation mechanisms were exploited by using plasmids that interact in the cytoplasm with particular transcription factors that facilitate nuclear import of the complex (123). Lipoplexes composed of one such plasmid (incorporating the SV40 enhancer/promoter region) and Lipofectin enhanced gene expression in nondividing CV1 cells 500-fold compared to lipoplexes containing only the CMV promoter. In another approach to nuclear targeting, the M9 sequence of heterogeneous nuclear ribonucleoprotein (hnRNP) A1 was conjugated to a cationic peptide scaffold derived from a scrambled sequence of the SV40 T-antigen consensus NLS to facilitate its binding to DNA. Lipoplexes prepared by complexing this construct with

Lipofectamine enhanced transfection activity in bovine aortic endothelial cells 63-fold (124).

### C. Facilitation of Gene Transfer by Membrane-Destabilizing or Fusogenic Peptides

Since lipoplexes are thought to enter cells primarily via endocytosis, it has been hypothesized that the use of peptides that can destabilize endosomes or facilitate the fusion of the lipoplexes with the endosomal membrane would enhance gene delivery. Incubation of COS-7 cells with a  $\beta$ -gal-expressing plasmid, and anionic or cationic derivatives of the N-terminal peptide of the HA2 subunit of the influ-

enza virus fusion protein, hemagglutinin, in the presence of Lipofectin, resulted in the enhancement of transfection activity over that of Lipofectin alone by a factor of 2–7 (125). The levels of Transfectam (lipopolyamine)-mediated transfection of H225 human melanoma cells could be increased by up to 1000-fold [over that obtained with a suboptimal charge-equivalent (1.5) of Transfectam/DNA] by adding the hemagglutinin-derived peptide INF6 to the preformed lipoplexes (126). The association of the pH-sensitive peptide GALA (127,128) with DOTAP/DOPE (1:1) liposomes before complexation with plasmid DNA resulted in about a 10-fold enhancement in luciferase expression in COS-7 cells at the optimal charge ratio of 1/1 (+/–) (111). For net negatively charged complexes (1/2), however, the enhancement in transfection activity was several orders of magnitude, since gene transfer by plain lipoplexes at this charge ratio was very limited. GALA lipoplexes were considerably more effective in gene transfer to COS-7 cells than to HeLa cells, presumably because internalization of the complexes was not rate limiting in the former (111). The combined use of GALA and transferrin or albumin in conjunction with cationic liposomes resulted in considerably higher levels of gene expression in primary, nondividing human macrophages compared to plain lipoplexes or ternary lipoplexes containing transferrin or albumin (38,112).

#### D. Serum-Resistant Lipoplexes

Crook et al. (95) reported that the inclusion of cholesterol in DOTAP liposomes (at 2:1 to 1:2 weight ratios, DOTAP:cholesterol) mediated substantial transfection in COS-7 cells, while gene transfer by DOTAP lipoplexes was almost completely abolished in the presence of 40% serum. They also showed that more DOTAP/cholesterol than DOTAP lipoplexes were attached to and taken up by cells, although the differences did not appear to be sufficient to explain the drastic difference in gene expression mediated by the two complexes in 40 or 80% serum. Cholesterol-containing lipoplexes were shown to disintegrate much slower in serum than those containing DOPE (101).

Increasing the charge ratio of the cationic lipid to DNA was found to overcome the inactivation by 20% serum of gene delivery by DC-Chol and DOTAP/DOPE lipoplexes (100). Prolonging the incubation time of the cationic liposome–DNA complexes before addition to cultured cells, a process termed “maturation,” also rendered the lipoplexes resistant to the inhibitory effects of 20% serum (35). This maturation was observed for complexes containing monovalent cationic lipids such as DC-Chol, DOTAP, and DOTMA, but not for those containing the

multivalent Lipofectamine. This process was accelerated by high charge ratios, high concentration of the lipoplexes, and elevated temperature. Lipoplexes containing DOGS/DOPE were found to be resistant to the effect of 10% serum, although complexes prepared with Lipofectamine were greatly inhibited in their transfection activity in HeLa cells (99).

Resistance to the inhibitory effects of serum was also conferred by the association of human transferrin or human serum albumin with DOTAP/DOPE or DOTAP/cholesterol liposomes before complexation with DNA (37,38,111). Increasing concentrations of serum actually enhanced the transfection of cultured cells by these ternary lipoplexes (37,38).

#### E. Steric Stabilization

Liposomes sterically stabilized by the incorporation of poly(ethylene glycol)-phosphatidylethanolamine (PEG-PE) are known to have prolonged circulation in vivo, most likely because they are not readily opsonized and are thus not taken up rapidly by the mononuclear phagocyte system (129–131). Lipoplexes prepared from cationic liposomes containing PEG-PE were stable upon prolonged storage and mediated gene delivery in vivo (132). However, in vitro studies performed in our laboratory have shown that lipoplexes prepared from cationic liposomes composed of DOTAP:DOPE:DSPE-PEG 2000 (1:1:0.02) were essentially inactive, while complexation with transferrin partially overcame this inhibitory effect (133). Inclusion of 5% PEG-PE in DODAC/DOPE liposomes completely inhibited transfection; this effect could be ascribed only partially to the inhibition of cellular uptake, suggesting that internalization of the complexes or subsequent steps are also affected by PEG-PE (11). A relatively short-chain PEG–ceramide conferred prolonged circulation to liposomes with a low cationic lipid content and entrapping DNA (employing a detergent dialysis procedure) (134–136). The PEG–ceramide could dissociate from the complexes inside endosomes, thus removing the inhibitory effect of the PEG from the liposomes.

#### CONCLUDING REMARKS

The studies outlined above indicate the progress made in gene delivery using cationic liposomes since the first report in this area in 1987 (16). One aspect of this nonviral method of gene delivery that has been rather puzzling is the difference in activity observed in vitro and in vivo. Nevertheless, it should be noted that experiments in vitro

without even the use of physiologically relevant levels of serum should not be expected to reflect accurately the in vivo conditions, let alone the high complexity of biodistribution following intravenous delivery of the vectors. Although cell culture results obtained in serum-free conditions cannot be translated directly to in vivo gene delivery, they can at least indicate which lipoplexes have the potential to be useful for applications in animal models or humans. It is advisable to examine the transfection activity of such lipoplexes in culture in the presence of high concentrations of serum before embarking on expensive animal experiments (37,38,111).

Although an enormous amount of work has been done on developing new cationic lipids and their derivatives, as well as on the characteristics of their complexes with DNA, the mechanisms by which they facilitate the delivery of DNA and gene expression are not well understood. Clearly much basic research in this area is needed to understand how lipoplexes interact with biological milieu, how they destabilize endosomes to enter the cytoplasm, where and how the DNA dissociates from the cationic lipids, and how the lipoplexes or free DNA reach and enter the nucleus.

## Biological Stimulus-Responsive Hydrogels

Takashi Miyata and Tadashi Uragami  
*Kansai University, Osaka, Japan*

### I. INTRODUCTION

Hydrogels are attractive objects consisting of cross-linked networks of polymer swollen with aqueous solutions, and have both liquidlike and solidlike properties. As hydrogels have a variety of properties including their sorption capacities, swelling behavior, mechanical properties, permeabilities, surface properties, and optical properties, they are highly promising materials for wide applications in various fields such as medicine, agriculture, and biotechnology (1–5). Such fascinating properties of hydrogels are governed by the characteristics of polymer chains in aqueous solutions and the cross-linking structures. In general hydrogels, the cross-linked polymer networks are formed by covalent bonds, electrostatic interactions, hydrogen bonding, hydrophobic interactions, van der Waals forces, physical entanglements, crystallite, and so on. The polymer chains in hydrogels are generally hydrophilic and compatible with aqueous solutions to be swollen. Therefore such cross-linked structures and polymer chains must be designed for developing useful hydrogels for a given purpose.

Hydrogels have the unique property that they undergo abrupt changes in their volume from the collapsed and swollen states. Since the unique property, the volume phase transition, of hydrogels was discovered experimentally and theoretically (6–10), the stimulus-responsiveness of hydrogels has attracted considerable attention in the biological and biomedical fields. The hydrogels that undergo swelling changes in response to environmental stimuli are

called stimulus-responsive, smart, or intelligent hydrogels. Stimulus-responsive hydrogels are considered for use in various devices such as switches, sensors, mechanochemical actuators, drug delivery devices, specialized separation systems, bioreactors, and, artificial muscles. In particular, the stimulus-responsive hydrogels that exhibit swelling changes in response to environmental changes such as pH (7), temperature (6,8,9,11), electric field (12,13), and other stimuli (14–17) can provide the tools for creating functional materials with a wide variety of uses because they can sense environmental changes and induce structural changes. The fascinating properties of such hydrogels suggest that they have many future opportunities as suitable materials for mimicking biomolecules and designing smart systems in the biochemical and biomedical fields.

An organ must respond to the presence of specific molecules as well as environmental changes like pH and temperature to maintain life. Stimulus-responsive hydrogels that can respond to specific molecules seem to be biomimetic materials because they have the functions of both sensing specific molecules and responding to them. Therefore, recently, the stimulus-responsive hydrogels that recognize a specific molecule and respond to it have become increasingly important, because of their potential application in the biomedical field and in the design of novel biomaterials. For example, stimulus-responsive hydrogels that respond to blood glucose are very useful in the treatment of diabetes in which a necessary amount of insulin should be administered in response to the blood glucose concen-

tration. This chapter provides a short overview of current research in such biological stimulus-responsive gels and their applications.

## II. PHYSICOCHEMICAL STIMULUS-RESPONSIVE HYDROGELS

The most important biosystems for maintaining life are closely associated with natural feedback system functions, so-called homeostasis. For example, the release of hormones from secretory cells is regulated by physiological cycles or by specific input signals. Mimicking such natural feedback systems enables us to develop novel intelligent systems having sensor, processor, and effector functions simultaneously. As temperature and pH are the most widely utilized triggering signals for modulated intelligent systems, studies on a variety of pH- and temperature-responsive hydrogels have been reported. The following subsections focus on pH- and temperature-responsive hydrogels as physicochemical stimulus-responsive hydrogels.

### A. pH-Responsive Hydrogels

A change in pH is the most useful signal in the human body, because variation in pH occurs naturally in some areas of the body. For example, as the pH of the gastric condition is much lower than that of the enteric condition, a pH-responsive hydrogel is a candidate as an intelligent device to deliver drugs to the small intestines while avoiding release in the stomach. In general, such pH-responsive hydrogels can be prepared by using polymers with ionizable groups. Some fine reviews dealing with various aspects of pH-responsive hydrogels have appeared in the past decade (1,18).

The pH change as an external signal influences the degree of ionization of the polymer with ionizable groups to govern its solubility in water. Therefore when a hydrogel is prepared from a polymer with ionizable groups, the swelling behavior of the hydrogel is strongly dependent upon pH. Carboxyl, sulfonic, and amino groups are very popular as ionizable groups to prepare pH-responsive hydrogels. There have been many reports on pH-responsive hydrogels prepared from monomers with such ionizable groups. For example, Siegel et al. (18–20) prepared lightly cross-linked hydrophobic polyelectrolyte hydrogels by copolymerization of methyl methacrylate (MMA) and *N,N*-dimethylaminoethyl methacrylate (DMA) with a small amount of the cross-linking reagent divinyl benzene. The copolymer hydrogels with amino groups were collapsed above neutral pH but became swollen at acidic pH. Fur-

thermore, caffeine release from the copolymer hydrogels with amino groups was investigated as a function of pH. Caffeine was not released at neutral pH, while it was released with near-zero-order kinetics at pH 3 and 5, the release rate being greater at pH 3. On the other hand, hydrogels with carboxyl groups were prepared by copolymerization of 2-hydroxyethyl methacrylate (HEMA) or poly(*N*-isopropylacrylamide) (PNIPAAm) with methacrylic acid or maleic anhydride and by the formation of interpenetrating polymer networks (IPNs) of poly(vinyl alcohol) (PVA) and poly(acrylic acid) (PAAc), and pH-responsive drug release systems were developed (21–23). The resultant hydrogels with carboxyl groups showed sharp swelling transition with small changes in pH, depending upon composition. Drug release systems controlled by pH-responsive swelling can be developed, which exhibit zero-order or near-zero-order release of the incorporated drug. Hoffman et al. (24) proposed a novel approach for preparation of pH-responsive hydrogels for enteric drug delivery. The pH-responsive hydrogels were composed of pH-responsive PAAc and temperature-responsive PNIPAAm. The special hydrogels were sensitive to both temperature and pH, and respond to the pH change to a much greater extent than normal hydrogels with carboxyl groups. Only a negligible amount of indomethacin as a model drug was released at pH 1.4, while more than 90% of the total drug in the gels was released at pH 7.4.

Very few studies on hydrogels with phosphate groups have been reported, although the phosphate group is a very important acidic group. Hydrogels with phosphate groups have been prepared by copolymerization of a monomer with a phosphate group and various comonomers (25,26). The swelling behavior of the hydrogels with the phosphate groups is strongly dependent upon the kind of comonomer. The swelling ratio of the hydrogels with the phosphate groups increased steeply at pH 5 and 10 because the phosphate group acts as an acidic charged divalent group. Furthermore, the hydrogels with the phosphate groups also showed swelling changes in response to temperature and solvent composition.

Immobilization of physiologically active compounds is very important in a variety of applications of the compounds in drug delivery systems, bioreactors, bioseparations, tissue engineering, and so on. Hydrogels with ionizable groups are promising supports to immobilize such physiologically active compounds based on their electrostatic interaction. For example, in order to immobilize a cationic protein, the hydrogels with phosphate groups were synthesized by copolymerizing the monomer with the phosphate group with *N*-isopropylacrylamide (NIPAAm) and *N,N'*-methylene-bis-acrylamide (MBAA) (27,28). Lysozyme, which is a cationic protein, could be immobilized

**Figure 36.1** Schematic of pH-responsive release of lysozyme from the hydrogel with phosphate groups. (From Ref. 28.)

efficiently within the hydrogels with phosphate groups through polyion complexation. The hydrogels with phosphate groups had a higher binding capacity for cationic proteins than hydrogels with carboxyl groups. Lysozyme release from the hydrogels with phosphate groups was influenced by conditions such as ionic strength and pH, because electrostatic binding between the phosphate group and lysozyme was sensitive to environmental conditions. In particular, the pulsatile release pattern indicated that lysozyme is released at pH 7.4 (enteric conditions) and resists release at pH 1.4 (gastric conditions) (Fig. 1). These studies demonstrated that pH-responsive dissociation of ionic binding enables us to deliver drugs to the small intestines while avoiding release in the stomach.

**B. Temperature-Responsive Hydrogels**

Most temperature-responsive hydrogels have been prepared on the basis of poly(*N*-isopropylacrylamide) (PNIPAAm), which has a lower critical solution temperature (LCST) in its aqueous solution. PNIPAAm homopolymer is soluble in water at a temperature of less than LCST (about 32°C) but becomes insoluble at more than LCST due to strong polymer–polymer interaction (29). Therefore a cross-linked PNIPAAm hydrogel was swollen at a temperature of less than LCST and collapsed at more than LCST. Such a temperature-responsive swelling change of the cross-linked PNIPAAm hydrogel is attributable to a dramatic change in hydrophilicity of polymer chain in water. The temperature-responsive PNIPAAm hydrogel and its derivative hydrogels are currently of great interest in biochemical and biomedical fields. Some articles provide overviews of current research in temperature-responsive

hydrogels prepared from PNIPAAm and their applications (30,31).

Hoffman et al. (32,33) used a cross-linked PNIPAAm hydrogel that exhibits LCST as a temperature-responsive drug carrier. They demonstrated that the temperature-responsive hydrogel is a candidate to absorb or release a variety of biologically and industrially important substances. After vitamin B<sub>12</sub> and myoglobin as model drugs were loaded into the temperature-responsive hydrogels swollen below LCST, their release behavior from the hydrogels was investigated above LCST. Their model drugs were released rapidly from the hydrogels due to the squeeze effect by their collapse as soon as the hydrogels were transferred from an aqueous solution below LCST to the release media above LCST (Fig. 2).

On the other hand, Okano and Kim et al. (34–36) synthesized cross-linked copolymer hydrogels consisting of NIPAAm and butyl methacrylate (BMA) and achieved on–off regulation of drug release in response to stepwise temperature changes. As the temperature-responsive hydrogels were swollen at a low temperature, the drug could be released from the hydrogels. However, when the temperature increased beyond their LCST, dense skin formation during the deswelling process stopped the release of the drug. Furthermore, they have systematically studied the sharp swelling/deswelling changes of the temperature-responsive PNIPAAm copolymer hydrogels and the pulsatile drug release from the hydrogels in response to temperature changes (37–39). In addition, comb-type grafted PNIPAAm hydrogels were prepared to accelerate the deswelling rate, and the effect of hydrogel architecture on the

**Figure 36.2** Schematic of delivery or removal of substances using temperature-responsive hydrogels. (From Ref. 32.)

deswelling kinetics was investigated (40–42). The comb-type grafted PNIPAAm hydrogels showed much rapider temperature responses during the deswelling beyond LCST than the conventional cross-linked PNIPAAm hydrogel. The rapid deswelling of the comb-type grafted PNIPAAm hydrogels was based on rapid hydrophobic aggregation of freely mobile PNIPAAm graft chains and the intrinsic elastic forces of the polymer network.

The opposite type of temperature-responsive hydrogels, which are swollen at high temperature and shrunken at low temperature, were also prepared by using hydrogen bonding between polymer chains (43–45). The temperature-responsive hydrogels were interpenetrating polymer networks (IPNs) composed of acrylamide (AAm) and acrylic acid (AAc). In the IPN hydrogels, AAm formed a complex with AAc by hydrogen bonding at low temperature, but the complex was dissociated at high temperature. As a result, the IPN hydrogels were swollen at high temperature due to the dissociation of the hydrogen bonding and shrunken gradually with decreasing temperature due to the formation of hydrogen bonding. (Fig. 3). Furthermore, they performed the release experiments of ketoprofen from the temperature-responsive IPN hydrogels in response to stepwise changes in temperature. In contrast to drug release profiles from the PNIPAAm hydrogels, the release rate of drug decreased at low temperature but increased at high temperature. The temperature-responsive IPN hydrogels showed that stimulus-responsive hydrogels can be prepared by using association and dissociation of a complex between polymer chains.

Some researchers reported that temperature-responsive PNIPAAm hydrogels are applicable as intelligent devices

**Figure 36.3** Swelling changes of temperature-responsive IPN hydrogel in response to stepwise temperature changes. (○) between 10°C and 30°C; (●) between 20°C and 30°C. (From Ref. 44.)

to separate molecules (46–48). Cussler (47) used a cross-linked PNIPAAm hydrogel as an extraction solvent for aqueous solutions. Low molecular weight solutes were adsorbed in the cross-linked PNIPAAm hydrogel during swelling, but proteins and other high molecular weight solutes were excluded. The adsorbed solutes were released when the cross-linked PNIPAAm hydrogel was collapsed at high temperature. Therefore the cross-linked PNIPAAm hydrogel can be easily regenerated by a slight increase in temperature. Kim et al. (48) showed that molecules of different sizes can be separated by a temperature-responsive hydrogel membrane consisting of NIPAAm and BMA. The swelling of the hydrogel membrane as a function of temperature strongly influenced the permeability of molecules of different sizes.

Temperature-responsive hydrogels are also novel intelligent supports to immobilize enzymes and proteins. For example, Hoffman et al. (49,50) immobilized asparaginase and  $\beta$ -galactosidase within temperature-responsive hydrogels consisting of NIPAAm and AAm. The enzyme activity was shut off when temperature increased above its LCST. When operational temperature was cycled between temperature below and above LCST, the activity of the immobilized enzymes almost fully recovered after each cycle.

### III. GLUCOSE-RESPONSIVE HYDROGELS

Diabetes is caused by the inability of the pancreas to control blood glucose concentration. As insulin, which is a hormone secreted from the Wrangell Hans island of the pancreas, controls the glucose metabolizing, various medicines made of insulin are developed to control the blood sugar value effectively. In the treatment of diabetes by insulin injection, the blood glucose concentration is monitored and a necessary amount of insulin is administered. Recently, several investigations have been undertaken for the purpose of developing drug delivery systems that can release insulin in response to the blood glucose concentration. Glucose-responsive hydrogels are promising artificial pancreases that can administer a necessary amount of insulin in response to the blood glucose concentration. Some approaches to develop glucose-responsive hydrogels are described in the following subsections.

#### A. Glucose Oxidase-Containing Hydrogels

Some researchers designed glucose-responsive hydrogels by combining glucose oxidase to sense glucose with pH-responsive hydrogels to regulate the permeation rate of insulin. In their systems, gluconic acid is produced from

glucose by glucose oxidase in the hydrogels. Since the produced gluconic acid induces a decrease in pH, the permeability of insulin through the pH-responsive hydrogels is enhanced due to their pH-responsive swelling. Glucose-responsive insulin permeation of their membrane can be explained by the tentative model in Fig. 4. Ishihara et al. (51,52) and Horbett et al. (53–55) prepared hydrogels with pendant amine groups as pH-responsive hydrogels, in which glucose oxidase was entrapped during the preparation. In their systems, when glucose diffuses into the hydrogels, glucose oxidase catalyzes its conversion to gluconic acid. Then the produced gluconic acid leads to lowering pH within the hydrogel microenvironment. The reduced pH results in increasing ionization of the pendant amine groups in the hydrogels. As hydrogels were swollen by the electrostatic repulsion between ionized amine groups, insulin can be permeated through the hydrogels. Ultimately, then, the insulin permeability is a function of glucose concentration external to the hydrogels, and insulin delivery is accelerated by an increase in glucose level. (Fig. 4)

Ishihara et al. (51) combined a copolymer membrane of *N,N*-diethylaminoethyl methacrylate (DEA) and 2-hydroxypropyl methacrylate (HPMA) with cross-linked poly(acrylamide) membrane in which glucose oxidase was immobilized. The insulin permeability through the complex membrane containing glucose oxidase was strongly independent of the glucose concentration. Furthermore, Ishihara and Matsui (52) prepared polymer capsules containing insulin and glucose oxidase by a conventional interfacial precipitation method and investigated insulin release from the capsules in response to the glucose concentration. Figure 5 shows the effect of the glucose concentration on the insulin release from the glucose-responsive polymer capsules. The insulin release rate was very low in the absence of glucose but was strongly enhanced by the presence of glucose. Glucose-responsive insulin release can be achieved by using pH-responsive co-

**Figure 36.4** Schematic representation of the glucose-responsive hydrogel membrane consisting of a poly(amine) and glucose oxidase-loaded membranes. (From Ref. 51.)

**Figure 36.5** Effect of the addition and removal of glucose on insulin permeation through the copolymer membranes containing glucose oxidase and on the pH of the feed side solution. (From Ref. 52.)

polymer capsules containing insulin and glucose oxidase, based on the combination of pH response of the copolymer membrane and the enzymatic reaction between glucose and glucose oxidase.

On the other hand, Horbett et al. (53–55) reported that hydroxyethyl methacrylate-*N,N*-dimethylaminoethyl methacrylate copolymer hydrogel membranes containing entrapped glucose oxidase demonstrated promising responsiveness to glucose concentration. The presence of glucose resulted in swelling of their membranes and enhanced insulin delivery from a reservoir by diffusion through the swollen hydrogel membranes. The pH indicator dyes that can convert a pH decrease to a color change were introduced into the glucose-responsive hydrogel membranes to examine pH changes in the membranes. Based on the results of the experiments, they developed a mathematical model to describe the steady-state behavior of the glucose-responsive hydrogel membranes. Their theoretical and experimental studies suggested that a glucose-responsive hydrogel membrane prepared by using glucose oxidase would achieve a maximum response at subphysiological concentrations of glucose and not respond to higher glucose concentrations. Their model showed that loading of sufficiently low glucose oxidase enables a progressive response to glucose concentration in the physiological range.

Peppas et al. (56,57) synthesized glucose-responsive poly(methacrylic acid-*g*-ethylene glycol) (poly(MAAc-*g*-EG)) hydrogels by copolymerizing methacrylic acid and poly(ethylene glycol) monomethacrylate in the presence of activated glucose oxidase. At low pH, the protonation of the carboxyl groups caused complex formation between carboxyl groups and etheric groups, and this resulted in a collapse of the hydrogel due to the lowering of the hydro-

phobicity in the polymer network. At high pH, however, the complex was dissociated as the carboxyl groups became ionized. As a result, the hydrogels were collapsed at low pH due to complexation between carboxyl groups of MMAc and etheric groups of EG, but were swollen at high pH. When the glucose-responsive poly(MAAc-g-EG) hydrogels were swollen from an initially dry state, the hydrogels at the high glucose concentration of hyperglycemic condition (200–500 mg/dL) were swollen at a slower rate than those at the lower glucose concentrations of normal blood glucose (80 mg/dL). At a high glucose concentration, the glucose oxidase catalyzed glucose reaction with oxygen and then produced gluconic acid to result in a decrease in the environmental pH. Then the hydrogels were collapsed due to complex formation between carboxyl groups and etheric groups with lowering pH in the hydrogels. Peppas et al. expected that such a collapse can “squeeze out” any incorporated drugs including insulin when the hydrogels are collapsed abruptly with a decrease in pH. Alternatively, as the glucose concentration decreases by the action of the released insulin, less produced gluconic acid results in an increase in the environmental pH. The hydrogels are expected to be swollen with this change in pH.

### B. Hydrogels with Phenylboronic Acid Moiety

Phenylboronic acid and its derivatives form complexes with polyol compounds such as glucose in aqueous solution. The complex between phenylboronic acid and a polyol compound can be exchanged by a competing polyol compound that can form complexes more strongly. The fascinating property of the complex between phenylboronic acid and a polyol compound suggests that the complex has many future opportunities as suitable glucose-responsive materials. Kitano et al. (58,59) prepared the copolymers with phenylboronic acid moieties (Poly(NVP-co-PBA)) by the copolymerization of *N*-vinyl-2-pyrrolidone (NVP) and 3-(acrylamido)phenylboronic acid (PBA), which formed its reversible complex with poly(vinyl alcohol) (PVA). Their strategy is to utilize the competitive binding of phenylboronic acid with glucose and PVA. As shown in Fig. 6, poly(NVP-co-PBA) formed a complex with PVA, and the resultant complex can be dissociated in the presence of free glucose. The formation and dissociation of the complex between poly(NVP-co-PBA) and PVA were estimated by the viscosity change of the system. These results suggested that the complex is glucose-responsive, and novel insulin release systems shown in Fig. 6 can be constructed (59). For example, a glucose-responsive electrode was prepared by coating with a polymer complex hydrogel consisting of the copolymer with phenylboronic acid and PVA (60). In the glucose-responsive electrode,

**Figure 36.6** Concept of glucose-responsive insulin release system using PVA/poly(NVP-co-PBA) complex system (polymer capsule type). (From Ref. 59.)

as the presence of free glucose induced swelling of the coating polymer hydrogel, increasing diffusivity of ion species resulted in the current changes. The fact that the current changes were proportional to glucose concentration suggested that they are indicative of high selectivity for glucose. However, this hydrogel is difficult to use in controlled release systems because of its intrinsically unstable complex at physiological pH of 7.4.

The complex between the phenylboronic acid and glucose was stabilized by the introduction of amino groups into the polymer or in the vicinity of the phenylboronic acid moiety due to the charge transfer interaction of nitrogen atom to boron atom under physiological pH 7.4 (61). A glucose-responsive hydrogel containing amino groups was prepared for the development of an advanced insulin delivery system at physiological pH. Gluconated insulin was bound with phenylboronic acid groups. As the complex between the phenylboronic acid and gluconated insulin can be dissociated in the presence of glucose by complex exchange between gluconated insulin and glucose, it can control insulin release in response to glucose (62).

The phenylboronic acid compounds are in equilibrium between the undissociated (or uncharged) and the dissociated (or charged) form (Fig. 7). Only charged phenylboronic acid groups can form a stable complex with glucose, and the complex between the uncharged form and glucose

**Figure 36.7** Equilibria of (alkylamido)phenyl boronic acid (1). (From Ref. 64.)

is unstable because of its high susceptibility to hydrolysis. When the charged phenylboronic acid groups form complexes with glucose, the equilibrium is shifted in the direction of increasing charged phenylboronic acid groups (2 + 3). As a result, the presence of glucose results in increasing total charged form (2 + 3) and in decreasing uncharged form. The ratio of the uncharged and charged forms strongly influences the solubility of the polymer in the aqueous solution, because the charged form is more hydrophilic than the uncharged form. To develop glucose-responsive devices, Kataoka et al. (61) used the shift in the equilibrium between the uncharged and charged forms of phenylboronic acid through its complex formation with glucose. They prepared a copolymer of *N,N*-dimethylacrylamide and PBA by radical copolymerization. The copolymer with phenylboronic acid groups was dissolved in a buffer solution of pH 7.4 at a temperature of less than 27°C but was insoluble at more than 27°C. This indicated that the copolymer with phenylboronic acid groups has LCST of about 27°C. The phenylboronic acid groups played an important role in the appearance of LCST, as the copolymer without the phenylboronic acid groups had no LCST. The addition of glucose to the aqueous solution of the copolymer with the phenylboronic acid groups led to a monotonic increase in LCST. The glucose-responsive LCST change is due to an increase in more hydrophilic charged phenylboronic acid groups by the complex formation between the phenylboronic acid groups and glucose.

Furthermore, the fascinating property of phenylboronic acid was combined with the temperature-responsive properties of PNIPAAm to improve the glucose-responsive LCST changes of the copolymers with the phenylboronic acid groups (63). A glucose-responsive ternary polymer was obtained by the copolymerization of NIPAAm, PBA, and *N*-(2-dimethylaminopropyl)acrylamide (DMAPAA). The LCST of the ternary polymer was strongly dependent upon the glucose concentration (Fig. 8). This suggests that

**Figure 36.8** Temperature dependence of optical transmittance for IB (dotted line) and IAB (solid line) copolymers in phosphate buffer solutions (pH 7.4) in the absence and presence of glucose. Glucose concentration: 0 mg/mL, (●); 1 mg/mL, (◇); 2 mg/mL, (□); 4 mg/mL, (▲); 10 mg/mL, (△). (From Ref. 63.)

the LCST of the ternary polymer can be controlled easily by a change in the external glucose concentration. Therefore a glucose-responsive hydrogel can be developed from the polymer containing both phenylboronic acid and NIPAAm, as the solubility of the polymer chain is strongly influenced by the glucose concentration at a constant temperature. Kataoka et al. (64) prepared totally synthetic polymer hydrogels composed of NIPAAm and phenylboronic acid, which undergo a sharp transition in the swelling ratio in response to glucose concentration. No insulin release from the hydrogel was observed in the buffer solution with a glucose concentration less than 1 g/L, but a remarkable release of insulin took place with a glucose concentration of 3 g/L. As shown in Fig. 9, furthermore, on-off regulation of insulin release was successfully repeated in response to stepwise changes in the glucose concentration.

**Figure 36.9** Repeated on-off release of FITC-insulin from the glucose-responsive hydrogel at 28°C, pH 9.0, in response to external glucose concentration. (From Ref. 64.)

**Figure 36.10** Schematic of Con A-glycosylated insulin derivative complex in a microcapsule. Con A (■), SAPG insulin (○), and glucose (△). (From Ref. 68.)

### C. Lectin-Containing Hydrogels

Lectins are carbohydrate-binding proteins of nonimmune origin that do not exhibit enzymatic activity. They interact with glycoproteins and glycolipids on the cell surface and can induce a variety of effects such as cell agglutination, cell adhesion to surfaces, and hormonelike action. These biological effects are of considerable interest because of molecular recognition of hormones and toxins that bind to carbohydrate receptor sites on membranes.

Brownlee and Cerami (65) and Kim et al. (66,67) were pioneers in the development of glucose-responsive insulin release systems using lectin, and their work has been expanded further by various researchers. Their method of developing a physiological insulin delivery system is to synthesize a stable, biologically active glycosylated insulin derivative that can form a complex with lectin, concanavalin A (Con A). A glycosylated insulin derivative binding with lectin can be released as a function of the free glucose concentration. Furthermore, Kim et al. (68) enclosed the self-regulating insulin delivery systems in polymer membranes to soluble, bead-immobilized, or cross-linked Con A, based on the concept of competitive binding between succinyl-amidophenyl-glucopyranoside insulin (SAPG insulin) and glucose to Con A. SAPG insulin was released from polymer membranes or microcapsules containing Con A and SAPG insulin in a quick response to changes in glucose concentration (Fig. 10). Based on the concept of competitive and complementary binding properties of SAPG insulin and glucose to Con A, SAPG insulin was released through the membranes in response to the concentration of free glucose (Fig. 11). The polymer membranes and microcapsules containing Con A and SAPG insulin

**Figure 36.11** Release of SAPG insulin in response to stepwise glucose changes. (From Ref. 68.)

were good self-regulating insulin release devices *in vitro* and can be optimized for use in *in vivo* studies.

Kokufuta et al. (69) loaded Con A in the cross-linked PNIPAAm hydrogel, which undergoes a volume phase transition at 34°C. The Con A-loaded PNIPAAm hydrogel was abruptly swollen in the presence of the ionic saccharide dextran sulphate at temperatures close to the volume phase transition because of the ionic osmotic pressure exerted by ionized saccharide. However, replacing the ionic saccharide dextran sulphate with the nonionic saccharide induced the collapse of the hydrogel back to its native volume. The swelling and shrinking changes of Con A-loaded hydrogel were determined by a balance among the pressure due to repulsive electrostatic interactions of ionized dextran sulphate molecules, the osmotic pressure owing to counterions from saccharide dextran sulphate, and the attractive hydrophobic interaction among NIPAAm moieties.

Polymers with a pendant saccharide have attracted much attention because of their potential applications as suitable materials for biochemical and biomedical applications (70). In particular, a variety of synthetic polymers having well-defined saccharide residues can be used for the investigation of molecular recognition processes in the interactions between saccharides and proteins. The complexation between a polymer with pendant glucose groups, poly(2-glucosyloxyethyl methacrylate) (PGEMA), and Con A was investigated in the absence and presence of various free monosaccharides (71). PGEMA in water was

flocculated by the addition of Con A, and the aqueous PGEMA solution became turbid owing to the complex formation between PGEMA and Con A. However, the addition of free glucose or mannose into the turbid PGEMA–Con A complex solution made the solution transparent, but the addition of free galactose did not. This is because the PGEMA–Con A complex is dissociated in the presence of free glucose or mannose by their exchange with the PGEMA, but the complex is not dissociated in the presence of free galactose. These results suggested that PGEMA can be recognized by Con A and that the affinity of Con A for PGEMA differs from the affinity for the free monosaccharides. Furthermore, the PGEMA–Con A complex can recognize the kind of free monosaccharides and is saccharide responsive. Therefore the PGEMA–Con A complex is a promising candidate for constructing a novel glucose sensor or an intelligent device for a glucose-responsive insulin release system. Similarly, Park et al. (72,73) investigated specific interaction between Con A and the copolymers containing allylglucose and revealed that hydrogels were formed immediately after mixing the copolymers and Con A. A sol–gel phase-reversible hydrogel responsive to glucose was prepared from the copolymers and Con A.

Recently, novel glucose-responsive hydrogels were prepared by application of the complex formation between Con A and pendant glucose groups in PGEMA to produce cross-linking points in hydrogels (74,75). The Con A–entrapped PGEMA hydrogels were obtained by copolymerizations of a monomer with a pendant glucose and a divinylmonomer in the presence of Con A. That the cross-linking density of the resultant hydrogels increased with increasing Con A suggested that Con A acts as a cross-linking point in the hydrogel due to complex formation between pendant glucose groups and Con A. When the Con A–entrapped PGEMA hydrogels were immersed in an aqueous glucose solution, their swelling ratio increased, depending on the glucose concentration. The glucose-responsive swelling of the Con A–entrapped PGEMA hydrogels was due to the dissociation of the complex between the pendant glucose groups and Con A by competitive exchange of pendant glucose groups with free glucose, as shown in Fig. 12. In addition, the Con A–entrapped PGEMA hydrogels were more strongly swollen in the presence of mannose than of glucose, but their swelling ratio did not change in the presence of galactose (Fig. 13). The presence of mannose can induce the dissociation of the complex between the pendant glucose groups and Con A more effectively than that of glucose, and the presence of galactose did not. This means that the Con A–entrapped PGEMA hydrogels can recognize a specific monosaccharide and respond to it. Therefore the Con A–entrapped PGEMA hydrogel has many applications in a novel glu-

**Figure 36.12** Schematic representation of glucose-responsive swelling changes of the poly(GEMA)–Con A hydrogel. (From Ref. 74.)

cose sensor and in a potential device for new closed-loop insulin-delivery systems. Obaidat and Park (76) also prepared glucose-responsive phase-reversible hydrogels based on the specific interaction between polymer-bound glucose and Con A. Release of lysozyme and insulin as model proteins through the glucose-responsive hydrogel membranes was examined using a diffusion cell consisting of two chambers. Poly(hydroxyethyl methacrylate) (PHEMA) membranes, which allowed diffusion of glucose and model proteins but prevented a glucose-containing polymer and Con A from being released, were used to sandwich the mixture of the glucose-containing polymer and Con A between the diffusion chambers. The release of model proteins through the glucose-responsive hydrogel membrane was strongly dependent on the concentration of

**Figure 36.13** Swelling ratio changes of poly(GEMA)–Con A hydrogel as a function of time, when the hydrogels are immersed in the buffer solution (pH 7.5) containing 1 wt% of monosaccharide: (○) glucose; (■) mannose; (●) galactose. (From Ref. 74.)

**Figure 36.14** Release of lysozyme through a glucose-responsive hydrogel membrane at the initial glucose concentrations of 1 (●) and 4 (○) mg/mL. (From Ref. 76.)

free glucose (Fig. 14). Their studies demonstrated that the glucose-responsive phase-reversible hydrogels are applicable to regulate the insulin release in response to the free glucose concentration in the environment.

#### IV. ANTIGEN-RESPONSIVE HYDROGELS

Antibodies have unique recognition sites that bind antigen specifically, and their antigen recognition and binding are associated with the complex immune responses to protect the organism from infection. The antigen–antibody binding occurs through multiple noncovalent bonds such as electrostatic, hydrogen, hydrophobic, and van der Waals. Therefore antibodies are widely employed in a great number of immunological assays to detect and measure biological and nonbiological substances in many fields because of their exceptional specificity, stability, and versatility (77).

Recently, antigen–antibody bindings were used for preparing novel antigen-responsive hydrogels because the specific antigen recognition of an antibody can provide the basis for fabricating sensing devices with a wide variety of uses for immunoassay and antigen sensing. The novel antigen-responsive hydrogels were prepared by the application of the antigen–antibody binding at cross-linking points in the hydrogel (78,79). The fundamental strategy for the preparation of antigen-responsive hydrogels is shown in Fig. 15. Rabbit immunoglobulin G (IgG) as an antigen was chemically modified by coupling it with *N*-succinimidylacrylate (NSA) in phosphate buffer solution to introduce vinyl groups into the rabbit IgG. After the resultant vinyl rabbit IgG was purified by gel filtration, it was mixed with goat antirabbit IgG (GAR IgG) as an antibody to form an antigen–antibody binding. Then the vinyl-rabbit IgG was copolymerized with acrylamide (AAm) as

**Figure 36.15** Synthesis of an antigen–antibody hydrogel. (From Ref. 78.)

a comonomer and *N,N'*-methylenebisacrylamide (MBAA) as a cross-linker in the presence of GAR IgG, to prepare a hydrogel having antigen–antibody bindings (antigen–antibody hydrogel). The antigen–antibody hydrogel was swollen by the addition of a free rabbit IgG in the buffer solution after its swelling attained equilibrium in the buffer solution. This means that the antigen–antibody hydrogel is rabbit-IgG responsive. Furthermore, the swelling changes to the antigen–antibody hydrogel caused by the presence of IgG from a different species were investigated in order to determine whether the effect is due to specific molecular recognition. The addition of free rabbit IgG resulted in a dramatic increase in the swelling ratio of the antigen–antibody hydrogel, but the addition of free goat IgG did not (Fig. 16). The antigen-responsive swelling of

**Figure 36.16** Changes in the swelling ratio of the antigen–antibody hydrogel by the addition of goat IgG (○) and rabbit IgG (●) after swelling attained equilibrium in the phosphate buffer solution. The concentration of the antigen in the phosphate buffer solution is 4 mg/mL. (From Ref. 78.)

the antigen–antibody hydrogel could be explained by the decrease in the cross-linking density in the hydrogel because of the dissociation of the antigen–antibody binding in the presence of a free antigen. These results suggest that the antigen–antibody hydrogel can recognize only rabbit IgG and exhibit structural changes. Other researches on molecule-responsive hydrogels reported previously focused on the hydrogels that undergo swelling changes in response to only low molecular weight compounds such as glucose described in Section III. Studies on the antigen-responsive hydrogels suggest a simple solution to the problem that is of relevance to many aspects of the development of specific macromolecule-responsive hydrogels that can respond to macromolecules such as protein and antigen.

Most potential applications of stimulus-responsive hydrogels require that their swelling behavior be reversible. However, the antibody was leaked out of the antigen–antibody hydrogel during the swelling in response to the antigen, as the antibody became free in the swollen hydrogel. The antigen–antibody entrapment hydrogel was not shrunken in the buffer solution without the antigen, and showed no reversibility in the antigen-responsive swelling changes. Therefore structures of the antigen–antibody hydrogel must be designed so that the antibody can form a binding with the antigen grafted with gel networks again in the buffer solution without the antigen. One approach is to introduce a semi-interpenetrating polymer network (semi-IPN) structure into the antigen–antibody hydrogel in order to immobilize the antibody in the gel network. A reversibly antigen-responsive hydrogel was prepared based on the strategy that the reversible binding between an antigen and an antibody is used as the cross-linking mechanism in a semi-IPN hydrogel (Fig. 17a) (79). The synthetic procedure of the antigen–antibody semi-IPN hydrogel is shown in Fig. 17b. As described previously, rabbit IgG as an antigen and GAR IgG as an antibody were chemically modified by coupling them with NSA to synthesize a vinyl antigen and a vinyl antibody. The resultant vinyl GAR IgG was copolymerized with AAm to synthesize the polymerized GAR IgG that acts as a linear chain in a semi-IPN hydrogel. Then the antigen–antibody semi-IPN hydrogel was prepared by the copolymerization of the vinyl rabbit IgG, AAm, and MBAA as a cross-linker in the presence of the polymerized GAR IgG. The linear polymerized antibody was interpenetrated through the network having the antigen in the resultant antigen–antibody semi-IPN hydrogel. The linear polymerized antibody was not leaked out of the semi-IPN hydrogel because it was entangled with the network. The antigen–antibody semi-IPN hydrogel was swollen immediately following the addition of free rabbit IgG into the buffer solution after its

**Figure 36.17** Strategy for the preparation of an antigen-responsive semi-IPN hydrogel. (From Ref. 79.)

swelling attained equilibrium in the buffer solution. In addition, the swelling ratio of the antigen–antibody semi-IPN hydrogel was strongly dependent upon the antigen concentration in the buffer solution. The antigen–antibody semi-IPN hydrogel did not recognize goat IgG but only rabbit IgG (Fig. 18). Because the presence of goat IgG did not result in the dissociation of the complex between the poly-

**Figure 36.18** Antigen recognition by the antigen–antibody semi-IPN hydrogel. (From Ref. 79.)

merized rabbit IgG and polymerized GAR IgG due to the antigen recognition of the GAR IgG, the swelling ratio of the antigen–antibody semi-IPN hydrogel did not change by the addition of goat IgG. These mean that the antigen–antibody semi-IPN hydrogel can recognize a specific antigen and change its structure chemomechanically. Furthermore, the swelling changes in response to stepwise changes in the antigen concentration were examined for investigating the reversibility of the antigen-responsive swelling changes. Figure 19 shows the swelling ratio change of the antigen–antibody semi-IPN hydrogel as a function of time when it was alternately immersed in buffer solution with and without a free antigen. The antigen–antibody semi-IPN hydrogel was swollen immediately in the presence of the free antigen and shrunken gradually in its absence. In contrast, the antigen–antibody entrapment hydrogel without a semi-IPN structure described previously was also swollen in the buffer solution with the free antigen but was not shrunken following immersion in the buffer solution without the free antigen. Therefore only antigen–antibody semi-IPN hydrogel undergoes reversible changes in its swelling ratio in response to stepwise changes in the antigen concentration. This re-

veals that the semi-IPN structure plays an important role in the reversibility of the antigen-responsive swelling changes. In the semi-IPN hydrogel, the polymerized GAR IgG is trapped in a network containing grafted rabbit IgG, and so the hydrogel can shrink reversibly because the cross-links between polymerized GAR IgG and grafted rabbit IgG reform in buffer solution without the free antigen.

Stimulus-responsive swelling changes of smart hydrogels can control the permeability of solutes such as drugs, and such stimulus-responsive hydrogels are promising candidates of intelligent devices for novel drug delivery systems. Therefore to investigate the possibility of the antigen-responsive hydrogel as the intelligent device, the pulsatile permeation of a model protein drug in response to stepwise changes in the antigen concentration was also investigated with a membrane of the antigen–antibody semi-IPN hydrogel (79). As a result, it became apparent from the permeation profile in Fig. 19 that a model drug is permeated through the antigen–antibody semi-IPN hydrogel membrane in the presence of free rabbit IgG, but the drug permeation is stopped in its absence. That is, the pulsatile permeation of a model drug in response to the specific antigen concentration can be achieved by using the antigen–antibody semi-IPN hydrogel. This means that the antigen–antibody semi-IPN hydrogel is useful as an intelligent device for a novel drug delivery system in which a drug can be released in the presence of a specific antigen and the drug release can be stopped in its absence. For example, drug targeting to a cancer with a specific antigen, in which an anticancer compound is released selectively to a cancer in response to its antigen, can be achieved by using such antigen-responsive hydrogels. Furthermore, some findings in these studies imply that a specific biochemical interaction, the binding between biomolecules, can be converted into a mechanical force. Developing specific molecule-responsive hydrogels using the method will contribute significantly to creating a novel intelligent system in which specific interactions can be converted into mechanical force.

**Figure 36.19** Reversible swelling changes and antigen-responsive permeation profiles of hemoglobin through the PAAm semi-IPN hydrogel (○) and the antigen–antibody semi-IPN hydrogel (●) in response to stepwise changes in the antigen concentration between 0 and 4 mg/mL. (From Ref. 79.)

## V. OTHER STIMULUS-RESPONSIVE HYDROGELS

### A. Molecular Imprint Hydrogels

Some proteins such as enzymes and antibodies have a molecular recognition ability that is based on fitting guest molecules into their molecular cavities. Molecular imprinting is an attractive technique to synthesize polymers having a molecular recognition function, and it has potential practical applications in separation science and tech-

nology (80,81). In most of the recent studies, after the functionalized monomer is prearranged around the print molecule by noncovalent interactions such as electrostatic, hydrophobic, and hydrogen bonding, it is polymerized by interacting with a print molecule. Then the print molecule is removed from the resultant polymer to form a molecular cavity. The cavity formed by the removal of the print molecule can recognize the guest molecule (print molecule) due to a combination of reversible binding and shape complementarity. Watanabe et al. (82) showed that the molecular imprinting is applicable to the preparation of the molecule-responsive hydrogels that undergo a large swelling change in accordance with the print molecules. They prepared temperature-responsive copolymer hydrogels consisting of NIPAAm and acrylic acid in the presence of guest molecules as print molecules. The hydrogels were swollen at a low temperature and collapsed at a high temperature. The swelling ratio of the hydrogel swollen at a low temperature was independent of the guest molecule concentration, but that of the hydrogel collapsed at a high temperature increased with increasing concentration. This suggests that the hydrogel in the collapsed state can respond to the guest molecule. It is noticeable that the guest molecule-responsiveness of the hydrogel prepared by the molecular imprinting technique was strongly affected by the preparation condition. The hydrogel prepared in 1,4-dioxane in the presence of the guest molecule exhibited the specific volume change, but that prepared in water did not. Figure 20 shows the swelling ratio changes at 50°C of the temperature-responsive hydrogels prepared in the presence of norephedrine and adrenaline as guest molecules. The hydrogel prepared in the presence of norephedrine was swollen with increasing norephedrine concentration but was not changed by increasing adrenaline, and vice versa for the hydrogel prepared in the presence of adrenaline. As the temperature-responsive hydrogels prepared in the presence of a guest molecule memorize the guest molecule, the hydrogels show specific volume change in response to the guest molecule owing to its specific adsorption into hydrogels.

### B. Other Biomolecule-Responsive Hydrogels

Deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) are composed of the nucleotides adenine, cytosine, guanine, thymine, and uracil and form double or triple strands with its complementary base pairs by hydrogen bonding and stacking of its bases. Aoki et al. (83) focused on uracil in the nucleic acid bases and synthesized poly(6-(acryloyloxymethyl)uracil) (PAU) having uracil moieties as side chains. PAU was insoluble in water due to the polymer complexes between uracil moieties at lower temperatures

**Figure 36.20** Equilibrium swelling ratios at 50°C as a function of concentration of either norephedrine (●) or adrenaline (○) for molecular recognition hydrogels prepared in the presence of norephedrine (A) and adrenaline (B). (From Ref. 82.)

and became water soluble above a characteristic transition temperature, showing an upper critical solution temperature (UCST). UCST of PAU was shifted to a lower temperature by the presence of adenosine in aqueous solutions because the uracil moieties form complexes with complementary adenosine. Furthermore, additions of adenosine and guanosine had different effects on the phase transition changes due to the different interaction of uracil moieties with adenosine and guanosine. This means that PAU changes its phase transition temperature in response to species of the additive nucleic acid bases. These results imply that hydrogels prepared from PAU must recognize species of the nucleic acid bases, and that they may undergo swelling ratio changes in response to the concentration of the nucleic acid bases.

In addition, Aoki et al. (84) synthesized a temperature-responsive copolymer composed of *N*-(*S*)-*sec*-butylacrylamide ((*S*)-*sec*-BAAm) and NIPAAm that exhibits hydration change in response to foreign optically active compounds as external stimuli. The resultant poly((*S*)-*sec*-BAAm-*co*-NIPAAm) with a (*S*)-*sec*-BAAm content of 50 mol% has LCST at 23.1°C. The presence of L-tryptophan

**Figure 36.21** Change in LCST of (S) BP-50 in water as a function of Trp concentration. LCST is defined as the temperature at 50% optical transmittance. (■) L-Trp; (▲) D-Trp; (◇) PNIPAAm + L-Trp. (From Ref. 84.)

(L-Trp) resulted in a remarkable shift in LCST to 34.5°C, but that of D-Trp did so to 28.7°C (Fig. 21). On the other hand, a racemic (*R,S*)-*sec*-BAAm-containing copolymer showed the same phase transition temperatures in the presence of D- and L-Trp. Therefore, the remarkable shift in LCST of poly(*S*)-*sec*-BAAm-co-NIPAAm is attributable to the stereospecific interaction between the optically active (*S*)-*sec*-BAAm in the copolymer and L-Trp. Furthermore, the LCSTs of the copolymers were strongly dependent upon the L-Trp concentration. Therefore these results revealed that the temperature-responsive copolymer with optically active moieties can respond to the enantiomers. Based on its concept, Aoki et al. (85) prepared temperature-responsive poly(*S*)-*sec*-BAAm-co-NIPAAm hydrogel and poly(*N*-(L)-(1-hydroxymethyl) propylmethacrylamide) (PHMPMA) hydrogel with optically active moieties that undergo phase transitions. The temperature dependence of the swelling ratio of their hydrogels was remarkably influenced by the addition of L-Trp. Therefore their hydrogels can recognize the difference between L- and D-Trp and can be called amino acid-responsive hydrogels.

## Biocompatible Polymers in Liver-Targeted Gene Delivery Systems

Edwin C. Ouyang, George Y. Wu, and Catherine H. Wu

*University of Connecticut Health Center, Farmington, Connecticut*

### I. POLYCATIONS AS DNA BINDING COMPONENTS

#### A. Polylysine

Poly-L-lysine is a polymer of varying numbers of lysine residues. Poly-L-lysine with its positive surface charge has been utilized to improve cell adhesion to solid substrates and can also be used for nucleic acid delivery to cells by noncovalently linking to negatively charged DNA phosphate backbones.

#### B. Polyethylenimine

Polyethylenimine (PEI) is another useful polycation applied in DNA-binding delivery systems. It also has positive charges on the surface with sizes from 6,000 to 60,000 daltons.

Poly-L-lysine can compact the size of DNA complexes to make it more accessible for internalization and provide protective effects to the complexes against degradation by serum nucleases. Without coupling to polymer–ligand, DNA alone is usually degraded completely within 15 minutes in serum, or 60 minutes in culture medium plus 10% fetal bovine serum, whereas 90% of DNA complexed with poly-L-lysine–ligand remained full length after 1.5 h or 3 h in serum or medium with 10% serum, respectively (1).

The stabilization of the DNA complexes is dependent on the length of poly-L-lysine. At least twenty residues of poly-L-lysine is required to maintain the proper complexation with DNA fragments. Poly-L-lysine–DNA complexes were found to be about 25–80 nm in diameter and increased to 50–90 nm when conjugated with ligand. Attaching of asialoglycoprotein (ASGP) was found to decrease the aggregation of poly-L-lysine–DNA complexes in saline (2).

The efficiency of delivery is also dependent on the length of the poly-L-lysine and the ratio of galactose residues conjugated to the polymer (3). Complexes that have longer polymers (MW 13,000–29,000) with more galactose residues (13 to 26) are more efficient in gene transfer than shorter polymers (MW 1,800) with fewer galactose residues (only 5).

Galactosylated poly-L-lysine (MW 13,000) was complexed with plasmid DNA encoding a CAT gene at weight ratio of 1:0.6. The size of the complex was measured to be 180 nm with a weakly negative charge (zeta potential of –20 mV) (4). Radioisotope-labeled DNA/galactosylated poly-L-lysine was rapidly eliminated from serum and taken up by hepatocytes, which were abolished by an excess of free galactosylated bovine serum albumin.

Chemically modified poly-L-lysine can be used to achieve liver-selective delivery. Galactose-modified poly-L-lysine can be delivered specifically into mouse hepato-

cytes via tail vein injection (5). The complex was shown to accumulate in the liver, and the uptake was inhibited by treating with an excess of galactose-modified bovine serum albumin. Artificial galactose-modified ligand has been applied in DNA–poly-L-lysine complex to target to hepatocytes (6). A ligand carrying tetra-antennary branches with terminal galactose residues was conjugated to poly-L-lysine. The complex was then coupled with a plasmid DNA encoding a reporter gene (luciferase) to target human and murine hepatocyte cell lines, HepG2, BNL CL2, respectively.

## II. LIVER TARGETING BY RECEPTOR-MEDIATED DNA DELIVERY SYSTEMS

Liver-directed gene therapy can theoretically be applied to many liver diseases (congenital deficiencies of hepatic enzymes, viral infections, liver tumors, etc.) to deliver genes of interest into hepatocytes directly. It has the potential to result in efficient and persistent expression with fewer toxic side effects than with conventional medical therapy. One of the best-studied liver-selective delivery systems utilizes polymers conjugated to asialoglycoproteins to target genes of interest to ASGP receptors located selectively on the surface of mammalian hepatocytes.

### A. ASGP-Mediated Liver-Specific Delivery Systems

#### 1. The ASGP Receptor

##### a. Expression and Distribution of ASGP Receptor.

ASGP receptors are located selectively on the plasma membrane of hepatocytes, mostly on the basolateral side (sinusoidal side). They bind specifically to desialylated serum proteins containing galactose (Gal) or N-acetylgalactosamine (GalNAc) at the nonreducing termini of oligosaccharide chains (7). Detailed aspects of ASGP receptor functions have been reviewed elsewhere (7–11). The human ASGP receptor is a 46 kD transmembrane protein consisting of approximately 300 amino acids, including an N-terminal 40 amino acid on the cytoplasmic side, a 20 amino acid hydrophobic transmembrane domain, and a long 220 amino acid C-terminal extracellular domain. A second ASGP receptor has been identified with a molecular weight of 50 kD as the minor form with very low expression in human liver (12,13). High homology has been identified among ASGP receptors across different species. For example, rat and human ASGP receptors show 70 to 80% homology in essential amino acid sequences. The

ASGP receptor itself is a glycoprotein with the C-terminal domain containing three glycosylation sites. However, carbohydrate side chains do not seem to play an important role in ligand binding ability (14–16).

##### b. Physiological Function of the ASGP Receptor.

The expression of the ASGP receptor may change at different stages of differentiation and in the presence of certain diseases. For example, after partial hepatectomy, the number of ASGP receptors decreases (8,17). A decreased number and binding ability of ASGP receptors can also be detected in various carcinogen-induced rat hepatocellular carcinoma models (18,19). In a diabetes mellitus rat model, the binding ability for ASGP receptors was found to be decreased during early stages and dramatically reduced in later or severe stages (20,21).

#### 2. The Ligand for the ASGP Receptor

The ASGP receptor may recognize and bind to natural proteins with terminal Gal/GalNAc residues, including asialoorosomucoid, asialofetuin, etc., as well as synthetic galactose-modified materials.

##### a. Asialoorosomucoid (ASOR).

A commonly used ASGP in liver-targeted gene therapy is the desialylated form of orosomucoid (OR, alpha<sub>1</sub>-acid glycoprotein). OR consists of 180 amino acids with a molecular weight of 46 kD (22). Glycosylation of OR decreases during liver diseases (23), while it increases in the presence of certain cancers (24).

##### b. Other Natural ASGPs.

Many serum glycoproteins can be desialylated to expose terminal Gal/GalNAc residues and can be internalized into hepatocytes through the binding with ASGP receptors. The binding affinities of these ASGPs differ greatly, largely depending on the density of terminal Gal residues on saccharide chains. Among these, ASOR with 15 exposed clusters of Gal residues has the strongest binding affinity, while asialotransferrin (ASTF) with only 4 Gal residues, has the weakest (25).

##### c. Galactose-Modified Materials.

Synthetic di-, tri- or tetra-branched oligosaccharides with Gal/GalNAc can be coupled to nongalactose bearing proteins enabling binding to ASGP receptor on hepatocytes, although the binding affinities are much lower than those of natural desialylated glycoproteins. Clustering of Gal

residues can enhance the binding affinity. The correct orientation of these Gal residues is critical (25).

### 3. Endocytosis and Recycling Pathway of Ligand–Receptor Complexes

Natural desialylated glycoproteins, such as asialoorosomucoid (ASOR), bind to the ASGP receptor through galactose residues on termini of ASOR. Then, the ligand–receptor complex is internalized by hepatocytes in clathrin-coated pits (26–28). Next, coated pits are pinched off from the plasma membrane and form coated vesicles in cytoplasm, which is further decoated to become smooth vesicles. Then the ligand–receptor complex is delivered into CURL (compartment of uncoupling receptor and ligand) in which a low pH environment dissociates the complex. Ligands are transferred to endosome-lysosome compartments and degraded. Meanwhile, unoccupied ASGP receptors are recycled back to plasma membrane through an alternative pathway (10,29). The entire endocytosis–recycling process happens rapidly, being completed within eight minutes, and is ATP- and  $\text{Ca}^{2+}$ -dependent (30).

### B. Low-Density Lipoprotein Receptor (LDL-R)–mediated Liver Delivery Systems

Another liver-targeting system utilizes LDL receptors to deliver genes of interest into hepatocytes. LDL receptors are expressed on hepatocytes as well as other cells such as spleen, adrenal, and certain tumor cells. An apoE liposome carrying a lipophilic derivative of daunorubicin (LAD) was administered to B16 melanoma bearing mice (31,32). The binding affinity of apoE liposome to LDL receptor was 15 to 50-fold stronger than that of LDL ligand alone or liposome alone, respectively. LAD were detected mainly in LDL-receptor expressing tissues such as liver or spleen, with the highest uptake in tumor cells.

### C. Other Targeting Systems Using Polymers

Transferrin receptor has been used as a ligand linked to poly-L-lysine for liver-directed delivery systems. A complex consisting of maleimidotransferrin coupled with poly-L-lysine was constructed and had significantly enhanced transfection efficiency compared with conventional transfection methods including electroporation, lipofection, and  $\text{CaPO}_4$  precipitation (33). The efficiency was correlated to the length of the lysine polymer, the concentration of the transferrin–poly-L-lysine complexes, the ratio of poly-L-lysine to DNA, and the treatment of target cells with chlo-

roquine. This method was efficient and had low cytotoxicity.

## III. APPLICATIONS OF POLY-L-LYSINE–ASGP CONJUGATES

To deliver genes to hepatocytes, a DNA–poly-L-lysine–ASGP carrier was constructed by conjugation of ASGP to polylysine, subsequently forming DNA complexes through noncovalent interaction between negatively charged DNA strands and positively charged polylysine. Orosomucoid from human donor blood was desialylated by neuraminidase. ASOR was chemically coupled to poly-L-lysine and then bound to DNA to form a complex. The DNA–poly-L-lysine–ASOR complex provided specific targeting to hepatocytes through the binding between ASOR on the complex and ASGP receptor on the surface of parenchymal liver cells.

Studies conducted in cell lines and animal models showed that ASGP–poly-L-lysine–DNA system can specifically deliver genes of interest to hepatocytes. For example, 10 minutes after intravenous administration of  $^{32}\text{P}$ -labeled ASOR–poly-L-lysine–DNA complexes into rats, 85% of the radioactivity was detected in the liver and only 15% remained in serum, whereas in control groups with  $^{32}\text{P}$ -labeled DNA alone, only 17% of the radioactivity was measured in the liver and 55% still remained in serum. Microscopy studies demonstrated that most of the targeted cells were parenchymal cells (hepatocytes) with few Kupfer cells involved (34). The uptake was shown to be exclusively through ASGP receptors on hepatocytes (35).

### A. Delivery of Medications

Side effects are frequent in the medical treatment of diseases. Specific delivery of medication, for example, to hepatocytes could significantly decrease the concentration of the drug in extrahepatic tissues, reducing the cytotoxic effects while increasing the concentration of the drug in liver cells to enhance the pharmaceutical effects. The ASGP–poly-L-lysine system has been utilized specifically to deliver certain drugs, such as cytotoxic agents or prodrugs, into hepatocytes.

Antiviral drugs have been delivered into hepatocytes of HBV-infected patients by receptor-mediated systems (36). Adenine arabinoside monophosphate (ara-AMP) modified with lactosaminated human albumin was administered into chronic HBV patients for 28 days, exerting similar antiviral efficiency to free drug groups without any clinical side effects. Recent attempts have been made to deliver drugs

by conjugating the drug with lactosaminated poly-L-lysine. This modified poly-L-lysine can be easily prepared by chemical synthesis, permitting high drug loading, and can be administered via intramuscular injection (37).

### B. Delivery of Genes of Interest

ASGP–poly-L-lysine as a DNA delivery system for therapeutic purposes was first tested by directing a normal albumin gene into analbuminemic rats (38). Nagase analbuminemic rats underwent partial hepatectomy, and ASOR–poly-L-lysine complexed with a plasmid carrying a normal human albumin gene was administered subsequently by tail vein injection. The plasmid was taken up by rat hepatocytes through ASGP receptor. Two weeks after treatment, the expression of human albumin in serum was detected as high as 34  $\mu\text{g}/\text{mL}$  and was stable four weeks thereafter. Other studies also showed that an ASGP delivery system could successfully transfer LDL receptor gene into Watanabe rabbits via intravenous injection (39) and a bilirubin-uridine diphosphoglucuronate (UDP)-glucuronosyltransferase-1 gene into Gunn rats (40). The gene of interest was expressed in sufficient amounts to correct the endogenous deficiency in these animal models.

### C. Delivery of Antisense Oligonucleotides

Antisense oligodeoxynucleotides (ODN) are attractive nucleic acids to deliver to cells because they can match corresponding RNA sequences and block translation or induce enzymatic digestion of the RNA–DNA hybrid by RNase H. For example, the ASGP-receptor-mediated system has been used to deliver antisense oligonucleotides into hepatocytes to block viral expression (41). A 21-mer antisense ODN against the HBV polyA signal sequence (nt 1903 to 1923) was synthesized and complexed with ASOR–poly-L-lysine carrier. The complex was administered to HepG2 2.2.15 cell lines possessing ASGP receptors and stable HBV viral expression and infectious particle formation. Twenty four h later, HBV DNA replication and HBsAg expression was found to be suppressed by 80%, and the effect persisted for up to 6 days thereafter. To investigate further whether treating cells with antisense ODN may actually protect cells from HBV infection, a phosphorothioate-modified 21-mer antisense ODN complementary to the HBV polyA signal and 5'-upstream sequence was prepared (42). The 21-mer was delivered to Huh7 cells [ASGP receptor (+) and HBV viral expression (–)] after forming a complex with ASGP–poly-L-lysine carrier. Subsequent transfection of these cells with HBV-encoding plasmids ( $6.5 \times 10^5$  copies per cell) showed strong suppression of HBV replicaton and gene expression. Compared with control groups treated with antisense ODN alone, in cells pre-

treated with antisense ODN delivered by the ASOR–poly-L-lysine system, HBV viral DNA was undetectable (less than 0.1 pg as determined by quantitative PCR), HBV viral transcription was suppressed by 60%, and HBsAg expression was decreased by 97%. Similar results were also demonstrated by Madon and Blum (43). In this case, an antisense ODN complementary to the HBV encapsidation signal was synthesized and coupled to N-acetyl-glucosaminated albumin–poly-L-lysine conjugates, which was cotransfected with an HBV-encoding plasmid into a chicken hepatoma cell line LMH. Viral replication was decreased significantly.

To study antiviral effects in animals, Bartholomew et al. administered antisense ODN (complementary to the polyA signal and adjacent upstream sequences of woodchuck hepatitis virus, WHV) complexed with ASOR–poly-L-lysine conjugates intravenously to infected woodchucks for five consecutive days. This significantly suppressed WHV viremia, detected as a 10-fold decrease in circulating viral DNA on day 25, and was persistent for at least 2 weeks (44).

## IV. RECENT IMPROVEMENTS IN POLY-L-LYSINE CONJUGATED RECEPTOR-MEDIATED SYSTEMS

### A. Coupling of Fusogenic Proteins

A major obstacle in applying ASGP receptor and other receptor-mediated systems has been the degradation of internalized DNA in lysosomes. Several attempts have been made to overcome this problem by adding viral fusogenic proteins or coinfecting with viruses that can fuse and disrupt endosome-lysosome vesicles. Influenza hemagglutinin (HA) protein (45,46) and vesicular stomatitis virus (VSV) G protein (47) were used to improve the gene delivery in targeting cells. Bongartz *et al.* (45) chemically conjugated HA protein to phosphorothioate-modified antisense oligodeoxynucleotides (anti-TAT) and cultured the DNA–protein complex with HIV-infected lymphocytes. The anti-HIV activity of the antisense ODN was enhanced up to 10-fold. Coupling of HA2 protein to poly-L-lysine–transferrin–DNA complex increased expression of reporter genes in targeted cells. Also, replication-defective adenoviral particles were conjugated with poly-L-lysine–ASOR–DNA complexes to deliver a canine factor IX gene into murine primary hepatocytes, resulting in significant expression of canine factor IX in culture medium (48). Wild-type adenovirus (type 5) or replication-defective adenoviral particles were conjugated to the ASOR–poly-L-lysine–DNA system. The number of infected cells increased by 200-fold, and expression of the targeting gene, HBsAg, was enhanced dramatically 13- to 30-fold.

## B. Modification of Polymers

Novel vectors have been prepared by covering DNA–poly-L-lysine complexes with protective hydrophilic polymers, such as polyethylene glycol (PEG), dextran or poly[N-(2-hydroxypropyl)methacrylamide] (pHPMA). These modified polymers resulted in self-assembly of DNA, shielded surface charge, increased solubility, and enhanced transfection efficiency (49,50).

PEG also has protective effects to DNA–poly-L-lysine complexes. Results showed that coating poly-L-lysine–DNA complex with PEG significantly enhanced the resistance to nucleases in vitro. The shielding effect was correlated to the length of the polymer (51).

## C. Application of Other Polymers

Polyethyleneimine (PEI) has been applied in receptor-mediated systems recently. PEI was conjugated with 5% galactose and coupled with plasmid DNA encoding a reporter gene (luciferase or beta galactosidase). This complex was then used to transfect a human hepatoblastoma cell line HepG2 with 50% efficiency. The transfection was galactose-residue-dependent and ASGP-receptor-dependent, as it was abolished in the presence of an excess of asialofetuin (52). In addition, galactocerebroside-incorporated liposomes were used to transfer PEI-coupled DNA complexes to the human hepatoma cell line Huh7 and to isolated rat hepatocytes (53). Recently, Bandyopadhyay et al. applied galactocerebroside-modified liposomes to transfer a lactosylated PEI-complexed chimeric RNA/DNA oligonucleotide carrying an A/C conversion at Ser365 of rat factor IX gene into isolated rat hepatocytes (54). Transfection efficiency was 100%, and the conversion rate was 19–24%.

## Bioartificial Pancreas

**Riccardo Calafiore**

*University of Perugia School of Medicine, Perugia, Italy*

### I. FOREWORD

The biohybrid artificial pancreas (BAP) represents one of the most challenging, complex, and promising applications of a relatively new science: tissue engineering. Tissue engineering has been defined as “an interdisciplinary field which applies the principles of engineering and life sciences towards the development of biological substitutes that aim to maintain, restore or improve tissue function” (1). Sometimes, even excellent artificial devices must comply with restrictions and specific requirements associated with the biological counterpart, in order to secure optimal functional performance.

In general, every organ that can be broken apart into single cells or cell clusters with no disruption of the original function is usually suitable for generating a bioartificial organ. However, it may be hard to preserve the functional identity of cellular units placed in environmental conditions that usually are quite different from their native site. Furthermore, only selected materials enable creation of a tissue/material interface that is harmless to both the embodied cells and the host’s tissue. Specific issues associated with natural or engineered tissues that are entrusted with prevalently mechanical tasks, such as skin, bone or cartilage, significantly differ from those involving sophisticated cell systems that govern complex metabolic functions, like endocrine and liver cells. Nevertheless, common pathways

should be explored regardless of the specific feature that is incorporated by a certain cellular system. In particular, special care must be taken not only to assess the material’s physicochemical properties and biocompatibility but also to select the tissue’s sources, in compliance with physiological competence and safety principles. Finally, the overall suitability of the newly developed biohybrid devices for clinical application must be also carefully assessed.

### A. Field of Application of the BAP

The BAP, composed of intact and viable insulin-producing cells that are protected from the host’s immune reaction by highly biocompatible, selective permeable and chemically stable artificial membranes, would ideally apply to the potential cure of insulin-dependent (type I or type II) diabetes mellitus (DM) by transplantation. In fact, a BAP that contains insulin-producing cells would provide for continuous insulin delivery, under strict regulation by the extracellular glucose levels. The goal of such a “totally automatic treatment” (Table 1) for DM could be also theoretically accomplished by creating an “artificial pancreas.” In this instance, a glucose sensor (1) implanted subcutaneously would continuously record extracellular glucose levels and convert the chemical information into an electronic signal by a minicomputerized system. This would regulate in turn the release of prestored insulin by a minipump in order to

maintain normoglycemia. This machinery, while able to reverse hyperglycemia, has been preliminarily proven to function, so far, for only very limited periods of time, due to still pending technical problems.

## II. DM: EPIDEMIOLOGY, PATHOGENESIS, AND CLINICAL FEATURES

DM is the most common endocrine disorder, hallmarked by metabolic abnormalities such as elevated blood glucose levels and their biochemical consequences, that may provoke acute illness or result, during the course of the disease, in secondary chronic complications (2). These mainly affect eyes, kidney, nerves and blood vessels. It is not an immediately life-threatening disease anymore, in the majority of instances, provided that the patients are promptly and adequately treated, but DM still represents a potentially lethal and certainly highly disabling disease. It is estimated that over 100 million people in the world actually suffer from either type I or type II DM, the difference between these two forms depending upon etiopathogenesis (Table 2). The prevalence of cumulative type I and type II DM in 1995 in Europe and the Americas was 32.8 and 30.7/1000 population, respectively, but these figures are expected to rise to 47.5 and 63.5/1000, respectively, in 2025 (3). At the clinical onset of type I insulin-dependent DM that affects mainly, but not exclusively, adolescent/young individuals, the majority of islet  $\beta$ -cells have been completely destroyed by autoimmunity. On the basis of a quite clear genetic susceptibility that can be identified in patients at risk of developing type I DM in the form of defined gene haplotypes, the disease process is triggered

by only partially known environmental, infectious (i.e., viruses), or chemical toxic agents. Environmental agents indeed play a major role in triggering the onset of overt DM, which is confirmed by observations in haploidentical twins. In fact, if type I DM were a pure genetic disorder, it would affect not 50%, as it actually does, but rather 100% of identical twins. Upon intervention of these agents, the autoimmune attack will begin, although this process is clinically silent, while the pancreatic islets are progressively being infiltrated with mononuclear cells (i.e., macrophages, monocytes) and activated cytotoxic T lymphocytes (“insulinitis”). At this time, in the serum of the affected individuals, several autoantibody fractions, specifically targeting selected  $\beta$ -cell antigens, are detectable (i.e., anti-insulin, antityrosin phosphatase, antiglutammic-decarboxylase acid, etc.). The condition where autoimmunity is active, but the patients still look healthy, is defined the “prediabetes.” This stage of the disease may last for variable periods of time, even years, but it abruptly ends when over 90% of the original  $\beta$ -cell mass has been destroyed. At this point, the residual endogenous insulin production is no more able to counteract elevations in blood glucose levels. The patients will develop hyperglycemia, polyuria, polydipsia, ketonuria, and body weight loss and will undergo severe derangements of fluid and electrolyte balance, culminating with ketoacidotic coma. If not promptly treated this condition may lead to ketotic coma and death.

Since type I DM patients will require lifelong, multiple daily insulin injections, they unfortunately represent a heavy burden to society. In fact, if these individuals have seen their life expectancy gradually improve from the introduction of insulin therapy, their increased longevity has not resulted in elimination of the risk of developing chronic, often very serious complications of the disease, such as premature blindness, terminal renal insufficiency, vascular disease, and disabling neuropathy. These complications may occur in spite of the selected insulin therapy regimens because it is very difficult to mimic performance of the glucose sensing apparatus incorporated in normal  $\beta$ -cells. Consequently, the physiological stimulus-coupled

**Table 38.2** Classification of Diabetes Mellitus

Primary	Secondary
Autoimmune (Type I)	Pancreatic disorders

Nonautoimmune	Genetic syndromes
Insulin-dependent	Miscellaneous agents
Non-insulin-dependent	
“Maturity onset” (MODY)	

insulin secretory response is far from being reproduced by subcutaneous exogenous insulin injections.

### III. DM: INSULIN THERAPY REGIMENS

The most actual and effective way to prevent the onset of secondary complications in patients with type I, insulin-dependent DM (T1DM) is based on strict blood glucose control, especially in coincidence with meals, so as to avoid hyper-/hypoglycemia. This goal may be achieved by injecting either short- or long-acting insulin molecules, as frequently as four times a day, according to the indications of the Diabetes Control Complications Trial (DCCT) Study Group (4,5). An important mirror of the ability to keep T1DM patients under good blood glucose control is represented by concentration of the glycosylated hemoglobin (HbA1c): the higher this parameter (reflecting % of glucose-bound hemoglobin), the worse the degree of metabolic control. Insulin administration, according to intensive, multiple daily-dose regimen protocols, as suggested by DCCT, actually represents the most effective tool to treat T1DM. Unfortunately, this therapeutic option is associated with at least two major pitfalls: (1) patients are exposed to a high risk of developing severe hypoglycemia, and (2) the risk of developing secondary complications of the disease is attenuated, but not eliminated. Finally, patients' compliance with intensive insulin therapy may be quite poor, because of both strict blood glucose monitoring that involves multiple finger pricks, and insulin injections. The imperfect blood glucose control achieved by subcutaneously injected exogenous insulin is a fundamental pitfall consisting of the physical distance between the insulin injection site and the liver, that represents the first physiological site of insulin action.

### IV. T1DM: "AUTOMATIC TREATMENT"

In light of the above-reviewed concerns, the "T1DM problem" could be solved only if the original physiological model, namely viable and functional insulin producing  $\beta$ -cells, was fully reconstituted. Such a goal might be accomplished by transplanting the endocrine pancreas as a whole organ or as isolated human/nonhuman, primary or engineered islet cells (6) (Table 3). BAP could offer the opportunity to graft the islet cells within artificial membranes so as to prevent immune destruction of the transplanted tissue with no recipient's general immunosuppression.

#### A. Whole Pancreas Transplantation

Whole pancreatic transplantation would apparently look closer than islets to short-term or mid-term clinical appli-

cability. Combined (simultaneous or temporally deferred) pancreas + kidney (PK) transplant in T1DM patients that are also affected by terminal renal insufficiency, and are in a waiting list for renal transplant, represents a relatively safe and viable procedure, as compared to kidney transplant alone, in terms of both patient and graft survival (7). However, this approach, in the best conditions, could only apply to patients with T1DM who require a simultaneous kidney graft, thereby inevitably cutting off younger patients, who are specifically eligible for pancreas transplant alone (PTA). Furthermore, PTA has been associated with significantly lower clinical success and higher morbidity in comparison with PK. The invariable need for life-long pharmacologic immunosuppression, based on still poorly selective agents, makes this approach ethically acceptable only to those patients with T1DM that either need PK or alternatively, suffer from brittle diabetes, and are not adequately responsive to conventional insulin therapy. These concepts have been included in the recommendations of the American Diabetes Association (8). It is worth mentioning that although much improved, the morbidity and mortality associated with whole pancreatic graft continue to be relevant. Consequently, whether to apply the whole-pancreas transplant to selected T1DM patient cohorts remains difficult. Hopefully, the introduction of more specific immunosuppressive agents will broaden the applicability spectrum of this therapeutic option in the not too distant future.

#### B. Islet Cell Transplantation

Isolated islet transplantation would be incomparably less invasive, in comparison with a whole pancreatic graft, since the islets, which represent only 1–2% of the total pancreatic mass, are usually injected through percutaneous cannulation of the porta vein, directly into the liver, under local anesthesia. However, in spite of the potential advantages associated with islets over whole organs (Table 4), the immune problems involved are similar, while clinical results, as reported by the last International Islet Transplant Registry Newsletter (9) look even poorer. According to the

**Table 38.4** Islets over Whole Pancreatic Grafts—Potential Advantages

1. Lower graft mass (1–2% of the whole pancreas)
2. Minor surgery
3. In vitro immunomanipulation
4. Cryogenic storage
5. Immunoisolation in artificial membranes

Islet Registry, as of June 1999 only about 8% of the patients with T1DM, receiving islet allografts (islets separated and purified from cadaveric human donor pancreata) have achieved full insulin-independence at 1 year post-transplant. The vast majority of these patients were affected by terminal renal insufficiency, and they either required a simultaneous or already carried a stable kidney graft. On the contrary, about 40% of totally pancreatectomized patients (usually undergoing upper abdominal exenteration for malignancy), receiving intrahepatic islet allografts, under general immunosuppression, have been reported to enjoy insulin independence at the same clinical follow-up time period (PIDM-Allo). The 1-yr remission percentage was raised to 50 when autologous islets were injected into patients that had undergone total pancreatectomy subsequent to chronic pancreatitis (PIDM-Auto) (Fig. 1). A major variable associated with these clinical trials was the host's immune competence, which obviously was more stringent for patients with T1DM than for those with pancreatectomy-induced diabetes, where no autoimmunity would ever occur. Autoimmunity has been clearly reported to recur in whole pancreatic grafts, and it has been deemed to play a major role in islet graft-directed immune destruction as well (10).

In summary, both immune rejection and recurrent autoimmunity have severely hampered the progress of islet transplantation into clinical trials, also in terms of the total

number of patients (close to 500) that have undergone, so far, this procedure, according to the Registry. The reasons for this limitation are multiple, beginning with restrictions for recruiting the potential candidates to graft. Only a major or life-saving organ graft could, in fact, justify general immunosuppression with its life-threatening side effects. Therefore only a few patients with T1DM have been thus far enrolled into clinical trials. Furthermore, the islets are not a solid organ, and while problems of islet yield and purity are gradually being overcome, in many instances it may be still difficult to separate an islet mass, from a single pancreas, that is adequate for grafting a single T1DM recipient. As far as immunity is concerned, very recent attempts to perform human islet allografts alone, using putatively safer and more selective immunosuppressants (Table 5) are in progress. It is too early to anticipate the outcome of these trials. However, even in the best case, where the stable reversal of hyperglycemia and the absence of severe immunosuppression-related side effects were achieved, a major issue would still be the restricted availability of cadaveric human donor organs. Finally, prevention of allograft-directed immune destruction, by use of old or newly developed immunosuppressive agents, may not equally succeed in obviating the autoimmune recurrence of T1DM.

A potential solution could be to use alternate islet sources to both avoid tissue shortage, while preventing recurrent autoimmunity, and in parallel develop alternate strategies to protect islet grafts from the immune destruction, with no recipient's general immunosuppression. It is current opinion that either adult (11) or neonatal (12,13) porcine islets might successfully replace human donor tissue, provided that they were properly immunoprotected. On one hand, pork insulin would be acceptable to humans, and on the other hand, it would be possible to create specific pathogen free (SPF) pig breeding stocks that comply with standard safety requirements.

With regard to alternatives to general immunosuppression, two main strategies seem to be feasible at this juncture (Table 6). Creation of properly assembled physical immunobarriers will be the subject of this review on the actual perspectives associated with the BAP. The possibility of inducing a state of donor's immune unresponsiveness continues to be appealing and controversial at the same time. Recent reports seem to speak in favor of using novel approaches to modulate the host's immune response. These would consist of employing new agents in conjunction with the induction of microchimerism, the latter being obtained by grafting homologous bone marrow cells, before islets. While this approach preliminarily looks encouraging (14), caution should be used in assessing whether such manipulation of the host's immune system may satisfactorily fulfill safety criteria that would apply even to pilot clinical trials.

**V. THE BAP: GENERAL FEATURES**

The basic principles that development of a safe and reliable prototype of a BAP should conform to are the following: (1) unlimited access to islet tissue sources, whether they are primary or engineered human/nonhuman islet cells, in strict compliance with recommendations of regulatory agencies and ethical committees; (2) availability of artificial materials that are properly engineered, so as to avoid any harmful effects on both the transplanted tissue and the host; (3) elimination of any kind of recipient’s general immunosuppression. Simply, a BAP is a hybrid device that embodies viable and functional islet cells within selective permeable and highly biocompatible artificial membranes.

The biological component, the islets, should be able to survive in a possibly hostile and certainly new microenvironment, while retaining the ability to secrete insulin, according to physiological algorithms, in order to avoid delays of insulin action.

The artificial component should fulfill specific criteria, such as membrane physicochemical properties that are compatible with a membrane’s selective porosity, filtration, and permeability. In fact, it is mandatory that the embodied islets receive adequate nutrient supply, in order to permit biochemical exchange, with special regard to oxygen and macro- and microsolute, glucose, and insulin included. Nonetheless, on the other hand, the membrane’s selective cutoff properties should strictly interdict access to cellular as well as humoral mediators of the islet graft-directed immune destruction.

The ambitious goal of generating a biohybrid device that is fully able to substitute the human endocrine pan-

creas has been relentlessly pursued for decades (15). No clear and ultimate success has been so far achieved, although there are initial promising results and novel research hints. What had initially appeared as quite a feasible task has been proven to represent one of the most difficult challenges in medicine. In fact, the islets cells constitute a highly differentiated cellular system, equipped with a sophisticated glucose sensing apparatus that is very difficult to reproduce. Moreover, adult islet  $\beta$ -cells do not replicate (mitotic rate 1–2%) (16), and there is consequently no hope that any eventual loss in the transplanted islet mass may be replaced by islet cell proliferation. Although some mitotic figures have been detected within microencapsulated islets (17), these are totally insufficient to secure sufficient islet  $\beta$ -cell turnover. As a further complication, the islets contained in any type of BAP, differently from naked islets, cannot be revascularized or reinnervated upon transplant, and their nourishment will solely depend upon gas/metabolite passive diffusion. With regard to this matter, a pivotal role seems to be played by the graft site, in strict relation to the device’s geometry. Some sites, such as the subcutaneous tissue, would provide  $O_2$  gradients that seemingly are insufficient for the islet cell metabolic requirements. Progressively relevant, over time, also is the issue of device morphology and configuration that is strictly associated with both immunoisolation capacity and provision for adequate nutrient supply. The window between the membrane’s molecular weight cutoff that permits ingress of indispensable molecules, while providing for immunoisolation, is very narrow, and it continues to represent the Holy Grail for the entire field of BAP clinical application to the therapy of T1DM.

## VI. BAP: PHYSICAL CONFIGURATION

Different prototypes of a BAP have been designed and developed over the past few decades (Fig. 2) (18). In general, the classification is still valid that keeps macrodevices and microcapsules as distinct entities, although many of the old notions in the field have become obsolete, in light of the latest accomplishments.

The greater attention devoted to microcapsules than to macrodevices in this chapter does not necessarily reflect the formers' better performance but rather outlines the wider body of information that has been achieved by microencapsulation. Nevertheless, the potential impact of newer macrodevice strategies on BAP development is well acknowledged.

### A. Macrodevices

A wide range of biomaterials have been considered suitable for the fabrication of devices that would allow for islet graft immunoisolation. The most common of them (Table 7) are still in use, with special regard to PAN-PVC, although many once innovative concepts are progressively fading away. In particular, the macrodevice geometry (Fig.

**Table 38.7** Biomaterials for Fabrication of Macrodevices

1. Polyacrylonitrile-polyvinylchloride (PAN-PVC)
2. Acrylates
3. Cellulose acetate
4. Cellulose mixed esters
5. Polytetrafluoroethylene (PTFE)
6. Alginates
7. Polyethylene glycol (PEG)

2) includes a few types, some of which hold mere historical value, at this juncture, although they have been associated with remarkable results in experimental islet transplantation trials in the past. In particular, hollow fibers have been extensively employed for subcutaneous (19) or intraperitoneal (20) islet grafts. The fibers were made of a selective permeable macromembrane (molecular weight cutoff—MWCO—50–70 kD) that while impeding ingress to immune cells and antibodies was supposed to be highly biocompatible and allow for biochemical exchange. While successful in a few rodent trials, these devices have shown to correct diabetes in higher mammals only sporadically. Major limitations derive from the low islet survival rate inside the chambers, possibly due to restricted nutrient

**Figure 38.2** Types of immunoisolation devices for islet transplant: (1) vascular chamber containing matrix-embedded islets (23); (2) vascular prosthesis containing AG/PLO encapsulated islets (24); (3) hollow fiber containing matrix embedded islets (19, 27); (4) Laminar AG thin sheet containing monolayered islets (Hanuman Medical, personal communication); (5) AG-based microcapsules of different size (CSM, MSM, CM) (25, 69, 40, 33, 57, 64, 61).

supply. The latter likely depended on the graft site but also on the physicochemical properties of the employed materials. A major, often erratically solved problem, was fibroblast overgrowth of the chambers that resulted in membranes' pore clogging, thereby further limiting O<sub>2</sub>/nutrient supply.

It was commonly observed that when loaded "plain" in the device, the islets were associated with quite a limited survival rate. This specific problem was overcome using a gel matrix to embed the islets prior to the fiber's loading process. The matrix, usually an alginate gel, greatly improved the islet viability. Unfortunately, the trade-off was that the matrix-embedded islet loading capacity was very low, thereby imposing the use of larger-size devices to obtain sufficient metabolic results in the grafted diabetic animal models (21). It is likely that if this order of magnitude were to be applied to a high mammal transplant setting, every patient would require several "meters" of fibers filled with matrix-embedded islets.

As far as the fibrotic overgrowth, and in particular the fiber environmental conditions for islet bedding, are concerned, significant progress has been made in an attempt to provide the embodied islets with sufficient O<sub>2</sub> nutrient supply: the idea of prevascularizing the device, prior to the islet entrapment, has resulted in interesting preliminary results in rodents (22). Whether these findings will foster renewed efforts in this specific research field will be the subject of future assessment.

Another possible strategy to use macrodevices for islet transplantation has consisted of seeding the islets in a special compartment chamber, directly anastomosed to blood vessels, usually as arterio-vein shunts. In this way, the islets were continuously perfused by blood ultrafiltrate, which seemingly facilitated biochemical exchange. The membrane, at contact with the bloodstream, was associated with an appropriate MWCO (commonly below 100 kD) so as to prevent immune cells or antibodies from crossing the islet containing chamber's wall. The vascular approach, while brilliant in principle, and preliminarily associated with results that were convincingly positive in diabetic dogs (23), although not in humans, where only partial and transient remission of hyperglycemia was achieved (24) (in this setting the islets had been microencapsulated prior to loading in the vascular prosthesis), has left open many issues. In particular, the risk for the devices' clotting/breakage, with subsequent need for intense anticoagulation of the recipients, has never permitted thorough assessment of the procedure's safety.

Recently, ultrathin immunoisolatory sheets, made of highly biocompatible alginate, where the islets are homogeneously monolayered, seem to be particularly appealing. The alginate sheet represents a very versatile macrodevice

that couples safety requirements such as (1) retrievability; (2) biocompatibility (one of the most studied biomaterials, Na alginate, is employed); (3) physical configuration (O<sub>2</sub>/nutrient supply is facilitated by the minimal diffusion distance) to reduce trauma. The sheet may be virtually implanted anywhere in the mesenteric area. Preliminary data with this new generation of macrodevices in pilot diabetic canine graft trials look encouraging, although it is premature to make any forecast on the future impact of this technology on islet transplantation (personal communication, Hanuman Medical, San Francisco, CA, USA, March 2000). In summary, while the past generation of macrodevices was associated with a number of disadvantages, the latest developed prototypes hold promises for broader application in diabetic higher mammals.

## B. Microcapsules

### 1. Technical Procedures

Microcapsules fabricated with alginic acid derivatives, chemically linked to polyaminoacids, have represented the most widely known and studied kind of microimmunobarrier for islet cell transplantation. According to the original Lim and Sun recipe (25), microcapsules were fabricated by suspending the islets in sodium alginate (AG), a polysaccharide seaweed derivative, and subsequently by extruding the alginate-islet mixture through a microdroplet generator (Fig. 3). The islet containing microdroplets were collected on a calcium chloride bath, which immediately turned them into gel microspheres. The calcium alginate gel microbeads were then subsequently coated with aminoacidic polycations, such as poly-L-lysine (PLL), or uniquely in our laboratory, poly-L-ornithine (PLO). The outer coat was comprised of highly purified sodium alginate that provided the multilayered selective permeable membrane with additional biocompatibility (Figs. 4 and 5). These "conventional-size microcapsules" (CSM), measuring an average of 700–800 μm in equatorial diameter, have

**Figure 38.3** Microdroplet generator for microcapsule fabrication. (From Univ. of Perugia.)

**Figure 38.4** Freshly prepared AG/PLO microcapsules containing human islets (staining with Dithizone, 25 $\times$ ); morphological integrity is evident. (From Univ. of Perugia.)

undergone several adjustments, including scale-up protocols, in our and a few other laboratories (26,27).

Other procedures, still involving the use of alginate, although by different chemistries or consisting of chemically different reagents, will be discussed later. In general, regardless of more or less pronounced differences in the fabricative procedure, a limited number of experimental trials has been reported on the use of these alginate alternatives for microencapsulation in diabetic animal graft trials.

## 2. Achieved Results

Most either allogeneic or xenogeneic islets containing AG-PLL/PLO microcapsules have been usually implanted in

**Figure 38.5** Scanning electron microscopy examination of AG/PLO microcapsules: intactness and smoothness of the coating membranes are evident (20 kV). (From Univ. of Perugia.)

the peritoneal cavity, into diabetic hosts that were not generally immunosuppressed. Unfortunately, the lack of standardized materials and procedures has hampered impartial assessment of the results communicated by different laboratories. In general, rodent studies were associated with greater and more consistent success, in terms of full remission of hyperglycemia, following microencapsulated islet TX, as compared to higher mammal trials (28). Nevertheless, the transplanted rodents carrying spontaneous autoimmune diabetes (NOD mice, BB rats) have shown lower remission rates than mice and rats, where diabetes had been artificially induced by streptozotocin (29,30). Briefly, the most experienced laboratories provided convincing evidence that the microencapsulated islet system may work satisfactorily in small-size animals. On the contrary, very few reports documented the reversal of hyperglycemia with the discontinuation of exogenous insulin injections in dogs with spontaneous or pancreatectomy-induced diabetes, receiving intraperitoneal microencapsulated canine or porcine islet grafts (Table 8). In this high mammal animal model, full reversal of hyperglycemia was partially accomplished when the encapsulated islets had been embodied in a special vascular chamber, directly anastomosed to blood vessels (31). The canine background permitted us to initiate pilot human clinical trials in our laboratory, that were associated with only partial and transient metabolic results. Preliminary success has been reported in dogs (32) and T1DM patients (33) receiving intraperitoneal canine or human islet allografts, respectively, but only when the recipients underwent a course of general immunosuppression with cyclosporin. An important exception to this uncertain trend was represented by a successful trial of AG-PLL encapsulated porcine islet xenograft into spontaneously diabetic, nonimmunosuppressed monkeys. In these animals, full remission of hyperglycemia and exogenous insulin withdrawal were achieved in all recipients, and sustained in some of them for extraordinary long periods of time, throughout 3 years of post-TX follow-up (34). This striking, so far unique result, indeed proves the principle that under the best conditions, microcapsules may constitute an effective, biocompatible, and immunoselective physical barrier that enables immunoprotection of islet xenografts with no general immunosuppression of the host.

## 3. Pitfalls

The trials of encapsulated islet cell allo- or xenografts in nonimmunosuppressed diabetic recipients have shown, with anecdotal exceptions, that the encapsulation system still needs to surmount unsolved problems. In particular, it has not yet determined whether AG-PPL/PLO represents the best chemical formulation to prepare highly biocompatible and selective permeable microcapsules. For this

**Table 38.8** TX of Allo/xenogeneic Islet Containing STD Microcapsules TX in Diabetic High Mammalians

purpose, studies focusing on generation of new biopolymers for microcapsulation should be highly pursued. It remains unclear whether the actual microcapsule design should be modified or implemented, in order both to improve the functional, possibly long-term performance of these membranes and better to regulate the enveloped islet mass (35). Moreover, the potential role of immune cells that may be part of the islet cell populations, within microcapsules, should also be studied (36).

**VII. GENERAL ISSUES RELATED TO IMMUNOISOLATED ISLET GRAFTS**

There are issues, in the development of BAP that require special attention.

**A. Mechanisms of Islet Graft Destruction**

1. Immunomediated

a. *Allograft*

*Naked islet transplantation.* Allogeneic and discordant/nondiscordant xenogeneic islet transplants have been studied in either patients or animal models of diabetes. From extensive observations, even if many aspects of the islet graft-directed immune destruction remain unknown, there are few doubts that two conditions need to be examined, Immune rejection, and the Recurrence of autoimmune diabetes.

*Role of cellular immunity.* According to Gill (37), T lymphocytes (Tc) detect foreign antigens as peptides that are presented in association with major histocompatibility complex (MHC) molecules. In particular, CD8 Tc recognize antigens presented in association with class I MHC molecules, whereas CD4 Tc generally recognize antigens presented with class II MHC. However, two signals are required for Tc activation: signal 1 is provided by Tc receptor/antigen binding; signal 2, “costimulator,” is provided by non-antigen-specific signals from an antigen presenting cell (APC) (ie, macrophage, dendritic cell, etc.). The process defined as costimulation comprises a

complex cell surface receptor–ligand interactions network, which has been partly clarified in recent years (Fig. 6). Typical participants in such interactions are CD80/CD86 molecules, expressed by APC which bind CD28 coreceptor molecules on Tc; interactions between CD40 on APC with CD40L on Tc also result in important costimulatory signals. The role played by costimulatory molecules in inducing islet allograft rejection is shown by observations where blocking CD40/CD40L interactions in vivo could result in indefinite islet allograft survival (38). Gill (39) has elegantly explained that two antigen presentation forms can fulfill this two-signal requirement for Tc activation:

Direct (or donor MCH-restricted) antigen presentation, in which Tc engage native MHC molecules directly on the surface of donor-derived APC

Indirect (or host MHC-restricted) antigen presentation, in which donor-derived antigens are captured by recipient APC, processed, and re-presented in association with recipient MHC molecules.

Exogenous antigens are usually processed and presented by class II MHC molecules and so are associated with predominant CD4 response.

**Figure 38.6** Pathways of β-cell-directed cellular immune attack.

*Autoimmunity.* A relevant issue that needs to be properly examined in islet cell transplantation in type I DM regards autoimmune recurrence of the disease on the transplanted tissue. Recurring disease has been shown to destroy transplanted islet tissue in either animal models of autoimmune diabetes or in man. Evidence can be now marshaled about the fact that Tc-dependent autoimmune islet injuries behave similarly to the xenograft-mediated response, in that islet damage can be triggered by autoreactive CD4 Tc, which are specific for islet-associated antigens, processed and presented by APC, similar to the indirect pathway immune response process. Although CD8 Tc may contribute to developing islet graft-directed autoimmune destruction, the latter clearly appears to be a CD4 Tc-mediated event.

Overall strategies so far employed to prevent islet allograft-directed immunity have included both general immunosuppressive agents, as mentioned elsewhere, and molecular mechanisms to block the costimulator pathway, such as blocking CD40-CD40L and B7/B28 interactions. The former have been usually applied to human islet allografts, by using different pharmacological agent cocktails. The latter have been preliminarily studied in lower and higher mammal animal models of diabetes (40).

#### b. Xenograft

When dealing with xenogeneic islet transplantation, both cellular and humoral immunity play a major role in inducing rapid destruction of the foreign tissue.

*Role of humoral immunity.* Hyperacute rejection will rapidly destroy xenogeneic discordant organ/tissue vascularized transplants by intervention of naturally occurring xenoreactive antibodies present in the host. These antibodies bind to antigens located on the surface of endothelial cells within the xenograft, an event that in turn activates complement with subsequent graft destruction (41). The most important target of these antibodies is represented by the terminal carbohydrate galactose  $\alpha(1,3)$ -galactose. The presence of  $\alpha$ -Gal in high levels, in all adult porcine endothelial cells, accounts for the immediate activation of a heterologous host's immune system.  $\alpha$ -Gal expression seems to be lower in neonatal pig islets, which should confer them a relatively higher extent of protection when implanted in xenogeneic hosts (41). Among several possible strategies that now are available for immunoprotection of xenogeneic discordant grafts, with special regard to potential use of pig tissue in humans, a recent one includes generation of transgenic pigs that express human complement-regulatory proteins (41). These proteins, CD 55 (DAF, decay accelerating factor), CD 46 (MCP-1, membrane cofactor protein), and CD 59 (protectin), do not impede anti- $\alpha$ Gal antibody binding to endothelial cells, and thereby

complement activation. These factors, however, inhibit subsequent steps of the complement cascade and finally prevent cell lysis. Results so far achieved with transgenically modified organs, and particularly with islet cells separated from the pancreata obtained from these animals, are still premature to interpret and seemingly warrant further investigation.

*Role of cellular immunity.* Islet xenograft rejection is less dependent on donor APC than allograft. In fact, depletion of passenger leukocytes is not associated with the beneficial effects described for allografts. Xenograft rejection may occur in the absence of CD 8 Tc, while CD 4 Tc are predominantly involved with the immune destruction process, which reflects the steps already described for the indirect pathway (Gill).

In conclusion, islet xenograft rejection is an extremely rapid and devastating process, that involves both the humoral and cellular loops of the host's immune response system and is very difficult to contrast with conventionally available strategies. Potential progress in this field could be represented by the availability of transgenically modified pigs, that should turn a "xenogeneic discordant" into an "allogeneic" islet graft system. Use of biohybrid device strategies could dramatically impact this particular islet graft setting.

#### c. Immunoisolated Islet Transplantation

*Allograft immunity.* Since the above mentioned immune mechanisms mainly consist of direct engagement of Tc subpopulations (ie, CD 8 Tc) with donor cells, physical isolation of the islet graft within a BAP device should result, by preventing direct cell-to-cell contact between graft and the host's immune system, in much easier biologic acceptance.

*Xenograft immunity.* If BAP may effectively prevent ingress of both various antibody (including xenogeneic naturally occurring antibodies) and complement fractions, owing to its membrane's cutoff exclusion properties, it cannot fully eliminate the risk for activation of CD 4-driven cellular reactivity. Small-size molecules ("shed antigens" such as proteins, enzymes, etc.) might cross the BAP membranes due to their small size, ranging on a few kD. These molecules could be incorporated, processed, and presented on a host's APC, thereby triggering CD 4-driven significant inflammatory reaction. Either small cytokines, or nitric oxide, or free oxygen radicals, released by the inflammatory cells, individually or collectively, could easily result in the final destruction of the immunoisolated islets. For this purpose, Gill has proposed that "immunoisolating" membranes should be simply defined as "isolating" (39).

*Autoimmune recurrence of disease.* As said above this

type of immune reactivity may be assimilated to xenograft immunity as far as the involved cellular mechanisms are concerned. It may eventually affect the extent of cellular inflammatory response that is elicited in the immediate vicinity of BAP subsequent to graft into a diabetic recipient (Gill).

However, these putative immune mechanisms of immunoisolated islet graft destruction are in contrast with several reports documenting long-term protection of the encapsulated islets from the host's immune response in either low or high diabetic mammals both *in vivo* and *in vitro* (42). For instance, we had made an original observation, in our laboratory, where in a static incubation system, either free or AG-PLO encapsulated rat islets had been exposed to 17 kD,  $\beta$ -recombinant human interleukin 1 (IL-1). Theoretically, such a small molecule should have easily crossed the capsular barrier, and provoked effects similar to those observed in unencapsulated islets that, upon IL-1 exposure, underwent loss of both cellular architecture (Figs. 7ab and 8ab) and functional competence (Fig. 9). On the contrary, the encapsulated islets were intact and retained their insulin secretion capacity. It probably was just a matter of physical distance, since in that experiment we had employed CSM, although a stereochemical molecule binding process might not be excluded. Therefore further study is required of the limits and pitfalls of immunoisolation strategies to prevent the islet graft-directed immune phenomena, as specifically reported below.

## 2. Not Immunomediated

Many potential pathways that do not include immune events may theoretically lead to restricted survival and functional performance of immunoisolated islet grafts. The BAP's (whether it be composed of macrodevices or microcapsules) overgrowth with fibroblasts is a common cause for graft failure. As said elsewhere, this phenomenon may depend on the material biocompatibility but also on the islet cell capacity to adapt to new environmental conditions. These obviously are quite distant from those of the native endocrine pancreas. For this purpose, a major problem, strictly correlated with the implant site, is represented by  $O_2$  supply (43,44). In fact, necrosis of the central islet cell core has been extensively documented in support of this assumption. Preliminary documented attempts have been made, as elsewhere mentioned, to connect somehow the naked or encapsulated islet containing immunoisolatory devices directly to the blood stream, or prevascularize them so as to overcome this specific problem, although other reports focusing on the same topic remain questionable (45). In general, while selected studies have proven to be on the right path, the overall results so far obtained

(a)

(b)

**Figure 38.7** *In vitro* (a) free and (b) AG/PLO microencapsulated rat islets prior to incubation with IL-1 (25 $\times$ ). (From Univ. of Perugia.)

are still too limited and poorly quantifiable to allow for systematic evaluation.

Another major problem lies on the adult islet  $\beta$ -cell low mitotic rate (1–2%) (16). Although the islet cells have been shown to be able to replicate (46), even within artificial membranes, the islet death rate overtook the islet cell proliferation rate. Therefore any islet mass loss occurring in the posttransplant period, as a consequence of either immune- or not immunomediated events, virtually is not replaceable by the newly generated  $\beta$ -cells. Islet cell regeneration within the neoimplanted tissue would be greatly facilitated by physical communication with the native pancreatic matrix. Increasing evidence, for this purpose, seems to demonstrate that the pancreatic ductal network may play an important role in inducing islet  $\beta$ -cell replication by virtue of the release of selective growth factors (ie, IGF II) (47). This being the case, reconstruction of the original

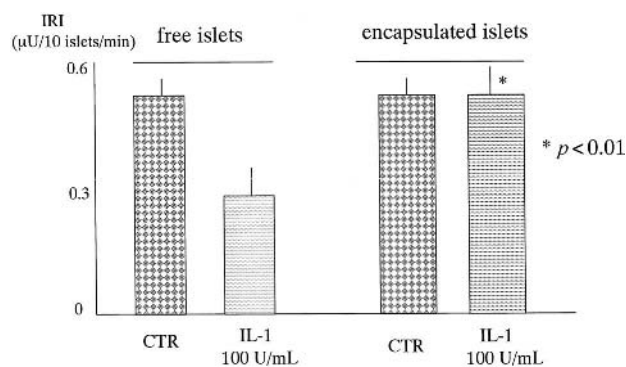

(a)

(b)

**Figure 38.8** In vitro exposure of (a) free and (b) AG/PLO microencapsulated rat islets to 17 kD  $\beta$ -recombinant human IL-1 (100 mU/mL); profound derangements (a) or normality (b) of the islet architecture are observed (25 $\times$ ). (From Univ. of Perugia.)

**Figure 38.9** In vitro exposure of free and AG/PLO microencapsulated rat islets to 17 kD  $\beta$ -recombinant human IL-1 (100 mU/mL); insulin secretory patterns are compromised for free but not for encapsulated islets ( $p < 0.01$ ). (From Univ. of Perugia.)

*pancreatic milieu* inside a BAP might greatly help to prolong survival of the enveloped islets.

It is finally worth mentioning the possible occurrence of apoptotic phenomena. These could account for loss of the originally implanted islet cells mass, not otherwise explainable by the occurrence of other  $\beta$ -cell targeting noxious events. However, the impact of apoptosis inducing decline in the original transplanted islet cell mass will require further study (48). Finally, a problem that seems to pertain closely to macrodevices, rather than microcapsules, is the fibroblasts' growth within the islet graft. Obviously, these opportunistic cells will thrive at the expense of the islet tissue, with additional subtraction of  $O_2$  nutrient supply.

## B. Biocompatibility and Specific Aspects of Membrane Configuration

Any artificial material that is introduced into the body is "foreign" and may therefore elicit some kind of response. Whether such a response is of a "benign" nature, self-limiting and composed of humoral/cellular elements that are relatively harmless to both the recipient and the implanted tissue, will depend upon either the nature of the constituent biomaterials or that of the graft site or finally the transplant procedure. On both the macrodevice's and the microcapsule's side, and increasing number of biopolymers, associated with more or less specified physicochemical properties, have been introduced in the past few years. Not always, however, have the improved membranes' technical features coincided with improvements of their biological acceptance. Neither has compliance with safety requirements. The interactions between the membrane and the embodied cells on the one hand, and the membrane and the host's tissue on the other hand, both the graft functional performance, and the host's reactivity being equally critical, represent the most important issues, regardless of the device's size and physical configuration. The ideal endpoint would be that the biohybrid organ is not simply tolerated by the host but rather becomes part of it. Following this principle, the artificial membrane, separating the grafted tissue from the host, would not represent something foreign that is simply in charge of regulating transmembrane nutrient/metabolite fluxes, while interdicting access to mediators of the immune system. Rather, the membrane should be fully integrated in a hybrid entity that incorporates the implanted cells and the host's tissue, within a system that finely adjusts its functional and immunological properties to physiological requirements of the hosting counterpart. If such an integrated system were in effect, many of the still open issues could possibly be overcome. There is no question that the device's size and geometry,

other than its bare chemical composition, deeply influence either the extent of the device-directed host's reactivity or its survival or finally the functional performance of the device-embodied live cells.

Size is very important. In fact, the bigger the grafted tissue volume, the more frequent are the unfavorable side effects observed in the recipient. Newly developed prototypes of the BAP aim to decrease the overall graft size. However, problems differ between macrodevices and microcapsules. In the former, the main issue is to couple an ideal tissue cell distribution, in compliance with the optimal biochemical/metabolic exchange, to the smallest possible appropriate size. In this regard, a possible innovation, as already mentioned, is the thin double-layer alginate sheet. The particular flat, and minimally invasive configuration of this macrodevice type seems to be suitable for islet grafting purposes.

As far as microcapsules are concerned, special care is now being taken in optimizing already established polymers, such as the alginates, by either improving the basic chemical formulations or creating new chemical blends to coat alginate gel microbeads. In particular, alginate-based microcapsules, associated with the possibility of dynamically altering the outer coating thickness so as to regulate the membrane's permeability/porosity, are in progress (49,50).

Practically, only a few attempts to use alternate polymers for islet microencapsulation in high mammals have been made. Many different polymers and materials belonging to different chemical categories have been proposed along the past 4 or 5 years, but none has proven able, at this juncture, to replace alginates effectively (see below). Whether it reflects insufficient examination of new chemistries, or the achievement of no tangible improvements, remains unclear. Microcapsules, because of their typical spherical shape, hold the important advantage of coupling ideal cell distribution to favorable diffusion properties. However, major efforts have been made, in few world laboratories, including ours, to reduce the original CSM size (600–800  $\mu\text{m}$ ) (51). CSM were, in fact, originally tailored for rodent graft trials, where they have indeed performed satisfactorily, and proved to reverse hyperglycemia in mice and rats with either spontaneous autoimmune or artificially induced diabetes. Unfortunately, in larger animals, the islet mass putatively able to reverse hyperglycemia coincided with a final encapsulated islet volume that was overwhelmingly big (ie, 80/100 mL per recipient dog), thereby resulting in mechanical and inflammatory reaction at the level of the peritoneal cavity. Obviously, the latter represented the only possible graft site for these capsules. To try to address this issue, attention was turned to develop smaller capsule prototypes,

measuring 300–400  $\mu\text{m}$ , all the way through “conformal” coatings that enveloped each individual islet within a skin-like hydrogel cast. This advanced capsule prototype virtually coincided with the islet's size itself. However, it is not demonstrated that conformal coatings, ideally fulfilling volume requirements, are also advantageous in terms of either metabolic performance of, or immunobarrier competence for, the embodied islets. We now believe that medium-size microcapsules, measuring an average 300 to 400  $\mu\text{m}$  in diameter, represent, as mentioned elsewhere, a good compromise between volume and functional/immunoisolation performance.

### C. Specific Issues and Pitfalls Associated with the BAP

#### 1. Macrodevices vs. Microcapsules

##### a. *Pros and Cons*

The search for an optimal device that couples the least invasive transplant procedure to the best functional performance is not over yet; it rather continues relentlessly. On the basis of the features that are associated with macrodevices and microcapsules, the advantages and disadvantages of each immunoisolation system can initially be recognized (Table 9).

As progress in validating refinements of previously developed devices or in generating newly configured devices, whether they are macromembranes or microcapsules, is gradually being established, some of the pro's and con's associated with either membrane's type likely require regular updates. Furthermore, new device engineering may introduce substantial changes in some principles previously indicated as sine qua non conditions. Some macromembranes are now able to fulfill the need for size restrictions that make them suitable for intraperitoneal or subcutaneous islet grafting in high mammals with no significant adverse side effects. Likewise, a wide spectrum of variably sized microcapsules is gradually being made available in order to fulfill multiple tasks (Fig. 10). One of these relates to the implant site that should not necessarily be restricted to the large peritoneal cavity, as it was for CSM. Furthermore, the smallest microcapsules could also eventually be deposited in bigger devices, so as to generate a multicompartiment entity that incorporates cells and other agents within a common immunoisulatory shield. This could represent an advanced version of the BAP.

#### 2. Chemistries

While, as elsewhere mentioned, AG-PLL/PLO continues to represent the most widely studied chemistry for the fabrication of islet containing microcapsules, alternate chemi-

**Table 38.9** Microcapsules vs. Macrodevices

	Pros	Cons
Microcapsules	Easier fabrication Favorable size/distribution Individual islet immunoprotection Minimal fibroblast growth Easier in vitro culture	Suitable chemistry Different retrievability Quality control of each capsule Assessment of long-term durability Tissue loading restrictions
Macrodevices	Uniform intact endocrine tissue distribution Easy retrievability	Size inadequacy for TX Fibroblast growth Traumatic TX procedure Thrombogenicity (vasc. dev.)

**Figure 38.10** Schematic representation of variably sized microcapsules with respective final graft volumes. (From Univ. of Perugia).

cal formulations have been described that may enable the formation of microcapsules.

#### a. Uncoated Ca-Alginate Microcapsules

Because of the very well known ability of the alginates to form highly biocompatible hydrogels, whether these are prevalently composed of guluronic or mannuronic acid derivatives, some groups have prepared alginate beads that were uncoated with poly-L-lysine or other polyaminoacids (52). Usually big Ca-AG microcapsules, measuring up to 3 mm in diameter, were fabricated and employed successfully to immunoprotect either allo- (53) or xenogeneic islet grafts in diabetic dogs or rodents, respectively (54). Although the capsules were proven to protect the islet allografts from acute rejection, a treatment course with general immunosuppressants was scheduled for the recipients in order to achieve sustained remission of hyperglycemia. The uncoated AG beads have posed a special problem that still remains open. In fact, MWCO associated with uncoated AG capsules should amount to several hundred kD, thereby virtually allowing for either immunoglobulins or large-size complement fractions to cross the membrane.

Why such events did not result in acute destruction of the capsules—embodied tissue remains unclear. The authors postulated AG negative surface charges that would prevent intracapsular access to similarly charged molecules. Moreover, prevention of cell-to-cell contact may play a role in circumventing the xenograft-directed immune destruction. While the immunoprotection capacity of these microcapsules warrants further investigation, their large size constitutes a problem per se, for the reasons reviewed above. Moreover, disposal of such a great amount of Ca-AG could be a problem per se, since biodegradation of this polymer is only partially known. Finally, need for using immunosuppressive agents in conjunction with the AG microcapsules would limit the impact of this microcapsule's type on islet graft immunoisolation technology.

#### b. Barium Alginate

Based on the principle that AG can be complexed with divalent cations to form hydrogels, some authors have employed Ba ions to generate Ba-AG microbeads. This is a one-step procedure, because Ba covalently binds to AG and it does not require additional coating (55). Although the simplicity of the method is attractive, and further refinements have permitted the authors to initiate the study of smaller microcapsules (56), there are two major issues with this microencapsulation procedure: (1) toxicity associated with Ba ions (Ba is toxic to live cells), since the Ba ion complexation rate cannot be precisely quantified; (2) questionable "immunoisolation" properties of the microcapsules that have been only partially elucidated. In particular, Ba-AG microcapsules do not seem able to provide the islet xenografts with sufficient immunoprotection (57).

#### c. Agarose

Agarose, like alginate, is a gelling agent extracted from seaweeds, and it is composed of repeating units of alternat-

ing  $\beta$ -D-galactopyranosyl and 3,6-anhydro- $\alpha$ -L-galactopyranosyl. Depending upon temperature conditions, agarose forms thermally reversible gels, with gelling occurring at temperatures that are far below the gel fusion point (58). Iwata and Ikada have developed several technical procedures to form agarose microcapsules to immunoprotect transplanted islets from the host's immune attack. Typically these authors have employed 5% agarose gel solutions to formulate their capsules, with no major problems adversely affecting the enveloped islet cell viability as assessed by *in vitro* studies. However, a potential technical problem occurred with the capsules' polydispersity, with variable amounts of empty microspheres burdening the overall graft volume. In terms of immunobarrier competence, agarose capsules have performed satisfactorily, within an islet allograft system (typically mouse islets into allogeneic mice with streptozotocin-induced diabetes) upon intraperitoneal transplantation (59). Noticeably, extent of immunoprotection afforded by these microcapsules seemed to decline when the recipients were NOD mice with spontaneous, autoimmune diabetes, thus raising an issue on the membrane's immunoselectivity (59). Further advances to cope with immune problems, specially associated with islet xenografts, have consisted of coating the agarose microcapsule's gel core with outer layers. These were composed of sulfated polyanions, complement activators (ie, poly-styrene sulfonic acid-polybrene polyion), and carboxymethylcellulose, the latter being added to improve the capsule's biocompatibility (59). Although these specially engineered agarose microcapsules have apparently prolonged the islet xenograft survival (hamster islets into C57BL/6 diabetic mice), there is no compelling evidence that blocking complement factors would *per se* provide the final solution to the many problems posed by encapsulated islet xenografts in nonimmunosuppressed diabetic recipients. Furthermore, no experience whatsoever has been achieved in diabetic higher mammals.

#### d. Polyethylene Glycol

The most appealing property of polyethylene glycol (PEG) for fabrication of immunoprotective microcapsules is its capability of forming a protein-repellent surface. In fact, protein adhesion has been indicated to initiate the cell aggregation process, on the capsule's surface, which could impair the membrane's diffusion properties (60). PEG has been used either to coat alginate-poly-L-lysine gel microbeads (61) or to create conformal coatings (62) that tightly envelop each individual islet. The latter process specifically addresses the capsular volume issue, already indicated as a potential cause for encapsulated islet graft failure. However, PEG has so far gained only limited con-

ference as a basic material for microcapsule formulation. Aside *in vitro* and *in vivo* biocompatibility studies, conducted with empty PEG capsules, few data on grafts of islet containing PEG microcapsules into diabetic recipients have been so far reported. Furthermore, while chemically elegant and sharp, the fabrication procedure of PEG microcapsules requires a laser-induced photopolymerization process that is initiated by eosin. No sufficient data on process safety have been provided to endorse this approach as a potential substitute for alginates, agarose, and other biomaterials. This being the state of the art with PEG microcapsules, *in vivo* studies, targeting both biocompatibility and immunobarrier competence of these membranes in transplants in lower and higher animal models of diabetes, are warranted.

#### e. Other Polymers

*Chitosan* has been proposed as a biomaterial that may be suitable for the immobilization of cells that retain viability and function, using a semiautomated process involving the use of alginates within the microcapsule's chemical formulation (63). The multiple functional and therapeutic properties (ie, wound healing, etc.) of chitosan require further investigation to assess whether the systematic use of this polymer, either alone or in combination with other molecules, would result in improving the microcapsules' physicochemical structure. This being the case, the environmental conditions to which the islets are exposed would consistently improve.

*Hydroxyethyl-methacrylate-methyl-methacrylate (HEMA-MMA)* is a polyacrylate copolymer (64) prepared by solution polymerization after careful monomer purification. Although the polymer is to some extent hydrophilic (25–30% water uptake), it also associates with mechanical strength, elasticity, and durability over time (Sefton). The polymer has proven suitable to fabricate small capsules that might represent the ultimate answer to the final graft volume-related encapsulated islet problems. A possible concern eventually lies in the use of potentially harmful technical steps, during the capsule fabrication process, such as exposure to shear forces and organic solvents that might damage live cells. However, several cell types, such as tumoral human and animal cell lines, and primary rat hepatocytes and islets, have been successfully encapsulated in HEMA-MMA, showing viability retention over long periods of time. Engineered cell lines that produce several factors have been also successfully encapsulated in HEMA-MMA (65). While HEMA-MMA might provide the enveloped cells with acceptable microenvironmental conditions, owing to its suitability for incorporating additional factors, the specific usefulness of these membranes

to encapsulate islet cells for transplantation in diabetic recipients remains undetermined, and it certainly will require further experimental study.

#### f. *Miscellaneous Strategies*

Many technical skills have been introduced by several authors in an attempt either to upscale the microcapsule fabrication process, and/or the individual microcapsule physicochemical characteristics, or to implement the immunoprotection shield provided by these membranes. The latter have been mainly addressed to treat diabetic NOD mice, which indeed represent a precious animal model of human type I diabetes, with molecules such as CTLA1g that interfere with costimulatory immune pathways resulting in the Tc system activation (Weber). These studies (66) have been of great interest because they have induced a significant prolongation of xenogeneic neonatal pig and rabbit encapsulated islet graft survival in diabetic NOD mice. This approach clearly addresses and aims to solve the problem posed by the complex immune interactions between an immunologically stringent host (NOD) and the reactivity associated with immunologically distant islet cells, as it happens in a xenogeneic islet transplant setting. It is likely, as mentioned elsewhere, that the simple mechanical barrier provided by microcapsules, based on an even refined polymer formulation, does not suffice for adequate tissue protection, and could, on the contrary, require the addition of other factors. Whether these should consist of agents that induce either substantial general changes of the host's immune system or modifications of the membrane formulations, including embodiment of molecules that prevent and/or attenuate activation of the host's immune system, requires additional study.

#### g. *Conformal Microcapsules (CM)*

Several methods have been described to envelop the isolated islets within conformal coatings. The rationale behind this procedure is to create immunoisolatory membranes that tightly envelop each individual islet, thereby eliminating any idle dead space between the islet and the outer capsule's membrane. These volume-sparing microcapsules could still provide the grafted islets with immunoprotection, although they would additionally be suitable for transplant in sites that are alternative to the peritoneal cavity. Among a few reported procedures to fabricate CM, our own consists of suspending the islets in a two-phase aqueous system comprising AG, dextran, and PEG that are emulsified extemporaneously. The microemulsion droplets engulf each islet, during brief incubation on a rocking plate, prior to immediate gelling upon reaction on Ca-

**Figure 38.11** Freshly prepared AG/PLO coherent microcapsules (25 $\times$ ). (From Univ. of Perugia.)

chloride. The gel microbeads are sequentially coated with PLO, at particular molar ratios, in order to avoid any membrane's shrinkage, and finally with diluted AG (67) (Figs. 11 and 12). Alternatively to alginates, PEG can be used to fabricate photopolymerized conformal coatings, as mentioned above.

#### h. *MSM*

In order to reduce the capsule's size from 700–800  $\mu\text{m}$  to 350–400  $\mu\text{m}$  and thereby obtain smaller but not conformal microcapsules, we have modified physicochemical variables of our original method for fabrication of CSM (67). In particular, we have adjusted the following parameters:

**Figure 38.12** Laser confocal microscopy micrograph of AG/PLO microcapsules containing canine islets: membrane integrity and viability of the islets are evident. (From Univ. of Perugia.)

- AG viscosity (increased)
- AG/islet suspension extrusion flow rate (increased)
- Air flow (increased)
- Temperature of the suspension (decreased)

By making these technical modifications, we have been able to obtain microcapsules that measured approximately half the size of the original CSM (Fig. 13). The question whether MSM might prevail over CM in immunoprotection of the enveloped islets while retaining a smaller size, is still the subject of intense study in our laboratory. However, canine islet allografts, immunoprotected in MSM, in two spontaneously diabetic, insulin-dependent dogs, was associated with full reversal of hyperglycemia and discontinuation of exogenous insulin that lasted in one animal for as long as 600 days of transplantation (Fig. 14) in our laboratory.

### 3. Microcapsules: Summary of Current Issues and Outlook

Overall, the following issues related to islet microencapsulation are now under scrutiny: (1) microcapsules' size, configuration, biomaterials, and membrane engineering; (2) TX sites; (3) the use of xenogeneic islets; (4) protection from both immune and not immune specific mediators of the host's reaction; (5) islets life span and functional survival within the special microenvironment of the capsules.

Some of these issues are closely related to each other. (1) From what was said above TX of islet containing conventional-size microcapsules (CSM) has consistently functioned only in small diabetic recipients, like rodents, thereby implying that new sizes and/or configurations need

**Figure 38.13** AG/PLO "medium size" (400  $\mu\text{m}$  in diameter) microcapsules containing adult pig islets (25 $\times$ ). (From Univ. of Perugia.)

**Figure 38.14** Long-term remission of hyperglycemia and discontinuation of exogenous insulin administration in two dogs with spontaneous insulin-dependent diabetes. (From Univ. of Perugia.)

to be explored, in order to put the system to work in higher mammals. In our laboratory and a very few others, research efforts for reducing the capsule size went even further and finally resulted in the development of new conformal microcapsules. In particular, a major advantage was that, because of their minimal size, CM could be grafted virtually everywhere, including in parenchymatous organs, otherwise interdicted to bigger capsules. A general major advantage of this encapsulation system has been that we have employed the same chemical polymer formulation (AG/PLO), although adjustments of the reagents' concentrations, to fabricate our differently sized microcapsule prototypes, were from time to time required. CM that would occupy a final volume of a few mL/patient have been shown to form highly biocompatible and immunoslective biomembranes in our laboratory (68). We have preliminarily documented that these membranes retain immunobarrier competence and protect allo- or xenogeneic islets, at subtherapeutic doses, upon TX into adult pigs (Figs. 15, 16, and 17) (69). However, the afforded immunoprotection lasted shorter for xenografts (ie, canine islets in CM) than allografts (ie, porcine islets in CM) implanted in the adult pig liver (unpublished data). In summary, CM and other conformal microcapsules, while favorably impacting the final TX volume, which would permit access to alternate TX sites, could be more vulnerable, because of the extra-thin nature of the coating membrane, in comparison with CSM or MSM, to noxious environmental either immune or not immune factors, that are part of the hosts' reactivity to the encapsulated islet TX. Just very recently we have determined the extent of the immunoprotection afforded to islets by differently sized microcapsules, namely CM vs. MSM vs. CSM, with the latter prototype still showing

**Figure 38.15** Porcine islets contained in AG/PLO CM, implanted into the liver of adult normal pigs at 30 days post-TX: full retention of islet cell viability and CM intactness (H&E 25 $\times$ ). (From Univ. of Perugia.)

**Figure 38.17** Canine islets contained in AG/PLO CM, implanted into the liver of adult normal pigs at 15 days post-TX: full retention of islet cell viability and CM intactness (H&E 25 $\times$ ). (From Univ. of Perugia.)

better immunoisolation properties. In light of these findings, microcapsule's geometry certainly requires further investigation. This looks like a priority together with further implementation of the membrane's functional competence in terms of improved immunoisolation capacity. Assessment of permselective properties associated with the currently available AG/PLO/PLL microcapsules is in progress and will likely be implemented in the near future. (2) This issue is related to the former, since the TX site has been virtually imposed so far by the final encapsulated islet volume and therefore the individual microcapsules' size. Obviously, CSM or MSM, because of their size, may

**Figure 38.16** Porcine islets contained in AG/PLO CM, implanted into the omentum of adult normal pigs at 30 days post-TX: full retention of islet cell viability and CM intactness (H&E 25 $\times$ ). (From Univ. of Perugia.)

be grafted only intraperitoneally, whereas CM or other conformal capsules, as mentioned above, could be transplanted elsewhere, including, for instance, the mesenteric leaflets or some parenchymatous organs. However, CM application to a higher mammal TX system may be more difficult than expected, as documented by early trials conducted in large animals in our laboratory. Also, it is premature to assess which TX site for encapsulated islets could better suit metabolic requirements of diabetic higher mammals, although it is quite plausible that the closer the site to the portal system, the better the TX functional performance. Moreover, although microencapsulated islets are not comparable to free islets, the lessons we have learned from the latter, with special regard to certain TX settings, as for instance, immunoprivileged conditions, like those provided by testis-derived Sertoli's cells (70), should be highly regarded. Consequently, attempts to transfer the immunoprivilege associated with given organs/tissues into the special capsules' microenvironment should be closely pursued. (3) Immunoisolation in microcapsules, differently from any other islet TX immunoprotection strategies, at this juncture, may offer the unique opportunity to employ nonhuman tissue as a resource for donor islets. In the specific instance of T1DM patients, access to xenogeneic porcine islets could successfully overcome the problems of the restricted procurement of human donor islets. Pig islets would in fact secrete an insulin molecule that differs negligibly from the human. Furthermore, pigs are omnivores and their glucose metabolism is very close to human. Finally, pigs are attractive because they can be genetically engineered, thus potentially providing for organs/tissues that are closer to human. Methods for bulk retrieval of

highly purified and intact islets, from selected donor pig breeding stocks, have been made available by our laboratory and a few others upon generation of the many technical skills that were necessary to fulfill all the specifications that are indispensable for the retrieval of viable and functionally competent pig islet tissue (71). Since it is well established that adult pig islets can easily lose their viability upon culture maintenance and *in vivo* transplant, some groups are now focusing their attention on neonatal pig islets. These islets might survive and eventually expand and mature, so as to acquire progressively their functional competence (72). Finally, even if pig islets would be the best candidates for xenogeneic functional islet tissue for humans, within immunoisolatory microcapsules, still some issues require additional and specific attention, prior to even thinking to embark upon clinical TX. In particular, the potential transmission of infectious agents, and in particular retroviruses, from pigs to humans has raised more than scientific discussions (73). However, there are strong reasons to believe that cellular transplants of such islet cells are different from solid organ grafts, since the former may enjoy immunoisolation in microcapsules or other artificial membranes, which makes a big difference, also under regulatory restrictions. This point has been recently recognized by international regulatory agencies and by groups, including our own, that are working in this field (74). (4) This issue is particularly difficult, because the immunoisolation membrane, depending on its MWCO, can be crossed by a very wide range of humoral substances and cell derivatives, many of which may trigger an intense inflammatory cell reaction. Although the microcapsule membrane's MWCO may be empirically tuned to the desired level, there are several technical limits. It is difficult, in fact, to determine the membrane's porosity as well as filtration/permeability which collectively represent a dynamic rather than static property. It also is implicit that not only immune specific mediators but also general cytotoxic agents such as free oxygen radicals, nitric oxide, etc. may be harmful to the encapsulated islet TX survival, and obviously there are no physical barriers that could interdict access to gases or very small molecules (75). An increasingly important islet graft destruction mechanism is represented by  $\beta$ -cell induced apoptosis. Cytokine-mediated expression of Fas receptor on  $\beta$ -cells may represent a target for FasL expressing CD4 and CD8, not to mention that an additional  $\beta$ -cell destruction mechanism could be represented by FasL expressed by  $\beta$ -cells themselves (48). To try to obviate these insidious mechanisms, major interventions are required on the capsules' outer membrane formulation, in an attempt to prevent the immediate impact of these mediators on the encapsulated islet grafts. Moreover, a simple three-dimensional monobarrier, like a sphere, may not suffice

for immunoprotection of highly immunogenic tissue such as xenogeneic islets, and an additional intervention on the membrane's engineering may be necessary. Finally, as mentioned below, an integrated physicochemical and biological immunodefense barrier is increasingly required to obviate the islet TX directed, specific immune destruction. Issue (5) is of critical importance for the encapsulated islet TX longevity, which should be at least sufficient to provide for substantial long-term reversal of hyperglycemia in the transplanted recipients. An important point is the islet mass that needs to be loaded into a single microcapsule or macrodevice, since only balanced islet cell populations that are sufficiently supplied with  $O_2$  and nutrients can result in effective functional performance. Also, the islet life span may be limited upon retrieval from the native pancreas by a number of variables, including hostile environmental conditions associated with the TX site. If neonatal islets were employed, they would even more require factors that implement their time-related maturation and acquisition of functional competence. Some groups have initially reported on the use of Sertoli's cells, originally situated in the testis, as a biological and immunological support to islets in transplant trials into diabetic rodents (76). These or other "ancillary" cells could greatly help the rearrangement of the special microenvironment that may mimic, although under completely different conditions, the biological hallmarks of the original pancreatic matrix. It is possible that the addition of growth factors may play a key role in enhancing the survival potential not only of fetal/neonatal (77) but also of adult islets (78). Comicroencapsulation of islets and purified Sertoli's cells has been preliminarily shown to improve islet cell viability and function (Fig. 18). The role of cotransplanting islets with other cells producing substances, like hormones, that

**Figure 38.18** AG/PLO microcapsules containing rat islets + prepubertal Sertoli's cells (12 $\times$ ). (From Univ. of Perugia.)

may consistently improve islet viability and functional performance is being increasingly recognized (79). Finally, as mentioned, it is necessary to counteract apoptosis mechanisms that may increase  $\beta$ -cell destruction. With respect to this specific matter, some cotransplanted cells, such as Sertoli's cells, may express FasL or release FasL as a soluble product that might help divert CD4-CD8 islet cell-directed immune attacks. As an actual ancillary strategy, which may be proved or disproved in the not too far future, artificial  $\beta$ -cell lines, compatible with higher mammal metabolic requirements, could be developed so as to provide for a virtually-inexhaustible islet tissue source (80). This could be another application for microcapsules, since the artificial  $\beta$ -cells could also be of nonhuman origin.

### VIII. FUTURE TRENDS

The BAP seems to offer the practical opportunity to transplant either human or nonhuman islets without general immunosuppression in the recipient. While the former is clearly limited by the restricted availability of cadaveric human donor pancreata, the latter could rely on the improved performance of methods for separation and purification of adult or neonatal islets from selected SPF pig breeding stocks. Should the problem of potential transmission of adventitious microbial agents be overcome, pig islets could represent an ideal tissue resource for human transplants, for all the above-mentioned reasons. Two alternatives are possibly ready to take over the pig islet source in the more or less far future: (1) engineered insulin producing cells; (2) in vitro regenerated islet cells. (1) could rely on methods that are more and more refined for generating cellular systems that are genetically engineered not only to secrete insulin but lately also to reproduce the glucose sensing apparatus that is uniquely associated with  $\beta$ -cells (81). Regulation of insulin secretion appears to be an indispensable feature of any insulin-producing tissue. Caution is still required prior to endorsing the use of this artificial tissue that is derived from tumor cells lines, for transplanting diabetes patients. Much additional study in this area is warranted for the years to come, although this cell source seems to be the most appealing solution to fulfill not only islet mass problems but also immune identity problems. Immune determinants of the artificial  $\beta$ -cells could be, in fact, engineered to that the cells would not be recognized by the immune system (81). Recently, methods to engineer endogenous cells that would be "educated" to synthesize and release insulin upon pharmacologic stimulation have been described (82). If successful, this approach could even obviate the need for transplantation. This ingenious strategy has been validated, at the moment and very preliminarily, only in rodents and requires further safety and efficacy studies, but it remains a very interesting

potential strategy for the final cure of T1DM. (2) is closely linked to (1). Recently attempts to regenerate islets from pancreatic duct stem cells has preliminarily succeeded (83). This procedure could make a virtually unlimited beta-cell mass available in vitro, to fulfill the demand for cell transplants in diabetes. The system's performance, which seems to require long-term in-vitro islet cell growing protocols, as well as safety restrictions, needs to be further elucidated in the near future. An important common feature of these new engineered cell strategies is that with a few exceptions, all of them will require an immunoprotection, and most likely an immunoisolation membrane. Therefore the BAP likely represents the best approach to put the engineered or otherwise artificially generated insulin-producing cells to work.

### IX. CONCLUSION

Multiple-competence strategies, incorporating diversified research fields, are now in progress to develop a cure for T1DM. Cell/tissue engineering gene therapy, or artificial device engineering might individually or synergistically fulfill the task of definitely restoring normal blood glucose levels in diabetic patients. Achievement of this goal would mean prevention of both acute and chronic complications of the disease. Among the available strategies, the BAP seems to be closest to human application. In fact, variably sized microcapsules, associated with increasingly refined immunoisolation and biocompatibility properties, are now available for islet graft immunoprotection with no need to treat the host with general immunosuppressants. Moreover, as problems of neonatal or adult porcine islet mass and purity are gradually being surmounted, the opportunity to employ nonhuman tissue as a resource for donor islets has come into sharper focus. Access to both immunoselective membranes and functionally competent cell tissue has greatly enhanced the BAP's potential. Toward this goal, artificial cells that are genetically engineered to synthesize and secrete insulin, contingent upon extracellular glucose levels, will also be available in the not too far future for application to in vivo trials. Conceivably, artificial cells, entrusted with the highly specialized task of replacing the normal islet  $\beta$ -cell function, are likely to take over human and animal tissue sources for transplant of patients with T1DM. Obviously, safety issues will require thorough scrutiny and specific solutions prior to enrolling the artificial cells into clinical use.

The ideal microcapsule should be versatile, in terms of long-term material stability, size, and immutable membrane selective properties (filtration/permeability/porosity), in order to access multiple and diversified implant sites. Suitability for replenishment would represent an additional useful feature. The ideal insulin producing cell/

tissue should be able to survive and thrive under likely difficult environmental conditions, regardless of the immune or not immune nature of adverse TX setting-related factors. To accomplish this objective, additional tissue and membrane engineering may be necessary. Multicompartment microcapsules, where the primary or engineered insulin-producing cells require the support of “nursing” cell systems, or rather pharmacological agents that may substantially improve their longevity and functional performance, could represent the final version of the BAP, suitable for second-level clinical trials.

Advances of the above reviewed research lines, in compliance with standard international safety and efficacy criteria, will unfold which prototype of BAP is readily available to begin human studies within the next few years to come.

### I. SKIN ANATOMY

Skin, the largest body organ, covers a surface area of approximately  $2\text{m}^2$  and receives about one-third of the blood circulating through the body (1). It maintains the integrity and function of the internal organs by restricting the passage of chemicals into and out of the body and stabilizes body temperature and blood pressure.

Histologically, the skin can be divided into two layers, the outer epidermis and the inner dermis with a total thickness of 2–3 mm, as illustrated in Fig. 1 (2–3). The epidermis is approximately 100  $\mu\text{m}$  thick and can be further subdivided into several layers of cells (4). These cells originate in the stratum germinativum (the basal layer of the epidermis) and undergo differentiation as they move up through the stratum spinosum, granulosum, and lucidum. The uppermost layer, the stratum corneum, is considered to be the rate-limiting barrier to the permeation of drugs (5–7). It consists of corneocytes, which are nonnucleated, flattened cells approximately 40  $\mu\text{m}$  long and 0.5  $\mu\text{m}$  in diameter, surrounded by an intercellular lipid-rich matrix. Elias described the stratum corneum in terms of a two-compartment model containing bricks (corneocytes) and mortar (intercellular lipid) (8,9).

The corneocytes have lost their cellular organelles and cytoplasm during the process of cornification. They are composed of keratin filaments that are stabilized by the formation of disulfide bridges and surrounded by cellular envelopes that consist of cross-linked proteins and covalently bound lipid. The corneocytes are also interconnected by polar structures termed the corneodesmosomes (10,11).

The intercellular spaces of the stratum corneum appear to be completely filled with intercellular lipids that are generated from the exocytosis of lamellar bodies during the differentiation of keratinocytes and to a lesser extent from sebaceous secretions (12–14). One of the most notable differences between the stratum corneum intercellular lipids and all other biological membranes is that these lipids are almost devoid of phospholipids. Instead, they are selectively enriched in ceramides, fatty acids, sterols, lesser quantities of glycolipids, sterol esters, triglycerides, cholesterol sulfate, and hydrocarbons (15,16). The lipid compositions of pig and human stratum corneum are shown in Table 1. The layer between the epidermis and the inner dermis is referred to as the epidermal–dermal junction, also known as the basement membrane (17). Beneath the basement membrane lies the dermis, which consists essentially of a matrix of fibroelastic connective tissue woven

from collagen fibers, elastic fibers, and an interfibrillar gel of glycosaminoglycans (18). The dermis can be further divided into two main layers: the papillary dermis and the reticular dermis (19). The papillary dermis consists of relatively loose connective tissue that contains smaller collagen and elastic fibers. It is also interspersed by the circulatory, lymphatic, and nervous system of the skin. In addition, it contains glycosaminoglycans and adhesive proteins known as fibronectins that attach fibroblasts to the collagen. The reticular dermis contains dense collagenous and elastic connective tissue and unlike the papillary dermis does not enclose many cells and blood vessels or glycosaminoglycans. It spreads over the subcutaneous fat, which functions as a heat insulator and reservoir for extra caloric intake.

The skin is breached by appendages such as sweat

glands, hair follicles, and associated sebaceous glands. These appendages extend through the epidermis and dermis to the subcutaneous tissue but occupy only about 0.1% of the total human skin surface (20).

## II. PERCUTANEOUS ABSORPTION PATHWAYS

Chemicals can permeate the skin through one of three possible routes: appendageal, transcellular, and intercellular (Fig. 2). The overall flux across the skin is the sum of the individual fluxes through each pathway that itself depends upon their number per surface area and path length as well as the compound diffusivity and physico-chemical properties such as compound solubility. These

pathways should not be treated as mutually exclusive (21).

### A. The Appendageal Pathways

The lower ducts of hair follicles and sweat glands are sites of physical discontinuity in the stratum corneum and as such serve as penetration pathways. The available diffusional area of the appendageal route is approximately 0.1% of the total skin area and only 0.01–0.1% of the total skin volume (22–24). The possibility that appendages form a pathway for percutaneous absorption has been demonstrated using fluorescence microscopy (25). These findings were consistent with previous investigations using autoradiography, which showed penetration of hair follicles by several substances such as adapalene, pyridostigmine, and 8-arginine vasopressin (25–27). Scheuplein et al. evaluated the percutaneous permeation of small nonelectrolytes through the appendageal and intercellular pathways. They found that appendageal pathways provide a poor barrier to

**Figure 39.2** Model of transcellular and intracellular pathways. (a) Penetration occurs via appendages that exhibit a reduced barrier to diffusion but occupy a relatively small surface area. (b) Permeation through the stratum corneum (transcorneal permeation) may be considered to occur through the intercellular lipid domain or through the corneocytes (transcellular route). (Reproduced with permission from Schaefer et al. (187).)

the diffusion of nonelectrolytes relative to the intercellular pathways. However, the relative surface area of the follicular pathways is relatively small (24). In view of these facts, the follicular pathway is predicted to be quantitatively more important at the transition (non-steady-state) phase of percutaneous absorption (22–24,28,29). On the contrary, the diffusivity through the intercellular lipid domain is relatively low, and as a result there is a corresponding longer lag time. The comparatively large surface area of this pathway contributes to a maximum flux for compounds with the appropriate physicochemical characteristics.

### B. Transcellular vs. Intercellular Pathways

The transcellular and intercellular pathways are considered the two major pathways for chemical penetration in the stratum corneum. The transcellular pathway involves the penetration of the substances through the inner lumen of

the stratum corneum corneocytes. The intercellular pathway involves the diffusion of the penetrants via the tortuous but continuous intercellular lipid pathway (30). The pathway through which the penetration occurs is largely determined by the physicochemical characteristics of the penetrants. It has been shown that a very important relationship exists between the hydrophobicity of the compounds and their permeability coefficients (31). This may suggest that the rate-limiting step for penetration through the skin involves a hydrophobic barrier, i.e., intercellular lipid. However, small polar compounds such as urea produced higher permeability coefficients than expected on the basis of their octanol/water partition coefficient. This may suggest that compounds penetrating the skin must pass through the intercellular lipid. However, that does not exclude that compounds can also pass through the inner lumen of the stratum corneum corneocytes.

### III. PRINCIPLES OF DRUG DIFFUSION ACROSS SKIN

Percutaneous absorption of most drugs takes place by a passive diffusion process that can be described by Fick's first law of diffusion (32). This principle is illustrated mathematically in Eq. (1), which shows that the amount of drug transported through a unit area of skin per unit time (flux,  $J$ ) is the product of the diffusion coefficient of the drug in the skin ( $D$ ), the concentration of the diffusing drug ( $C$ ), and the space coordinate measured normal to the skin, which is actually the path length of diffusion from the skin surface ( $x$ ). The negative sign in the equation indicates that the flux occurs in the direction of lowest concentration.

$$J = -\frac{D\delta C}{\delta x} \quad (1)$$

Fick's first law is compounded by certain factors when used to describe the drug permeation across the skin. It is generally applied to steady-state flux from an infinite dose along a unidirectional path through a homogenous membrane. Furthermore, Fick's first law assumes that only the drug molecules diffuse through the stratum corneum, the vehicle neither diffuses nor evaporates significantly, the components from the skin do not alter the properties of the donor solution, and the drug concentration remains constant in the vehicle during the experiment. The stratum corneum is not homogeneous by nature but it is composed of lipid and protein domains. Therefore diffusion is not constant over all dimensions, as demonstrated by the first law. In addition, changes in the composition of the vehicle can occur during the permeation experiments, affecting the

solubility of the drug and hence the calculated flux. To examine the rate of change of drug concentration at a point in the system, Fick's second law is used. Prior to steady state, the second law relates the rate of change of concentration at a point to the spatial variation of the concentration at that point, and this can be described as

$$\delta C = \frac{D\delta^2 C}{\delta^2 x} \quad (2)$$

In *in vitro* diffusion studies, the concentration differential is present during the experiment when sink conditions are maintained. This can be achieved by using saturated drug suspensions in the donor compartment and the maintenance of low receptor concentrations (sink conditions). It is expressed mathematically by Eq. 3:

$$M = \frac{ADKC_0}{x(t - x^2/6D)} \quad (3)$$

$M$  is the cumulative amount of drug diffusing through the membrane of area  $A$ , of thickness  $x$ , in time  $t$ .  $C_0$  is the concentration at time = 0 and is assumed to be constant.  $D$  is the diffusion coefficient.  $K$  is the partition coefficient. This equation describes the diffusion process at steady state. Differentiation of this equation with respect to time gives the steady-state permeation rate as

$$\frac{dM}{dt} = \frac{ADKC_0}{x} \quad (4)$$

or in terms of steady-state flux ( $J$ ) as

$$J = \frac{DKC_0}{h} \quad (5)$$

Flux is the slope of the graph of  $M$  vs.  $t$  after steady state is reached. If the steady state line is extrapolated back to the time axis, the intercept gives the lag time. Lag time ( $t_{lag}$ ) is used to determine the time that is needed to establish steady state across the membrane. This value can also be used to estimate the diffusion coefficient, provided that the thickness of the stratum corneum is known ( $x$ ) as shown in Eq. (6):

$$D = \frac{x^2}{6t_{lag}} \quad (6)$$

### IV. TRANSDERMAL THERAPEUTIC SYSTEMS

The transdermal route offers distinct advantages over other routes for the systemic delivery of drugs. For example, drug administration through the skin eliminates variables that influence gut absorption, such as changes in pH along

the gastrointestinal tract, food and fluid intake, stomach emptying time, intestinal motility, and transit time. Once absorbed, the first pass effect of the liver is eliminated, thus avoiding another profound site of potential metabolism and improving drug bioavailability (33). In addition, the transdermal route reduces the dose frequency by providing a continuous controlled zero-order absorption through the stratum corneum into the systemic circulation, which is somewhat similar to that provided by an I.V. infusion. However, unlike, an I.V. infusion, delivery is noninvasive, and no hospitalization is required. The uniform drug plasma levels reduce the side effects associated with oral dosage forms, permit the use of drugs with short half-lives, and improve patient compliance. Furthermore, the transdermal route can use drugs with a low therapeutic index.

The systemic delivery of drugs through the skin, i.e., transdermal delivery, was first introduced in 1981 when Transderm V® (now called Transderm Scop®) was marketed for motion sickness. Since then more than 25 different transdermal drug delivery systems (TDS) have been commercialized for the systemic treatment of a variety of diseases such as scopolamine (34), nitroglycerin, isosorbide dinitrate, clonidine, fentanyl (35), estradiol, (36,37), testosterone (38,39), timolol (40–42), triprolidine (43), and nicotine (44–46).

### A. Drug Candidate Selection

The selection of a potential candidate for the development of a TDS has been extensively reviewed (34,47). Table 2 summarizes the major physicochemical properties and pharmacokinetic characteristics of drugs incorporated in

TDSs. It can be speculated that drug candidates with low molecular weights permeate the skin at greater rates than compounds with higher molecular weights. Generally, they should have appropriate lipid solubility, i.e., log [octanol/water partition coefficient] between  $-1$  and  $2$ , since compound with log [octanol/water partition coefficient] lower than  $-1$  will have difficulty in distributing from the TDS into the stratum corneum. Moreover, compounds with log [octanol/water partition coefficient] of less than  $2$  may have problems in achieving steady plasma concentrations in reasonable time spans because the drug is delayed in the stratum corneum where a reservoir may be established (47). Drug crystallinity or melting point influences drug skin permeability. In general, the lower the drug melting point, the higher its permeability through the skin. In addition, drug candidates should have short half-lives, and this was suggested by the observation that a longer biological half-life increases the steady state concentration of the compound. Simultaneously, the time needed to reach steady state is significantly increased under these conditions (it takes five half-lives to reach steady state), which may be overly long as compared to the duration of patch use. The drug candidate should not exhibit any skin irritation, toxicity, or allergy. The drug should also be potent, and the therapeutic response should be obtained by the systemic delivery of no more than  $25$  mg/day. The equation used to determine the flux required to maintain a therapeutic concentration of a drug in the plasma is

$$J_{skin} = CL_{SS} \times CL_T \quad (7)$$

where  $J_{skin}$  is the flux ( $\mu\text{g}/\text{cm}^2/\text{h}$ ) required to obtain a therapeutic drug concentration,  $CL_{SS}$  is the unchanged drug

plasma concentration (ng/mL), and  $CL_T$  is the drug clearance rate (L/h).

## B. Design of Transdermal Delivery Systems

Transdermal drug delivery systems are pharmaceutical dosage forms that can deliver therapeutically safe and effective concentrations of drug molecules from polymeric patches applied on the human skin over extended periods of time. These systems can be classified into four main categories as shown in Fig. 3.

### 1. Membrane-Moderated Transdermal Drug Delivery Systems (MMT)

It is generally recognized that the membrane-moderated transdermal delivery systems (MMT) consist of a drug res-

**Figure 39.3** Cross-sectional illustration of the four main marketed transdermal system designs. (Reproduced with permission from 3M.)

ervoir compartment that lies between an uppermost impermeable flexible backing layer that prevents the drug permeation from the top and a semipermeable rate-controlling membrane with an adhesive layer that resides below the drug reservoir (2). The lowermost layer is a release liner that protects the system during storage.

In the drug reservoir, the drug is either completely solubilized or suspended in a liquid phase (e.g., Carbomer gel) (48). The drug diffuses passively through the rate-controlling membrane toward the skin. In a suspension formulation, the drug release follows zero-order kinetics. These release kinetics are considered the one of the primary advantages of this delivery system (40,48–50).

The semipermeable rate-controlling membrane must demonstrate preferential permeability of the drug over the reservoir media. The membrane can be either microporous or a nonporous continuous film. The microporous membranes contain interconnected pores that are made of polyethylene or polypropylene. These pores are filled with liquid such as mineral oil or ethanol. The drug is transported through the interconnected pores by diffusion through the liquid phase. The nonporous continuous membranes are made of polyethylene, polydimethylsiloxane, polypropylene, or ethylene vinyl acetate copolymer. The drug transport mechanism involves partitioning of the drug in the upper side of the membrane and then diffusion through the polymer film (51).

A thin layer of drug–skin compatible adhesive lines the external surface of the rate-controlling membrane. These adhesives are composed of polymers that can adhere to the skin when slight pressure is applied. Adhesives are a critical component in MMT. In addition to their usual requirements of functional adhesive properties, they must demonstrate good biocompatibility with the skin, chemical compatibility with the drug, various components of the formulation, and provide controlled and consistent transdermal delivery of the drug with several years of shelf stability. Furthermore, they should be easy to remove when desired, without causing trauma to the skin. Adhesives should maintain their functional properties of tack, release, adhesion, and cohesive strength in the presence of drugs and excipients. Appropriate selection of the adhesive is required for a consistent and predictable delivery of drug to systemic circulation. Most of the adhesives utilized are within one of the following general classes: silicone, polyisobutylenes, or acrylate (52–55). Silicone polymers are inert and compatible with many drugs and excipients. However, they have a high tendency to react with basic amine functional groups in compounds that may compromise their shelf stability by reducing their tack and skin adhesion properties or increasing the force required to remove the release liner. To increase their compatibility, the

Figure 39.4 The chemical structure of polyisobutylene.

reactive hydroxy-functional groups can be eliminated by an end-capping process. Polyisobutylenes are homopolymers of isobutylene and are composed of a long straight hydrocarbon backbone with an unsaturated terminal (Fig. 4).

Polyisobutylenes are relatively nontoxic, odorless and inert and are used when prolonged skin contact is desired, since they are less likely to cause skin irritation than other adhesives (56). However, Fang et al. evaluated skin adhesion properties of polyisobutylenes and compared them with these provided by silicone adhesive. They found that the adhesion properties of silicone adhesive were higher than the polyisobutylenes adhesive. To improve polyisobutylene adhesion properties, tackifiers such as polyisoprene and secondary tackifiers (terpene polymer; Px 1150) were incorporated into the formulation (57). Acrylate-based adhesives are extensively used for a variety of medical applications, since they are highly resistant to oxidation and do not require the addition of stabilizers. In addition, they are less irritant than silicone adhesives and are available in porous grades that are air and water vapor permeable. They are produced by copolymerizing acrylic esters with other comonomers (Fig. 5).

The flow chart in Fig. 6 outlines the manufacturing process and equipment for the production of MMT patches.

## 2. Matrix Diffusion-Controlled Transdermal Drug Delivery Systems (MDC)

The matrix diffusion-controlled transdermal delivery system (MDC) has the simplest design of the four TDS cate-

Figure 39.5 The chemical structure of polyacrylate.

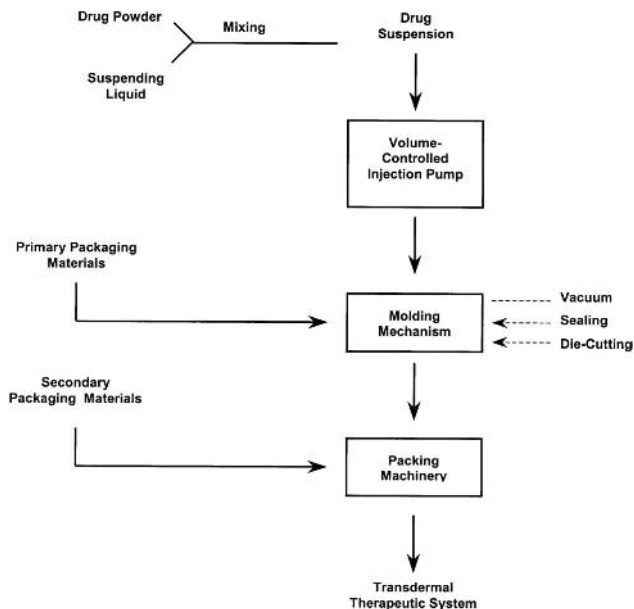

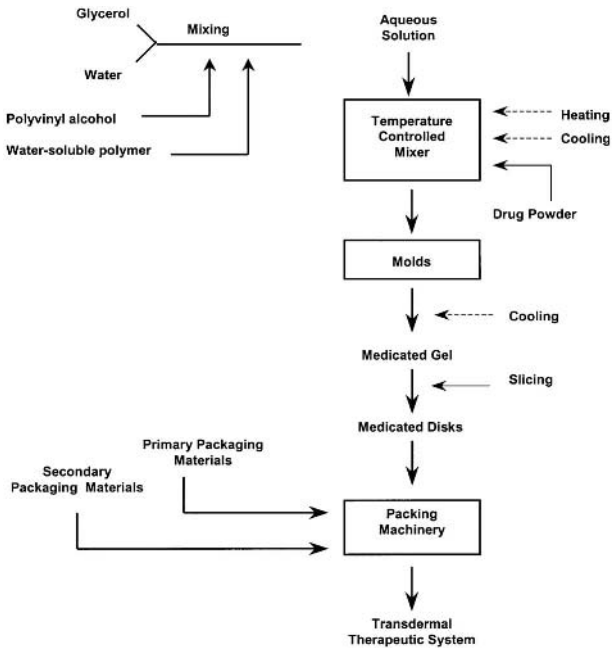

Figure 39.6 Flow chart of the process and equipment involved in the production of the Transderm-Nitro® system, a membrane moderated transdermal therapeutic system. (Reproduced with permission from Chien (2).)

gories. Its components are similar to those found in MMT (Fig. 3). Unlike MMT, the drug reservoir contains a homogeneously dispersed drug in a semisolid hydrophilic or lipophilic matrix. The adhesive layer is spread on the circumference of the drug reservoir disc. This may eliminate all possible drug/excipients adhesive interactions. Furthermore, the drug reservoir is not lined by a rate controlling membrane layer. As a result, the rate of drug delivery is regulated by the stratum corneum (56). Consequently, the rate of drug delivery across the skin can be modified by the incorporation of excipients that may alter the stratum corneum barrier properties such as transdermal enhancers (see below).

The flow chart in Fig. 7 shows the process and equipment involved in the production of MDC patches.

## 3. Adhesive Dispersion-Type Transdermal Drug Delivery Systems (ADT)

Adhesive dispersion-type transdermal drug delivery systems (ADT) technology is based on suspending the drug and excipients in the skin adhesive polymer (e.g., polyisobutylenes or polyacrylate). The adhesive layer must provide skin contact for a specified period of time. Simultaneously, the drug must be released from the adhesive layer in a consistent and reproducible manner. So as to fulfill these two requirements, ADT formulation is considered to

**Figure 39.7** Flow chart of the process and equipment involved in the production of the Nitro-Dur® system, a matrix-diffusion-controlled type transdermal drug delivery system. (Reproduced with permission from Chien (2).)

be the most complex to formulate within the four basic TDS.

Unlike MMT, the drug release rate from ADT patches follows first-order kinetics. The drug release rate will decline as the drug concentration in the adhesive layer decreases due to drug release. To overcome first-order kinetics, a reservoir of suspended drug particles may be incorporated in the adhesive formulation, or a multilaminate concept may be used.

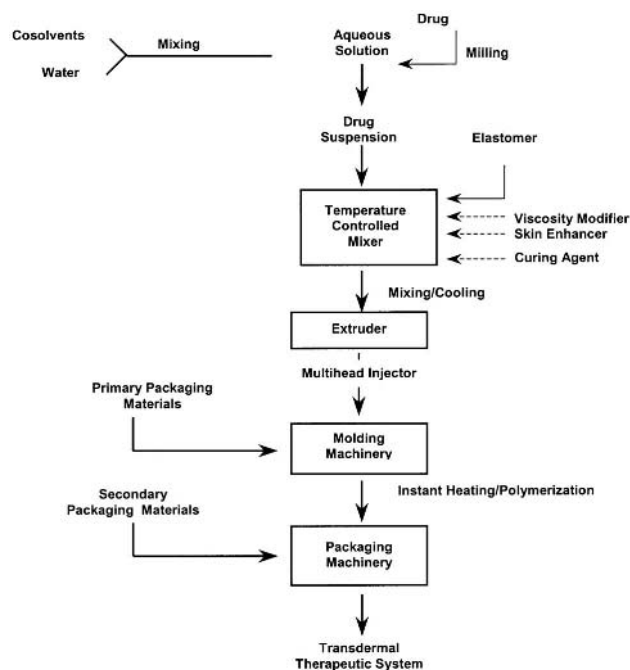

The flow chart in Fig. 8 shows the process and equipment involved in the production of ADT patches.

#### 4. Microreservoir Dissolution-Controlled Transdermal Drug Delivery Systems (MDCT)

Microsealed transdermal drug delivery systems combine the properties of the membrane moderated and matrix diffusion-controlled transdermal delivery systems (Fig. 3) (58,59). The system is made of two basic components, a biologically compatible polymer container and an inner biologically compatible silicone polymer matrix with microsealed compartments. The microsealed compartment contains the drug such as nitroglycerin in a hydrophilic solvent system, in which the ratio of the partition coefficient of the drug between the hydrophilic solvent system and the inner biologically compatible silicone polymer matrix is between 1 and  $10^4$  mL/ $\mu\text{m}$ . The biologically compatible polymer container should be biologically and pharmaceutically acceptable. They must also be nonallergenic and non-irritating. Furthermore, the polymer should not be soluble, because both dissolution and/or erosion of the system may affect the release rate of the drug. The polymer container should have a glass transition temperature below room temperature. Examples of the polymer container components include polyethylene, polypropylene, ethylene/propylene copolymer, ethylene/ethylacrylate copolymers, ethylene/vinyl acetate copolymers, silicone rubbers, especially medical grade polydimethyl siloxane, neoprene rubber, vinyl chloride copolymer with vinyl acetate, polymethacrylate polymer, vinylidene chloride, ethylene and propylene, polyethylene terephthalate, butyl rubber, epichlorohydrin rubbers, ethylene/vinyl alcohol copolymer, ethylene/vinyloxyethanol copolymer, and the like. The pharmaceutical delivery device is in an aqueous environment that is composed of a hydrophilic solvent system

that is inserted with a hydrophobic solvent system into the silicone matrix. The hydrophilic solvent is mostly composed of 10–30% polyethylene glycol 400 in distilled water. The hydrophobic solvent system is made of about 5 to 15% w/w of a product chosen from isopropyl palmitate, mineral oil, cholesterol, or a triglyceride of a saturated coconut oil, or a mixture thereof. The flow chart in Fig. 9 shows the process and equipment involved in the production of MDCT patches.

## V. ENHANCEMENT OF SKIN PERMEATION

The transdermal route offers several advantages over other routes for the delivery of drugs with systemic activity. These advantages are well documented and are discussed in Section IV. However, the use of this route is often hindered by the poor permeability of the skin, primarily attributed to the outermost layer, the stratum corneum (SC). A number of approaches, chemical and physical, have been used that reversibly alter the barrier layer of the skin and allow the delivery of drugs into the systemic circulation.

This section focuses on the various approaches, that have been developed to reduce the skin barrier properties and promote drug permeation.

### A. Chemical Penetration Enhancers

Chemical penetration enhancement using accelerants or sorption promoters is the most widely utilized technique to increase drug permeation across the skin (60). These compounds alter the permeability characteristics of the stratum corneum, allowing an increased rate of percutaneous absorption of coadministered drugs. Ideally, an enhancer should have the following properties (34,61,62):

1. Be nonirritant, nonallergenic, nonphototoxic, and noncomedogenic.
2. Be colorless, tasteless, odorless, and cosmetically acceptable, with a suitable skin “feel.”
3. Be compatible with all formulation components.
4. Be chemically and physically stable and pharmacologically inert.
5. Be potent, with an immediate, predictable, and reversible effect on the skin barrier properties.
6. Have a solubility parameter close to that of skin (i.e.,  $10 \text{ (cal/cm}^3)^{1/2}$  (63).

Williams and Barry have published extensively on the mode of action of chemical enhancers on the skin barrier properties (64). They proposed that enhancers may act by one or a combination of the following mechanisms: interaction with the highly ordered intercellular lipids to impart disorganization, thus increasing the paracellular diffusivity through the membrane; interaction with the intracellular proteins to promote the transcellular permeation through the corneocytes; and/or increasing the partitioning of the drug into the SC.

#### 1. Water

Water alters the barrier properties of the SC and is a safe and natural penetration enhancer. Normally, the SC is partially hydrated, containing 5–15% water, and when fully hydrated, the SC can hold as much as 50% water. Barry et al. reported a 10-fold increase in the rate of permeation of the fully hydrated SC relative to its value when it is perfectly dry (65).

Hydration increases the permeation of both polar and nonpolar substances, and Barry attributed this to the water effect on the lipid fluidity and keratin of the SC (66). Water increases the lipid fluidity by reducing the intermolecular forces via hydrogen bonding with lipid polar head groups. This loosens the lipid packing and increases the permeation of drugs paracellularly. The dry SC is a dense struc-

ture with a significant constraint on the rearrangement and folding of the intercellular protein molecules. As skin water content increases, restrictions on protein rearrangements lessen and the intermolecular hydrogen bonding between protein molecules is reduced. This is thought to increase drug permeation transcellularly.

## 2. Sulfoxides

Dimethylsulfoxide (DMSO) was one of the first compounds to be tested for its penetration enhancing activity (Fig. 10). There have been several publications in which the enhancing activity of DMSO was evaluated using a variety of drugs including steroids (67), flufenamic acid (68), acyclovir (69,70), vidarabine (71), and salicylates (72). Several theories were advanced regarding the mechanism of enhancement of DMSO. Among these are the displacement of water from the lipid head groups and loosening of the dense polymeric structure of the protein molecules within the corneocytes (73). The second theory suggests that DMSO extracts stratum corneum lipids, lipoproteins, and nucleoproteins, altering the barrier function and increasing drug permeability (74,75). The third theory proposes that DMSO may promote the drug permeation by osmotically delaminating the SC, thus disrupting the structure of the SC and increasing drug permeability (76).

DMSO use as a penetration enhancer was precluded by primary disadvantages. DMSO penetration enhancing activity is concentration dependent where high concentrations, greater than 60%, are required to produce enhancement activity (71). Unfortunately, at these high concentrations, DMSO was found to produce irreversible skin damage (77) and to cause side effects such as erythema (78,79) and wheals (80). Furthermore, unpleasant taste and mouth odor were reported to follow the topical application of DMSO due to dimethylsulfide, a metabolite of DMSO (81).

Sekura and Scala investigated several alkyl homologues of methyl sulfoxide (Fig. 10) with respect to their absorption enhancement and transdermal permeation of sodium nicotinate and thiourea across guinea pig skin in vitro (82). In the series ( $C_2$ - $C_{14}$ ), the best enhancement activity for the

**Figure 39.10** The chemical structures of (a) DMSO and (b) alkyl-DMSO.

permeation of both sodium nicotinate and thiourea across guinea pig skin was provided by  $C_{10}$  analog, decyl methyl sulfoxide (DCMS). DCMS provided 4.6 times greater penetration than DMSO. Later, the effect of DCMS on the skin permeation of a number of drug molecules was extensively studied. DCMS enhanced the permeation of progesterone (82,83), 5-fluorouracil (84), phenyl propanolamine, propranolol, acyclovir, and hydrocortisone (74,85). The experimental findings suggested that DCMS is an effective enhancer for hydrophilic compounds rather than lipophilic molecules. The major advantages of DCMS over DMSO are that DCMS was reported to be a more potent enhancer, and it can be used at concentrations as low as 0.1%. Unlike DMSO, it has a reversible action on the skin (86).

## 3. Amides

*N,N*-dimethylacetamide (DMAC) and *N,N*-dimethylformamide (DMF) are short chain amides (Fig. 11). Like DMSO, they are aprotic solvents that were reported to enhance the permeation of lidocaine (87), griseofulvin (88), caffeine (89), and hydrocortisone (90) in vitro. The mode of action of DMAC and DMF is similar to that of DMSO (73). However, they are less effective than DMSO (91).

Michniak et al. prepared several clofibrac acid amide analogues and showed their effectiveness as penetration enhancers using male athymic nude mouse skin as a model membrane (92). Using hydrocortisone 21-acetate and betamethasone 17-valerate as permeants, they found that clofibrac acid octyl amide demonstrated the highest enhancement activity; coadministration increased the cumulative amount of hydrocortisone 21-acetate after 24 h 51.6-fold and that of betamethasone 17-valerate 10.3-fold. In another study, Michniak et al. screened a series of acyclic alkyl amide using hairless mouse skin in vitro and hydrocortisone 21-acetate as a model drug. These authors demonstrated that some compounds provided higher enhancing activity than Azone® (increasing the flux up to 35.2-fold over control with no enhancer) (93).

Ogiso and coworkers studied the effect of *N,N*-diethyl-

**Figure 39.11** Chemical structures of DMAC and DMF.

**Figure 39.12** Chemical structure of *N,N*-diethyl-*m*-toluamide.

*m*-toluamide (DEET) (Fig. 12) and other transdermal enhancers such as *N*-octyl- $\beta$ -D-thioglucoside, DMSO, *N*-methyl-2-pyrrolidone, *n*-octanol, Azone®, isopropyl myristate, sodium oleate, oleic acid, monoolein, oleyl oleate, cineole, and limonene on the permeation of indomethacin and urea using male hairless rat skin *in vitro* (94). Aqueous ethanol solution (40% ethanol) was used as control. They found that DEET enhanced the permeation of indomethacin and urea relative to the control. In addition, DEET increased the partitioning of indomethacin in the skin and enhanced the thermodynamic activity of drug in the vehicle. In previous research reported by Windheuser et al., DEET was evaluated against a variety of drugs including hydrocortisone, hydrocortisone acetate, hydrocortisone 17-butyrate, hydrocortisone 17-valerate, dibucaine, benzocaine, indomethacin, erythromycin, tetracycline hydrochloride, griseofulvin, myco-21-phenolic acid, and methylsalicylate using hairless mouse skin *in vitro* (95). DEET provided significant increase in the permeation of all drugs tested. The investigators attributed this to the DEET solvent effect on the skin.

In summary, several amides show promise as potential penetration enhancers. However, further studies need to be performed to evaluate their toxicities, appropriate enhancer concentrations, and model drugs that can be used with these enhancers.

#### 4. Amines

Several amines, namely diphenhydramine base, chlorpheniramine, and nicotine-were evaluated for their enhancing activities using procaterol base and hairless mouse skin *in vitro*. The mode of action of these compounds is still nuclear. The highest flux and permeability coefficient was provided by nicotine > chlorpheniramine > diphenhydramine base (96).

In a study on the enhancing activity of 12 long chain amine enhancers with secondary and tertiary structures using hairless mouse skin *in vitro* and hydrocortisone as a model drug, Michniak et al. found that the cyclic tertiary

and secondary acyclic amines are less active for increasing hydrocortisone flux than tertiary acyclic amines (97). Furthermore, alkyl amines were poorer flux enhancers than their corresponding amides. In general, both cyclic and acyclic amines were weak transdermal penetration enhancers.

#### 5. Urea and Analogs

Urea ( $\text{NH}_2\text{CONH}_2$ ) is a natural substance that is commonly used in the treatment of scaling conditions such as ichthyosis and psoriasis (98,99). Several investigators evaluated urea as a potential enhancer of drug permeation. Feldman and Maibach were the first to investigate the enhancing effect of urea on the permeation of hydrocortisone acetate from a cream formulation across the skin of volunteers *in vivo* (100). They found a twofold increase in the permeation of the drug when 10% urea in a cream formulation was applied. A similar study by other groups concluded that 10% urea can enhance the efficacy of the coadministered steroid (101,102).

It is worth noting the the activity of urea is largely dependent on the vehicle as well as the concentration of urea. Kim et al. evaluated the effect of vehicle composition on the urea enhancing activity of ketoprofen permeation using rat skin *in vitro* (103). Ketoprofen permeability was not enhanced when urea in PG or PG/ethanol/water mixtures was used. However, its permeation was slightly enhanced when skin was pretreated with a 20% aqueous urea solution. Naito and Tsai evaluated the effect of urea concentrations in an ointment base on the percutaneous absorption of indomethacin using rabbit skin *in vivo*. A marked increase in the drug absorption was provided with 0.5% urea in the formulation. However, a decrease in the drug absorption was reported when urea concentration was increased to 2.5 or 5%. This was attributed to the high pH of the aqueous phase of the ointment, which may have reduced the partition of the drug into the skin (104).

Using a series of urea analogues, Williams and Barry evaluated the transdermal permeation of a model drug 5-fluorouracil in human epidermal membranes *in vitro* (105). They also correlated the effect of vehicle composition with the activity of the tested urea analogues. The series include 1-dodecylurea, 1,3-didodecylurea, and 1,3-diphenyl urea. The vehicles tested were light liquid paraffin, dimethylisobornide, and propylene glycol (PG). The chemical structures of the urea analogues are illustrated in Figure 13.

When light liquid paraffin was used as a vehicle, urea analogues did not have significant permeation enhancement activity relative to the liquid paraffin. However, when other vehicles were used, a pronounced effect on the enhancing activity of the urea analogues was noticed. The

Figure 39.13 The chemical structures of the urea analogues.

permeation of 5-fluorouracil from saturated solutions from PG was higher than drug saturated solutions in dimethylisobutyl sorbide and light liquid paraffin. In addition, no correlation was established between the log partition coefficient (octanol/water) and the enhancement ratios of the urea analogues. Wong et al. prepared a series of cyclic, unsaturated, biodegradable analogs of urea penetration enhancers. Their investigations were designed to produce penetration enhancers that maintained their excellent penetration effect and possessed low toxicity. The enhancer consisted of two parts: a highly polar parent moiety that is an unsaturated cyclic urea (1-alkyl-4-imidazolin-2-one) and a long chain alkyl ester group (106). They evaluated the penetration enhancing activity of these enhancers on the transport of indomethacin in petrolatum ointment through shed skin of the black rat snake and reported a penetration enhancement of indomethacin with three of these analogues to be comparable to or better than that of Azone® (107).

## 6. Pyrrolidone Derivatives

*N*-methyl-2-pyrrolidone (NMP) is a hygroscopic and aprotic solvent used for pesticides, chemicals, and polymers. Recently, pyrrolidone and its derivatives were intensively evaluated for their potential penetration enhancing activity.

Sasaki et al. prepared a series of alkyl-substituted pyrrolidones and evaluated their effects on the transdermal

permeation and skin accumulation of phenosulfonphthalin (phenol red) using rat skin in vivo and in vitro (108). A relationship was established between the partition coefficients of the pyrrolidone derivatives and the flux of phenol red. This suggested that high enhancer lipophilicity is crucial for enhancing the penetration of the hydrophilic compound. The skin accumulation of the enhancers and phenol red were reported to be concentration dependent (109). In a later study, NMP was reported to promote the permeation and to develop a reservoir of drug in SC with 5-fluorouracil, triamcinolone acetonide, indomethacin, flurbiprofen, aminopyrine, tetracycline, betamethasone 17-benzoate, ibuprofen, and sulfaguanidine (108–114.)

Yano et al. demonstrated that *N*-[2-(decylthio)ethyl]-2-pyrrolidone (HPE-101) showed similar enhancing activity relative to Azone® (115,116). In another study, the same group of investigators reported a synergistic effect for the enhancing activity of prostaglandin E<sub>1</sub> percutaneous permeation by NMP when glycols, glycerin, water, or triethanolamine were used as vehicles. However, NMP enhancement activity was lost when isopropylmyristate, alcohols, peppermint oil, or hexylene glycol were used (117,118). Like DMSO, the widespread clinical use of pyrrolidone derivatives was limited because of their damaging effects on the skin especially at high concentrations (81).

## 7. Azone and Its Analogues

Azone® (1-dodecylazacycloheptan-2-one or laurocapram) is the most extensively studied penetration enhancer since being patented in 1976 (119). It is a chemical combination of cyclic amide (pyrrolidone) and alkyl sulfoxide (DCMS). Azone® is a highly lipophilic structure with a log[octanol/water partition coefficient] of 6.4. The chemical structure of Azone® is thought to relate directly to its mode of action and imparts both hydrophilic and lipophilic characteristics to the molecule. Molecular modeling studies suggested that Azone® assumes a spoon-shape configuration which allows it to insert into the lipids of the stratum corneum and interact with the hydrophilic domains, thereby disrupting their packing and increasing drug penetration (120). When compared with other transdermal enhancers, Azone® provides many advantages. It is not irritating or allergenic when applied to human skin, it is absorbed dermally, but minimally absorbed into the systemic circulation. In addition, it has been incorporated into various topical formulations such as creams, ointments, suspensions, and patches and has promoted drug permeation at low concentrations (1–5%). The enhancing activity of Azone® was investigated using drugs with different lipophilicities

including 9-desglycinamide-8-arginine vasopressin, heparin, indomethacin, nitroglycerin, propranolol, timolol, and acyclovir (26,42,121–124). Barry and Bennett speculated that Azone® may be more effective in promoting the permeation of hydrophilic compounds than for enhancing the permeation of hydrophobic compounds (125).

Due to the permeation enhancing activities of Azone®, several investigators developed new Azone® analogs and tested their penetration enhancing activities. Mirejovsky and Takruri developed a series of hexamethylene lauramide (pyrrolidine, piperidine, and hexahydro-1*H*-azepine) with alkyl chain (seven, eleven, and fifteen carbons) derivatives using hairless mouse skin *in vitro* and *in vivo* (126). Three model drugs were investigated: hydrocortisone, griseofulvin, and erythromycin, and the effect of pretreatment time with enhancer on the permeation of hydrocortisone was also evaluated. The results suggested that hexamethylene lauramide had a broad spectrum of enhancer activity. Furthermore, the longer the pretreatment, the lower the amount of hydrocortisone permeated. The *in vitro* results also suggested that the permeation of hydrocortisone through hairless mouse skin *in vitro* was slower than the penetration through living skin *in vivo*.

Okamoto et al. evaluated the enhancing effect of a series of azacycloalkanone analogues using guinea pig skin *in vitro* and 6-mercaptopurine and 5-fluorouracil as model drugs (127). Two parameters were determined, drug diffusivity and partitioning into the skin using aqueous and ethanolic systems. In the aqueous system, the partitioning of the drugs into the skin was enhanced by pretreatment with enhancers, which also increased drug accumulation in the skin. However, drug diffusivities were little affected. In the ethanolic system, the enhancement was less than that provided by the aqueous system. In another study by the same group, Okamoto et al. showed that the enhancement effect of various azacycloalkan-2-one derivatives was related parabolically to model drug lipophilicity (128).

Michniak et al. evaluated a series of Azone® analogues for their enhancing activities by substituting various sized rings, new heteroatoms such as sulfur or nitrogen, and incorporating changes in the chain structure of the alkyl residue using hairless mouse skin *in vitro* and hydrocortisone as a model drug. They reported that most of the derivatives were not as effective as Azone® in delivering the hydrocortisone across the hairless mouse skin. In addition, thioamide enhancers were less effective than their oxygen-containing counterparts (129,130).

In summary, Azone® has been shown to be an effective penetration enhancer for a variety of drugs and is often used as a standard for comparison when newer agents are being evaluated.

## 8. Iminosulfuranes

Kim et al. and Strekowski et al. evaluated the penetration enhancing activity of three novel series of iminosulfuranes using hydrocortisone as a model drug and hairless mouse skin *in vitro* (131,132). All enhancers tested were applied to the skin as saturated suspensions in propylene glycol to ensure their maximum thermodynamic activity. From the evaluated series, *S,S*-dimethyl-*N*-(4-bromobenzoyl)iminosulfurane, *S,S*-dimethyl-*N*-(5-nitro-2-pyridyl)iminosulfurane, and *S,S*-dimethyl-*N*-(4-phenylazaphenyl) iminosulfurane provided significantly higher flux over 24 h relative to the control (propylene glycol without enhancer). However, *S,S*-dimethyl-*N*-(benzenesulfonyl)iminosulfurane, *S,S*-dimethyl-*N*-(2-methoxycarbonyl benzenesulfonyl)iminosulfurane, and *S,S*-dimethyl-*N*-(4-chlorobenzenesulfonyl)imino sulfurane all decreased the permeation of hydrocortisone significantly relative to the control. The authors suggested that these three compounds could function as skin drug permeation retardants.

## 9. Surfactants

Surfactants are extensively used in topical and dermatological formulations to increase product stability and to promote drug permeation through the skin. Surfactants can be generally classified based on the charge of their hydrophilic head at physiological pH into cationic, anionic, nonionic, and zwitterionic. It is generally accepted that the use of nonionic surfactants results in less skin irritation compared to other surfactant groups, yet they provide lower transdermal enhancing activity. Ashton et al. investigated the transdermal enhancement activity of a cationic (dodecyltrimethylammonium bromide “DTAB”), anionic (sodium dodecyl sulfate “SDS”), and nonionic (Brij 36T™) surfactants (133). By evaluating the flux of the model drug methyl nicotinamide using human cadaver skin *in vitro* they reported that Brij 36T™ showed the lowest enhancing activity compared to the other two surfactants. Furthermore, Brij 36T™ provided the shortest lag time, which suggested that nonionic surfactant penetrates the membrane more rapidly but binds less with the skin components. Similar findings were demonstrated by Gershbein, who evaluated the skin irritation induced by the application of cetyltrimethyl ammonium bromide and sodium lauryl sulfate (SLS) and correlated it with their transdermal promoting activity (134). He reported that the two enhancers damaged the skin, leading to a significant increase in transdermal drug permeation.

In view of the damaging effects of cationic and anionic surfactants, Rhein et al. investigated the effect of amphoteric surfactants on the swelling of isolated human stratum

corneum secondary to sodium lauryl sulfate (SLS) (135). They found that the swelling was significantly reduced when 1% alkyl ethoxy sulfate was coadministered with 1% SLS. They attributed the lowering of stratum corneum swelling to either a competition between the two surfactants for binding sites in the stratum corneum or mixed micelle formation that may reduce the number of SLS monomers available to interact with the stratum corneum. Borrás-Blasco et al. investigated the enhancing activity of SLS on compounds with different lipophilicity using rat skin *in vitro* (136). They concluded that the enhancing activity of SLS was more significant on compounds with lower lipophilicity, i.e.,  $\log[\text{octanol/water partition coefficient}] < 3$ .

Kushla evaluated the effect of alkyl chain length of three classes of cationic surfactants: alkyl dimethylbenzyl ammonium halides, alkyl trimethyl ammonium halides, and alkyl pyridinium halides, on the percutaneous permeation of lidocaine and water through human epidermis *in vitro* (137). Lidocaine was applied to the skin in the form of a suspension in propylene glycol : water mixtures containing cationic surfactants of varying alkyl chain lengths from the three classes given above. Increasing the concentration of surfactant was associated with higher enhancement ratios of both penetrants relative to control. In summary, alkyl chain lengths of 12 or 14 carbons provided the highest enhancement activity.

## 10. Alcohols

Small alcohols such as methanol and ethanol have been commonly used in topical formulations as transdermal penetration enhancers and solvents. Bommannan et al. evaluated the mechanism of action of these compounds (138). Alcohols exert their action by extracting the stratum corneum polar lipids, hence the increase in drug permeation is lower than that observed with Azone®. Ethanol was shown to be an effective enhancer for a variety of drugs including estradiol (139), nitroglycerin (140,141), buprenorphine (142), diclofenac (143,144), alclufenac, and ibuprofen (145). It is important to note that the enhancing activity of ethanol is concentration dependent. For example, at an ethanol volume fraction of 0.7 or below, nitroglycerin flux was improved, whereas at higher alcohol concentrations the drug permeation was hindered (141).

The enhancement activity of alcohols is a function of their alkyl chain length. Friend et al. evaluated the effect of alkyl chain length using levonorgestrel as a model drug (146). The enhancement activity of alkanols was re-

duced as the alkyl chain length was increased beyond 4 carbons.

## 11. Cyclodextrins

Cyclodextrins (CDs) are naturally occurring biocompatible substances that are made of six, seven, or eight glucopyranose units:  $\alpha$ ,  $\beta$ , and  $\gamma$  CDs, respectively with a hydrophilic outer surface and a lipophilic cavity in the center. Depending on the drug and treatment protocol, these agents can act as enhancer, or mild dermal retardants. They are known to increase lipophilic drug solubility by forming inclusion complexes. Williams et al. evaluated the permeation enhancement activity of  $\beta$  and 2-hydroxypropyl- $\beta$ -CDs alone and complexed with other penetration enhancers for the model drugs 5-fluorouracil and estradiol using human cadaver skin *in vitro* (147). They demonstrated that CDs did not enhance the permeation of either drug. Furthermore, complexation of lipophilic terpene with the CDs reduced enhancer efficacy. They concluded that CDs do not act as penetration enhancers. In addition, some CDs can be incorporated into topical formulations to retard the absorption of toxic materials. These findings conflict with data published by Vollmer et al. (148). They evaluated the enhancement activity of different concentrations of 2-hydroxypropyl- $\beta$ -CDs and 2,6-dimethyl- $\beta$ -cyclodextrin using liarozole (cytochrome P450 inhibitor) and a rat model *in vivo*. At 20% aqueous solution of 2-hydroxypropyl- $\beta$ -CDs, the absorption of liarozole was increased three-fold. However, a 20% aqueous solution of 2,6-dimethyl- $\beta$ -cyclodextrin retarded the percutaneous absorption of liarozole in blood by a factor of 0.6. It is interesting to note that pretreatment with 2,6-dimethyl- $\beta$ -cyclodextrin (20%, 4 h) promoted the transdermal absorption 9.4-fold. Differential scanning calorimetry (DSC) studies suggested that 2,6-dimethyl- $\beta$ -cyclodextrin enhanced the permeation of liarozole by interacting with protein and lipid fraction, whereas 2-hydroxypropyl- $\beta$ -CDs enhanced the drug permeation by affecting the drug partitioning into the skin.

## 12. Terpenes

Terpenes are naturally occurring hydrocarbon constituents of essential oils that are not aromatic in character. They have been found to be promising penetration enhancers with low cutaneous irritancy and good toxicological profiles at low concentrations (1–5%) (149). Terpene enhancers were reported to increase the percutaneous absorption of lipophilic as well as hydrophilic compounds (150–153). In their study on the effect of terpene en-

hancers on the percutaneous absorption of indomethacin in rats in vivo, Nagai et al. found that limonene was as effective a penetration enhancer as Azone at a concentration of 1% in an indomethacin gel ointment (154). In addition, limonene was reported not to affect the partitioning of indomethacin into the skin, and it was suggested that it enhanced indomethacin permeation mainly by affecting the highly ordered structure of the stratum corneum lipid. Oxygen-containing terpenes in this study did not increase the permeability of indomethacin, a nonpolar drug. However, the oxygen-containing terpenes carvone,  $\alpha$ -terpineol, and 1,8-cineole did enhance the transdermal delivery of the polar drug 5-fluorouracil across human cadaver skin in vitro (155). Williams and Barry conducted differential scanning calorimetry and Fourier transform infrared studies to evaluate the mechanism of action of terpene enhancers (156). These studies supported the theory that terpenes increase the drug percutaneous permeation mainly by interrupting the highly ordered intercellular packing of the SC lipids. The same authors evaluated the reversibility of terpene enhancing effects using 5-fluorouracil as a model drug and human epidermal sheets in vitro. They demonstrated that 5-fluorouracil flux in terpene-treated skins decreased with time after washing out of the terpenes from the skin surface (64). Unlike Azone, terpene enhancers were reported to produce lower skin irritation (149).

### 13. Fatty Acids and Fatty Alcohols

A parabolic relationship has been established between enhancement of drug permeation across the skin and the chain lengths of saturated fatty acids and fatty alcohols. Aungst evaluated the enhancement activity of naloxone penetration across human skin using saturated fatty acids ( $C_7$ - $C_{18}$ ) and fatty alcohols ( $C_8$ - $C_{18}$ ) (157). From the two series the  $C_{12}$  alkyl chain lengths demonstrated the highest flux of naloxone. In addition, they reported that  $C_{18}$  unsaturated acids and alcohols provided more enhancement for naloxone permeation relative to the saturated compounds. Ogiso and Shintani reported in another study the parabolic relationship between the chain length of the saturated fatty acids ( $C_6$ - $C_{18}$ ) and the flux of propranolol across rabbit skin (158). Since the  $C_{10}$  and  $C_{12}$  alkyl chain lengths are similar to the alkyl chain length of cholesterol, it has been proposed that these fatty acids and fatty alcohols disrupt ceramide-cholesterol and/or cholesterol-cholesterol interactions in the SC. Aungst evaluated the effect of branched and substituted fatty acids using human cadaver skin in vitro and naloxone (157). He did not report any difference between branched and linear fatty acids of the various chain lengths studied except for the  $C_{18}$  compounds. Isos-

tearic acid provided more penetration enhancement for naloxone than stearic acid.

### 14. Polymeric Enhancers

Aoyagi et al. investigated the use of polymers made of benzalkonium chloride surfactants as percutaneous permeation enhancers using 5-fluorouracil as a model drug and rabbit skin in vitro (159). In this study, *p*-vinylbenzyltrimethylalkylammonium chloride having a long alkyl chain was polymerized to variable average molecular weights ranging from 3,000 to 32,000. This enhancer increased the permeability of 5-fluorouracil significantly relative to the control with no enhancer. In addition, an inverse relationship was established between the molecular weight of the polymer and the permeation enhancement. Furthermore, these polymers demonstrated lower skin irritation, which was attributed to their low skin permeability due to their large molecular weight, as suggested by DSC studies. The polymeric enhancer approach offers many significant advantages such as low skin permeability of enhancers and the chance to modify the structure of these compounds to generate molecules of different lipophilicity and different charge distribution characteristics (which have a major impact on their interaction with the skin, donor vehicle, and drug molecules).

Polydimethylsiloxane (PDMS) has been used extensively in the medical and pharmaceutical fields. It has many favorable physicochemical properties such as high flexibility, hydrophobicity, good biocompatibility, and physiologic inertness (160). Recent studies on polymeric enhancers have focused on using PDMS-based polymers. In general, most of the evaluated polymeric enhancers possess polar and nonpolar groups. Such a combination provides the polymeric enhancers with different physicochemical properties that enable them to interact with both the skin and the drug. In another study by the same group, Aoyagi et al. prepared PDMS enhancers with different polar substituents at one chain end, such as *N*-methylpyridinio, quaternary amino, phosphoramid, carboxyl, and 1-alkyl-2-pyrrolidone-3-yl. These polymeric enhancers with polar end groups were effective surface active agents and penetration enhancers. They were also nonirritating due to their low skin penetration and the physiologic inertness of the PDMS backbone (161). These early PDMS polymers were shown to be effective only for lipophilic drugs. This was attributed to the mechanism of action of these polymers, primarily interacting with the surface of the skin, resulting in a change of the partitioning of the drug into the skin. As a consequence, the same research group developed a new class of polymeric enhancers containing a

hydrophilic segment such as polyethyleneglycol (PEG). These copolymers containing a quaternary ammonium moiety at one end of the chain were shown to be effective in enhancing the permeability of both hydrophilic and lipophilic drugs (146). The effect of polymeric enhancer molecular weights on the percutaneous parameters of evaluated drugs depended on the type of polymeric enhancer used. Studies with diethyl phosphoramidate or carboxy terminated dimethylsiloxane and benzalkonium chloride-based polymers demonstrated a decrease in the activity of the polymer with an increase in the degree of polymerization. On the other hand, ammonio or pyridinio terminated polydimethylsiloxane showed an increase in the enhancing activity with an increase in molecular weight (159–162). The end chain group had a major effect on the penetration enhancing activity of the polymeric enhancers. Cationic groups such as the ammonio or pyridinio groups precluded the permeation of coadministered anionic drugs (indomethacin). However, pretreating the skin with cationic enhancer resulted in an increase in the amount of the anionic drug permeated through the skin. Several mechanisms were advanced to explain to explain this behavior. DSC studies and curve fitting analysis revealed that these polymers did not have an effect on the stratum corneum lipids, as shown by the absence of changes in the transition temperatures obtained. However, these polymers are known to increase the partition coefficient of the drug into the skin. These data support the idea that these polymers are adsorbed onto the surface of the skin and consequently create a new layer into which the drug can partition (163).

## B. Physical Approaches

Although the chemical penetration enhancer method has been widely studied, not many enhancers have been approved for use in marketed products. This is mainly due to the unresolved question concerning the reversibility of their actions as well as their safety. Recently, physical approaches that include phonophoresis, iontophoresis, and electroporation have been extensively evaluated for their ability to enhance drug permeation across the skin.

### 1. Phonophoresis

Phonophoresis, also known as sonophoresis or ultrasonophoresis, is defined as permeation of drug molecules with a coupling/contact agent across the skin under the influence of ultrasonic perturbation (164–170). Phonophoresis has been used in medicine for many years, and its use as an aid for delivering medication transdermally is gaining increasing recognition. The mechanism of ultrasound induced skin permeation enhancement is not completely un-

derstood, but a combination of thermal, mechanical, or cavitation effects are involved in this process (165).

Levy et al. evaluated the effect of ultrasound on skin permeation of D-mannitol, insulin, and physostigmine in rats and guinea pigs (164). They found that ultrasound altered the permeability of skin temporarily and reversibly and it nearly eliminated the long lag time usually associated with the delivery of drugs across the skin. Furthermore, the transdermal permeation of insulin and mannitol in rats was increased by 5–20-fold relative to control within 1–2 h after ultrasound treatment. Ultrasound also substantially promoted the inhibition of cholinesterase after the first hour following its application in both physostigmine-treated rats and guinea pigs ( $p < 0.05$ ). The *in vivo* ultrasound-treated guinea pig group had a  $15 \pm 5\%$  decline in the blood cholinesterase activity following 1 h ultrasound application. However, in the control guinea pigs, no significant inhibition of cholinesterase was recorded after the 2 h application of physostigmine. In rats, cholinesterase level inhibition following 1 h ultrasound application was  $53 \pm 5\%$  in the ultrasound-treated group and  $35 \pm 5\%$  in the control group. The authors suggested that mixing and cavitation effects could be involved in the diffusion phenomenon through the membranes both *in vitro* and *in vivo*.

Mitragotri et al. evaluated the role of various ultrasound-related phenomena, including cavitation, thermal effects, generation of convective velocities, and mechanical effects, in the ultrasonic enhancement of drug delivery across the skin (165). The results suggested that cavitation appeared to play a profound role in the enhancement of drug permeation across the skin following ultrasonic application. Furthermore, confocal microscopy results indicated that cavitation occurs in the keratinocytes of the stratum corneum upon ultrasound exposure. The authors also hypothesized that oscillations of the cavitation bubbles induce disorder in the stratum corneum lipid bilayers, leading to enhancement in drug permeation across the skin.

There are a number of factors that must be considered prior to the use of phonophoresis, including the frequency and intensity of applied ultrasonic energy, the media between the ultrasonic applicator and the skin, and the length of exposure time.

Frequencies ranging from 20 kHz to 10 MHz are commonly used in phonophoresis. Mitragotri et al. used low frequency ultrasound to enhance insulin permeation across skin. This study was based that on the hypothesis that if cavitation plays the major role in ultrasound enhanced skin permeation and since the cavitation threshold increases rapidly with an increase of ultrasound frequency, lower frequency may lead to more cavitation, and as a result higher drug delivery across the skin may be expected

(167). They found that the increase in the ultrasound intensity was associated with an exponential increase in the insulin permeation. This may suggest that there is a nonlinear dependence of cavitation on ultrasound intensity. They also investigated the efficacy of ultrasound in promoting the insulin flux in an *in vivo* hairless rat model. An intensity dependent decrease in the blood glucose concentration was observed upon the application of ultrasound. They concluded that low-frequency ultrasound can be an effective tool in delivering insulin across hairless rat skin in an intensity-dependent model. On the contrary, Bommannan et al. used high ultrasound frequency to increase drug permeation across the skin. They referred this to the hypothesis that higher ultrasound frequency would localize the acoustic energy more within the stratum corneum and this may significantly alter the skin barrier layer and promote drug permeation (166). They evaluated this hypothesis using salicylic acid and hairless rat skin *in vivo*. Salicylic acid permeation across hairless rat skin *in vivo* was more significant when 10 MHz ultrasound was used compared to that provided by 16 MHz. However, 16 MHz was more effective in enhancing salicylic acid relative to 2 MHz.

The intensity used for sonophoresis typically ranges from 0.1 to 3 W/cm<sup>2</sup>. Several research groups have independently evaluated the effect of ultrasound intensity on phonophoresis enhancement activity (164,166,168,169). Miyazaki et al. investigated the relation between the plasma concentration of indomethacin permeated across hairless mouse skin and ultrasound intensity (171). The plasma level of indomethacin increased threefold relative to control after 3 h of phonophoresis (0.25 W/cm<sup>2</sup>). Further increase in the intensity to 0.75 W/cm<sup>2</sup> increased the indomethacin level 33-fold. The contact agents that are widely used in phonophoresis are ultrasonic gels and propylene glycol–water mixtures (170), and contact times of 5 min are usually reported for most phonophoresis studies (166,170).

## 2. Iontophoresis

Iontophoresis can be defined as the enhanced transport of charged molecules across the skin under an externally applied constant small amount of physiologically acceptable electric current (< 1.0 mA) (172–174). This technique has been extensively used for decades to deliver drugs topically. Lately, the use of iontophoresis for the delivery of drugs across skin has gained much attention, since this method of delivery is particularly promising for the delivery of large macromolecules such as peptide and protein drugs across the skin (175).

During passive application, the nonionized species penetrates the skin much more readily than the ionized coun-

terparts. However, following iontophoresis, a large concentration of ionized species is found at the regions of lower diffusional resistance, including sweat glands and hair follicles. This data was supported by studies performed by different research groups (172,173,176–178). It should be emphasized that the pore pathways do not just include appendages; the ultimate pathway is still the intercellular space between the hair follicles and epidermal cells (179).

Different parameters affect the systemic iontophoretic delivery of drugs across the skin including formulation pH (180) and ionic strength, applied current strength (181), drug concentration (182), and molecular size (183).

It is postulated that the morphology and permeability of the skin are only temporarily changed during iontophoresis (184). This change could be due to a localized heating within the pores as the current passes through the skin.

## 3. Electroporation

Electroporation involves the application of high-intensity electric field pulses (equivalent to several hundreds of volts for micro or milliseconds) to the cell membrane so as to create transient aqueous pathways in the cell membrane lipid bilayer. As a result, the permeation of the exogenous materials from the surrounding media to the inside of the cells will be significantly increased. Recently, this technique has been recognized as a powerful one for delivering macromolecules such as oligonucleotides and proteins or even smaller molecules across the skin for systemic activity (172–174,185).

The mechanism of drug permeation enhancement across lipid membranes using electroporation has been extensively investigated. Briefly, when an electric field is applied on a lipid membrane, it forces water to enter the lipid structure. Newly created aqueous pores will be formed when the water molecules from both sides of the lipid membrane meet. The pore size may increase as long as the electric field is applied. However, pores will collapse once the electric field is stopped.

Prausnitz et al. evaluated the reversibility of the action of electric voltage range on the flux of calcein across human epidermal membrane *in vitro*. The electric voltage was applied every 5 seconds for 1 h and ranged from 0 to 500 volts. The authors found that full reversibility of calcein flux was seen over the 0–100 volt range. Above 100 volts the reversibility of calcein flux was significant yet not full, suggesting permanent changes in the skin structure had occurred.

Vanbever et al. compared the effects of short (approximately 1 ms, high-voltage (approximately 100 volt) and long (approximately 100 ms), medium-voltage (>30 volt)

pulses on the skin electrical properties and the transdermal permeation of sulforhodamine in vitro. They reported that long pulses of medium-range voltage were more efficient in enhancing the permeation of sulforhodamine across skin. However, skin resistance was reduced threefold (with short pulses) and twofold (with long pulses) followed by incomplete recovery in both situations (186).

In another study by Prausnitz et al., the effect of high-voltage pulses on the permeation of a highly charged macromolecule (heparin) was investigated using human skin in vitro. The flux of heparin occurred at therapeutic rates (100–500 mg/cm<sup>2</sup>h) that were reported to induce systemic anticoagulation. It is interesting to note that the heparin that was permeated across the human skin was biologically active, but it retained one eighth the anticoagulant activity of heparin in the donor compartment. This was attributed to the preferential transport of small (less active) heparin molecules (185).

### I. INTRODUCTION

The route of drug delivery for a particular drug is of great importance for its onset, intensity, and duration of pharmacological action. Although direct placement into the bloodstream by intravenous injection can give the fastest onset, and control over intensity and duration, it is clearly not convenient nor usually desirable from a patient point of view; thus alternative routes of drug delivery become attractive. Historically, the most common alternative route of drug delivery is the oral route, presumably because of its convenience to the patient. However, this is a relatively hostile portal of entry for a drug. In addition, collecting intestinal blood vessels go directly to the liver and not to the general circulation, and thus orally absorbed drugs are subject to first-pass metabolism. For these and other reasons there has been increasing interest in other noninjectable routes of drug delivery including nasal, pulmonary, buccal, sublingual, transdermal, rectal, and vaginal. All of these portals of entry into the body, with the exception of transdermal and vaginal, are referred to as mucosal routes of delivery and are characterized by tissue with high blood flow and possessing numerous barriers to drug absorption (Fig. 1).

To design a drug delivery system properly for these mucosal routes of drug delivery, it is necessary to:

1. Have an understanding of the anatomy and physiology of these routes

2. Have a good knowledge of the barriers to drug absorption and strategies to deal with these barriers
3. Be able to integrate a drug into a delivery system that is user-friendly while permitting an optimum performance of the drug

This chapter will first describe the characteristics and permeability properties of selected mucous membranes and then review the relevant anatomy and physiology of certain routes of drug delivery. This will be followed by examples of drug delivery systems for these mucosal routes.

### II. CHARACTERISTICS OF MUCOUS MEMBRANE (1,2)

Surface epithelium and its underlying connective tissue are regarded as a functional unit called a “membrane.” There are two kinds of epithelial membranes, serous and mucous, present in the body. These membranes are kept moist by secretions from specialized epithelial cells and fluid extruded from underlying capillaries. Mucous membranes, also called *mucosae*, line the cavities of most organs that open to the outside of the body, namely, the alimentary canal, the respiratory tract, and the genitourinary tract. The multiple functions of mucosa are absorption, secretion, lubrication, entrapment, and antibacterial. This tissue can be highly specialized, i.e., the absorptive structures, lining the

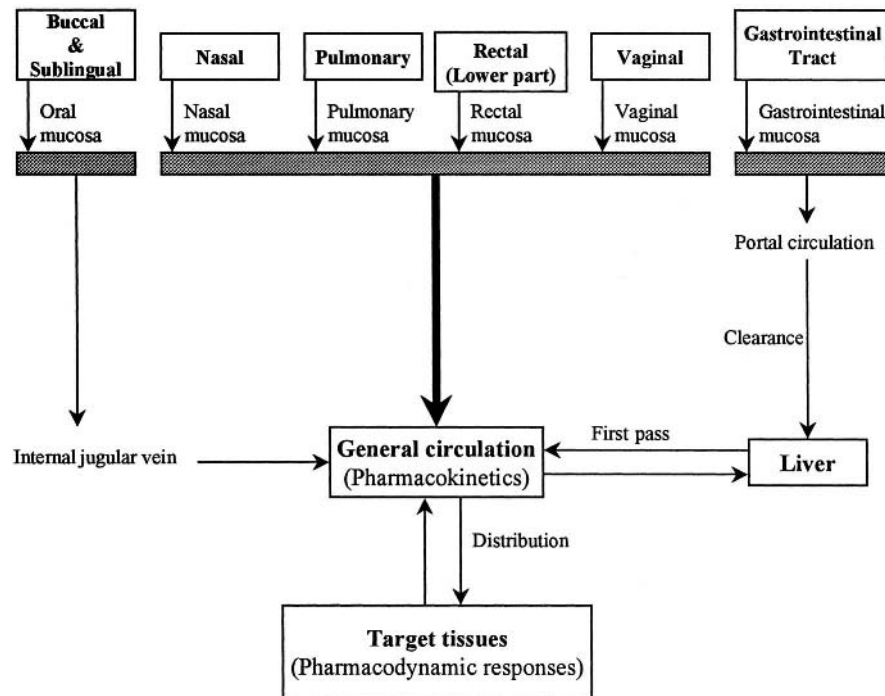

Figure 40.1 Drug delivery via mucosal routes.

digestive tract, or secretory. The secretions produced may be of a rather watery consistency, with an abundance of active enzymes, as in serous cells, or more viscous, where lubrication is the principal function, as in mucous cells. In the respiratory system, mucus traps foreign particles from inspired air and may also have bacteriocidal properties. In the stomach and intestines, the enzyme-rich digestive juices of the mucosae aid in the breakdown of food into simple nutrients available to the cells. A typical mucosa consists of four layers, namely, surface epithelium, basement membrane, lamina propria, and muscularis mucosa.

### A. Surface Epithelium

The surface epithelium is a moist inner layer, which may be formed by many types of epithelium. These cells vary in morphology and function depending on their location. For example, the mucosa of the respiratory system has many ciliated cells but sparse microvilli. In contrast, interspersed among the simple columnar cells lining the digestive tract are many goblet cells whose mucoid secretion protects the intestinal lining cells and aids in movement of the intestinal contents. Also the apical ends of the columnar cells are completely covered by closely packed

microvilli that greatly increase the absorptive area of the gut.

Classification of the various epithelia of the body is based on the arrangement and shape of the cells. Thus the terminology is related to structure and not function. Epithelium can be described as *simple*, consisting of one cell layer, or *stratified*, consisting of two or more cell layers. The individual cell may be described as squamous, where the width and depth of the cell are greater than its height; cuboidal, where the width, depth, and height are approximately the same; or columnar, where the height of the cell appreciably exceeds the width and depth. Two special categories are typically included in this classification, i.e., pseudostratified and transitional epithelium. A pseudostratified epithelium is actually a simple epithelium because all of the cells rest on the basement membrane. However, some of the cells do not reach the free surface at the lumen site, so the appearance of this epithelium looks similar to stratified. Transitional epithelium is a special name applied to the epithelium lining the pelvis of the kidney, ureters, urinary bladder, and part of the urethra. The morphology of the epithelium and its resident cells can also be related to its functional activity, and thus epithelia involved in secretion or absorption are typically simple. Examples of epithelial cell types in different areas are (3)

1. *The simple squamous epithelium* forms a thin layer and lines most blood vessels.
2. *The simple columnar epithelium* is a single layer of columnar cells, which is found in areas such as the stomach and small intestine.
3. *The stratified epithelium* is several cells thick and is found in areas that have to withstand large amounts of wear and tear, i.e., the inside of the mouth and esophagus.
4. *The pseudostratified columnar epithelium* typically lines the respiratory passageways.

### B. Basement Membrane

The basement membrane is composed of two layers. The inner layer located next to the base of the epithelial cells is called the “basal lamina,” a homogenous, electron-dense, 50–100 nm thick layer. The outer layer is the “reticular lamina,” a tangle of fine reticular fibers interposed between the basal lamina and the underlying loose connective tissue layer, the lamina propria. The basement membrane acts as a two-way filter or diffusion barrier to protect the body from the entrance of harmful macromolecular substances into the bloodstream. It also provides an elastic support for protection against trauma from hard and rough materials as they pass through the lumen of an organ.

### C. Lamina Propria

The lamina propria is the thickest layer, consisting of loose connective tissue in which lymphoid nodules are often located. It has an abundant supply of blood and lymph capillaries, which lie close to the basal surface of epithelial cells. Therefore the exchange of nutrients and gases across the capillary wall and the cell membrane is greatly facilitated by their close proximity. It also has a large population of lymphocytes and plasma cells that are important in the body’s defense against pathogenic bacteria, viruses, and other foreign substances. This layer can provide an effective shock absorber for the passage of bulky materials, especially through the gastrointestinal tract, because of its loose and spongy structure.

### D. Muscularis Mucosa

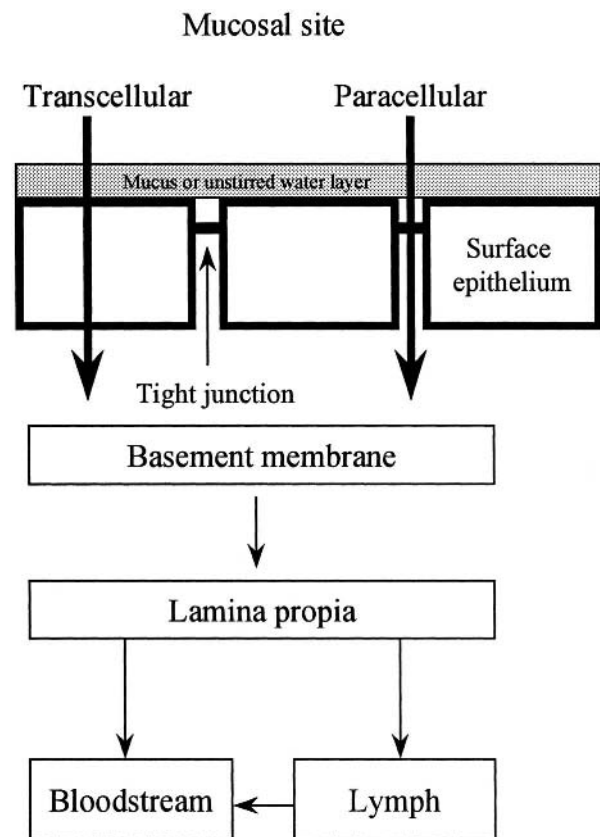

The muscularis mucosa is the outermost component of the mucosa. It is a layer of muscle surrounding the mucosa and usually consists of a few smooth muscle fibers, which may be oriented in the circular or longitudinal directions. It modifies the shape of the mucosa into folds or rugae, to

increase surface area, and may also contribute slightly to the peristaltic action of the gut.

## III. PERMEABILITY OF THE MUCOUS MEMBRANE

### A. Mechanisms

The epithelia of different mucosae are well characterized. Each mucosa varies in cell type, thickness, and function. However the basic drug transport mechanisms are the same (4–8). The principal routes of a substrate flux from the mucosal site into the bloodstream or lymph are shown in Fig. 2. The substrate can transport through the mucosa by passive diffusion, a process that begins with drug diffusion through mucus or unstirred water layer, followed by two major routes, transcellular (intracellular) and paracellular (intercellular) pathways. After that, the substrate is transported into the lamina propria, which is richly endowed

**Figure 40.2** The principal pathways of substrate flux from the mucosal site into bloodstream or lymph.

with capillaries, and where the substrate can readily be taken. Substrates which cannot pass the capillary wall end up in the lymph and are carried through the mesenteric lymph vessels into the thoracic duct, which empties into the bloodstream (9). Therefore the two major pathways that could be the rate-limiting steps in transmucosal permeation of substances across the mucosa, namely the transcellular and paracellular routes, will be discussed.

### 1. Transcellular Pathway

The transcellular pathway involves permeation across the apical cell membrane, the intracellular space, and the basolateral membrane by passive transport (partition and diffusion) or by active transport (carrier-mediated diffusion, endocytosis, and transcytosis) (10–11). In general, passive transport is the movement of a solute along its concentration gradient, while active transport is mediated by membrane transport proteins and energy sources. Therefore, in active transport, the solutes can be transported against a concentration gradient. This pathway is important for the absorption of lipophilic molecules (passive transport) or molecules capable of specific recognition of a membrane site (active transport).

### 2. Paracellular Pathway

The paracellular pathway involves passage between the cells through the intercellular lipid material of the intercellular space. The two components of the paracellular pathway are the tight junction (zonula occludens) and the underlying intracellular space (10,12). Actually, the tight junctions are dynamic structures that consist of plasma membranes brought into extremely close apposition, but not fused, so as to occlude the extracellular space. They can assemble or disassemble in response to various physiological stimuli. For instance, lowering the extracellular  $\text{Ca}^{2+}$  concentration induces the opening of tight junctions (13–16). This pathway is important for the absorption of hydrophilic compounds, which cannot transport by an active transport process.

## B. Barriers

A problem that commonly limits the development of suitable drug delivery systems for mucosal routes is poor drug bioavailability. This occurs because of the presence of barriers. Two main barrier classifications have been made in drug transport across mucosa, namely physicochemical and metabolic (17). An understanding of these

barriers is essential to formulating ways to overcome these problems.

### 1. Physicochemical Barrier

The transcellular route consists primarily of two main barriers, the apical and basolateral cell membranes. These are barriers for hydrophilic drugs, which cannot easily partition into the cell membrane. The paracellular pathway can be considered as either a single barrier, the tight junction, or as two barriers, the tight junction and the intercellular space (7). Each of these epithelial barriers has two properties that can be measured experimentally. First is the general permeability or magnitude of the barrier, which is largely controlled by the tight junction and may be simply quantified by electrical resistance. Epithelia can be classified as leaky or tight by the magnitude of these values. Leaky epithelia are those with a tissue resistance less than 1,000 ohm  $\text{cm}^2$  (7). The second property is the permselectivity of the barrier, which is a quantitative measure of the ability of the epithelia to discriminate or show preference for the transport of molecules of different charge type. The physicochemical properties of the different mucosae are compared in Table 1. Note the wide variation in magnitude of barrier permeability among different epithelia. The rank order of the intrinsic membrane permeability is intestinal  $\approx$  nasal  $\approx$  bronchial  $>$  vaginal  $>$  rectal  $>$  buccal. With respect to the permselectivity barrier, all epithelia are selective to positive charged solutes, the magnitude of selectivity being comparable in most epithelia (18).

Several studies suggest that the mucus layer can also be a rate-limiting barrier to drug absorption (19–21). For example, results reported by Wikman and coworkers (20), who used the mucus layer producing human intestinal goblet cell line (HT29-H), indicated that the mucus layer is a significant barrier to the absorption of testosterone. Nimmerfall and Rosenthaler (19) showed that the absorption of a series of alkaloids correlated with their diffusion coefficients in a mucus layer. Therefore, the reduction in permeability coefficients through mucosa due to mucus needs to be considered for all compounds that must traverse any mucus layer prior to absorption or action.

### 2. Metabolic Barrier

The metabolism of drugs and other foreign substances can be considered to be part of the body's defense mechanisms. Drug metabolism takes place in many parts of the body including the liver, bloodstream, spleen, kidney, brain, lumen of the GI tract (bacteria), wall of the GI tract, and many other tissues. However, the major organ in which drug metabolism takes place is the liver (22). During the

**Table 40.1** Permeability and Permselectivity of Various Mucosae in Rabbit

Mucosa	R(ohm · cm <sup>2</sup> ) <sup>a</sup>	pd(-mV) <sup>b</sup>	DP(-mV) <sup>c</sup>
Nasal	261 (55) <sup>d</sup>	13.8 (4.4)	10.22 (2.43)

Source: Ref. 18.

transmucosal permeation process, drugs may be subjected to metabolism by several enzymes in the lumen of the route of administration, the mucosal surface environment, or in the mucosal membrane. The presence of peptide and protein drugs makes the metabolic barrier more important, because this barrier plays a critical role in the delivery of these drugs via the mucosal routes. In this case, the barrier is composed of exopeptidases and endopeptidases, which are able to cleave peptides and proteins at their N and C termini, and at an internal peptide bond, respectively (23). The exopeptidases are grouped into amino and carboxy peptidases according to their substrate specificity. The endopeptidases are classified into serine, cysteine, and aspartic proteinases according to mechanism rather than substrate specificity. These enzymes can inactivate peptide and protein molecules during absorption, presenting a pre-systemic first pass effect (17). It should be also noted that peptides and proteins are susceptible to degradation not only at the site of application but also in the blood, liver, and endothelial membrane (24,25). The role of the proteolytic barrier in limiting peptide and protein absorption appears to be dependent on the specific mucosa and the nature of the peptide and protein drugs. For example, comparative studies on peptidase activity against enkephalins (26), insulin, and proinsulin (27) in the absorptive mucosae (nasal, buccal, vaginal, and rectal) of the rabbit demonstrated that the vaginal mucosa is consistently low and the rectal mucosa is consistently high in proteolytic activity against all three peptides, but the rank order of proteolytic activity between nasal and buccal mucosae varies with the peptides.

### C. Penetration Enhancers

Penetration enhancers are compounds that can increase the absorption of coadministered drugs by increasing mucosal permeability and hence absorption of poorly permeable drugs (28). Examples of penetration enhancers and their possible mechanisms are shown in Table 2. The mechanism of penetration enhancers can be divided (8,28,58) as follows:

#### 1. Altering the Permeability of the Membranes

##### a. Action on the Mucus Layer

The mucus layer covering the surface of the mucosal membrane can be seen as an unstirred layer, acting as a barrier to the diffusion of drug molecules. Ionic surfactants such as sodium deoxycholate, sodium taurodeoxycholate, and sodium glycocholate are able to reduce mucus viscosity and elasticity by disrupting the associated structure of the glycoproteins (40). Consequently, the barrier function of the mucus layer is reduced, and the permeability of drugs through this layer is increased.

##### b. Action on Tight Junction (Enhanced Paracellular Transport)

At a tight junction, the interacting membranes are so closely apposed that there is no intercellular space and the membranes are within 2 Å of each other. Therefore a tight junction is one of the major barriers to paracellular transport of macromolecules and polar compounds. These junc-

**Table 40.2** Classification of Penetration Enhancers and Their Mechanisms

Penetration enhancers	Mechanisms	Ref.

tions can be disrupted by regulating the controlling physiological factors including concentration of AMP (59), intercellular calcium concentrations (14), and transient mucosal osmotic pressure (60). Hence, treatment by chelator (EDTA), cytochalasin, or increasing glucose or amino acids can cause a temporary change in the integrity of the tight junction and increase paracellular transport. The increasing water influx through the intercellular space, which is Na dependent, is another factor that involves enhancement in paracellular absorption (61). An increase in water influx may affect drug absorption by one of the following mechanisms: (1) increase in concentration gradient for penetration, (2) increase in solvent drag, and (3) increase in blood flow at the absorption site (62).

### c. Action on the Membrane Structure (Enhanced Transcellular Transport)

Major components of the biological cell membrane include lipids (cholesterol, phospholipid, and sphingolipid), proteins, and carbohydrates attached to the proteins or lipids as glycoproteins or glycolipids. Enhancers that increase transcellular permeability to drugs probably do so by affecting membrane lipids and proteins. Some fatty acids and their derivatives have been found to act primarily on the phospholipid component of membranes, thereby creating disorder and resulting in increasing permeability (63). However, some fatty acids act on the protein component in membranes (64).

## 2. Altering the Physicochemical Properties of the Drugs

Solubility and dissolution rate of a drug are very important properties related to absorption. A penetration enhancer can promote absorption by increasing drug solubility and/or dissolution rate (65). Penetration enhancers such as sodium salicylate and bile salts are thought to increase absorption by this effect (66).

## 3. Inhibition of Enzymatic Activity

Protein and peptide drugs are subject to degradation by proteolytic enzymes during passage through mucosal membrane (25). A significant inhibition of this degradation can promote permeability by increasing the effective concentration of protein and peptide drugs at the absorption site. This may result in an increase in the absorption and bioavailability of the drugs. LueBen et al. (67) found that two bioadhesive poly(acrylates), polycarbophil and carbomer, showed an inhibitory effect on the proteolytic activity of the luminal enzyme trypsin. This can be explained by the pronounced  $\text{Ca}^{2+}$  binding affinity of the polymers. Therefore  $\text{Ca}^{2+}$  is depleted out of the trypsin structure and enzyme activity is reduced.

# IV. DRUG DELIVERY SYSTEMS

## A. Nasal

### 1. Relevant Anatomy and Physiology

The nasal passage, which measures from the nasal vestibule to the nasopharynx, has a length of approximately 12 to 14 cm (5,68) with a surface area of about 150  $\text{cm}^2$  and a total volume of about 15 mL (69). This upper respiratory tract provides a modification of the inspired air by filtration, controlled temperature, and humidity. It also provides a highly efficient defense system that protects the lungs against inhaled particles and toxicants. The main regions of the nasal cavity are the nasal vestibule, the respiratory region, and the olfactory region. First, the vestibular region serves as a baffle system, and its surface is covered with a keratinized stratified squamous epithelium where the long hairs may provide the function of filtering inhaled particles (10). Second, the respiratory region comprises the largest part of the nasal cavity. This area is covered with pseudo-stratified columnar cells containing mucus and numerous cilia. The respiratory epithelium is highly vascularized, supplying the lamina propria of the epithelium with a dense network of fenestrated capillaries. Thus the respiratory region is assumed to be the major site for drug absorption. Finally, the olfactory region is generally free of inspiration

airflow. It is covered with pseudo-stratified columnar cells, specialized olfactory cells, supporting cells, and serous and mucous glands (70). Absorption may also occur in this region through the olfactory nerve ending into the brain (71,72).

### 2. Major Biological Barriers and Appropriate Strategies

The nasal mucosa is considered to be permeable to small molecules, while penetration enhancers can be used to increase the absorption of larger molecules. Several enzymes also exist in nasal secretions and have been reportedly involved in the metabolism of different kinds of drugs (73–78). For example, several researchers observed that the respiratory mucosa contains detectable amounts of cytochrome P-450 and monooxygenase activity; however, the levels are generally lower than those found in the liver. The level of these enzymes is also related to species differences and variation in the nasal mucosa regions (74,79). The proteolytic activity in the nasal region is also comparatively low compared with other mucosae in the body (79,80).

One of the most important defense mechanisms of the nose is mucociliary clearance. This is a function of the physical properties of the mucus coupled with appropriately functioning cilia (81,82). The mucus layer on the nasal mucosa consists of two layers. The outer layer is relatively viscous (gel) and rests on a thin watery (sol) layer that tends to facilitate the action of the underlying cilia and is probably the most significant physical factor to affect nasal drug absorption (83). The speed of the mucus flow is about 5 mm/min with a range from 0 to more than 20 mm/min, while the mucus will tend to reconstitute itself every 10 to 15 minutes (70,84). Temperature, relative humidity, airway secretion, and specific drug formulations can affect the nasal mucociliary function. For example, drying of the nasal mucosa will cause cessation of ciliary activity; however, moistening will promptly restore its normal activity (17,70). A study by Hardy et al. (85) showed that approximately 40% of the dose administered via the intranasal route cleared rapidly with average half-times ranging from 6 to 9 min. Following this rapid phase, clearance of a spray was much slower than drops. Thus development of nasally administered drugs must take into account this clearance mechanism.

### 3. Examples

The efficacy of drugs delivered intranasally, whether for local or for systemic therapy, will depend upon the initial pattern of deposition and the subsequent rate of clearance.

It therefore depends on dosage forms and delivery devices. Several dosage forms can be used in nasal drug delivery, such as solutions, suspensions, emulsions, powders, microspheres, and liposomes, while delivery devices, such as dropper, spray pump, metered dose inhaler, dry powder inhaler, and nebulizer, have been used.

Solution dosage forms, applied as drops, showed a short residence time in the nasal cavity (85–87) because the nasal drops dispersed more extensively into the posterior part of the nose, where they were cleared more rapidly by mucociliary clearance. This can be improved by using spray systems (85–87), adding bioadhesive (88–90), or using a powder form (87,88,90–92). Harris et al. (86) showed that desmopressin solutions containing  $^{99m}\text{Tc}$ -labeled human serum albumin administered intranasally as a spray were deposited anteriorly, and small portions were cleared slowly into the nasal pharynx. In addition, the plasma level of desmopressin and the biological response were clearly enhanced after administration of the spray. Studies have shown that spray preparations containing 0.25% methylcellulose decreased mucociliary clearance (93), resulting in a prolonged absorption of nasally administered desmopressin (94). However, highly viscous solutions have the disadvantage of being difficult to administer. Therefore solutions of thermogelling systems, which have low viscosity at room temperature and form a gel at body temperature, have been introduced. These systems are easy to apply to the nasal cavity at room temperature, whereas the gel state at body temperature adheres to the mucosa. Examples of these systems are Poloxamer 407 solutions (95) and combinations of ethyl (hydroxyethyl) cellulose and a small amount of sodium dodecyl sulfate in water (96,97). Gellan gum (Gelrite®) can also be used as a phase-change polymer system, because the gellan gum solution can form a gel if a physiological level of cation, such as  $\text{Ca}^{2+}$ , is added. Therefore a promising way of lengthening the residence time of drugs with gellan gum could be forming a gel through the contact of a solution with the nasal mucosa (98).

A powder dosage form of insulin was evaluated by Nagai et al. (91). Hydroxypropyl cellulose and Carbopol 934 were the bioadhesives, which they used as excipients in a powder form. They found that a powder dosage form showed higher bioavailability of insulin than a liquid dosage form. Nakamura et al. (88) studied the adhesion of powder bioadhesives to the nasal tissue. They suggested that at the initial stage, bioadhesive powders absorb water from mucus on the nasal mucosa and gradually gel. Therefore these systems can prolong residence time in the nasal cavity. Xanthan gum showed the longest residence time, followed by tamarind gum, hydroxypropyl cellulose, and polyvinyl alcohol. Moreover, they found that mixing two

or more bioadhesives with different properties could modify the bioadhesive property of a system. Microspheres also show an increased residence time in the nasal cavity (99–103). Bioadhesive microspheres show the same mechanism as the bioadhesive powder, as they absorb water and form a gellike structure after swelling. Illum et al. (102) used albumin, starch, and DEAE-dextran microspheres to increase residence time in the nasal cavity and thus increase bioavailability of the drugs. The results indicated that these microspheres exhibited a half-life period of about 4 hours, which was much longer than the about 15 minutes observed for solutions and powder. The enhancing effect of microspheres on nasal drug absorption is caused not only by an increase in residence time but also by a temporary widening of the tight junctions, as shown in a Caco-2 cell monolayer in the presence of bioadhesive microspheres (99,100). Hence when the microspheres absorb water from mucus and swell, the nasal mucosa is dehydrated, which causes the tight junctions to separate. Recently, Witschi and Mrsny (103) evaluated microparticles of starch, alginate, chitosan, and Carbopol 971 as nasal platforms for protein delivery. They found that protein transport across polarized Calu-3 cells, a well-characterized human respiratory tract epithelial cell line, was enhanced using Carbopol and chitosan microparticles.

Liposomes are lipid vesicles composed of layers of membranes enclosing an aqueous phase. The use of liposomes as a nasal delivery dosage form has been considered because they may either prolong residence time in the nasal cavity or sustain the duration of action. Vyas et al. (104) prepared multilamellar liposomes containing nifedipine using a conventional cast film method. An *in vivo* experiment in rabbits showed that the nasal administration of liposomes could maintain an effective drug concentration for prolonged periods of time with improved bioavailability. Liposomes can also be used as vaccine adjuvants. An influenza vaccine composed of liposome-entrapped glycoproteins from the envelope of influenza virus was administered intranasally. It induced a strong systemic immunity and a local IgA response that protected against virus infection. Alpar et al. (105) incorporated tetanus toxoid into liposomes composed of equimolar concentration of distearoyl phosphatidylcholine and cholesterol. They found that liposome formulations delivered via the nasal cavity significantly improved the immune response when compared to free antigen. Note that this work was in guinea pigs, and a concentration of tetanus toxoid used in nasal delivery was ten times higher than intramuscular delivery. In spite of the positive response to liposomes, the stability of liposomes should be an important concern because of the presence of an aqueous phase in the system. Therefore proliposomes, a free-flowing form that creates a liposomal

dispersion on adding water, were introduced (106). Ahn et al. (107) studied the possibility of using proliposome as an intranasal dosage form for the sustained delivery of propranolol. The results showed that nasal administration of proliposomes to the rats could sustain the plasma concentration profile of propranolol better than the solution, proliposome-loaded sorbitol, and hydrated proliposomes. Moreover, the bioavailability of the nasal proliposomes (~97.5%) was much higher than that of an oral solution (~14.2%).

Emulsions were tested as a nasal delivery formulation for lipid-soluble drugs. Kararli et al. (108) used oleic acid/monoolein emulsion formulations to delivery a renin inhibitor. Using the rat as a model animal, the percent absolute bioavailability of a renin inhibitor was enhanced from 3–6% in control polyethylene glycol 400 solution to 15–27% when the emulsion formulations were used. Ko et al. (109) applied three different charged testosterone submicron-size emulsion formulations intranasally in rabbits, and compared the bioavailability to intravenous injection. The results suggested that emulsions might have considerable potential for nasal delivery, especially for positively and negatively charged emulsions, because these formulations showed bioavailability of 55 and 51%, respectively, as compared to only 37% for neutral charged emulsion.

Delivery devices are also an important factor to improve accuracy, reproducibility, and patient acceptability of drug delivery to the nasal cavity. For a better understanding of delivery devices, the reader is directed to other reviews (110–112).

## B. Pulmonary

### 1. Relevant Anatomy and Physiology

The respiratory tract consists of all structures that conduct air between the atmosphere and the alveoli. The parts of

the respiratory tract that lie outside the lung are the nose, pharynx, larynx, trachea, and main bronchi. Within the lung, each main bronchus branches extensively to a smaller diameter and a higher number, as shown in Table 3. The exchange zones of the lung with the blood stream are the alveolar ducts and alveolar sacs, which consist of numerous spherical alveoli. The surface area for gas exchange, as well as drug absorption, of the alveoli is about 60 to 80 m<sup>2</sup>. Dense vascular beds of pulmonary capillaries also match this large surface area of the alveoli. The bronchial epithelium consists of pseudo stratified ciliated columnar cells and mucus-secreting goblet cells (115). The alveoli are covered by a very thin epithelium (0.1–0.2 μm) without cilia and a mucus blanket (116). This epithelium consists of granular pneumocytes and membranous pneumocytes, which are responsible for secretion of surfactant phospholipids and are involved in gas exchange, respectively. The pore size of this sievelike epithelium is about 0.5 to 0.6 nm (115).

### 2. Major Biological Barriers and Appropriate Strategies

The primary barrier mechanisms for pulmonary drug delivery are the geometry of the airways, mucociliary clearance, macrophage activity, and pulmonary metabolism. The branching airways act like an impaction filter for inhaled particles. There are three basic mechanisms, which effect the deposition of particles in airways, i.e., inertial impaction, sedimentation, and Brownian motion (117). Impaction occurs when particles have inertia such that they are unable to travel with the airstream when they change direction as an airway branches. Thus they impact on the mucus surface of ciliated epithelium. This mucus is continuously moving out of the lung into the throat, where it is swallowed or coughed up. Impaction is important for

**Table 40.3** Subdivision of the Respiratory Tree

Name	Diameter	Length	Total cross-section area (cm <sup>2</sup> )	Number
Trachea	1.8 cm	12.0 cm	2.54	1
Main bronchi	1.2 cm	4.8 cm	2.33	2
Lobar bronchi	0.8 cm	1.9 cm	2.13	3 on right, 2 on left
Segmental bronchi	0.6 cm	0.8 cm	2.00	10 on right, 8 on left
Terminal bronchioles	1.0 mm	2.0 mm	180.00	about 48,000
Respiratory bronchioles	0.5 mm	1.0 mm	about 1,000	about 300,000
Alveolar ducts	400 μm	0.5 mm	about 10,000	about 9 × 10 <sup>6</sup>
Alveoli	250 μm	—	about 8 × 10 <sup>5</sup>	about 3 × 10 <sup>9</sup>

Source: Refs. 113, 114.

particles above 5  $\mu\text{m}$  in size, which tend to deposit in the upper respiratory tract. Smaller particles (0.6–5  $\mu\text{m}$ ) are able to move with the airstream; however, sedimentation can occur in the lower respiratory region, which has a lower air velocity. Finally, particles below 0.6  $\mu\text{m}$  can deposit by Brownian motion. Therefore the efficiency of drug delivery via this route is often not high enough because of the difficulty in targeting particles to the sites of maximum absorption (alveoli). The degree to which inhaled particles penetrate into airway spaces is controlled by a number of factors, i.e., particle size and size distribution, shape, and density (118). The particle size is usually referred to as an aerodynamic diameter, defined as the geometric diameter of a sphere with unit mass density, and has the same velocity as the test particle (118,119). Small particles (mean geometric diameter <5  $\mu\text{m}$ ) with high density tend to aggregate and can be rapidly phagocytosed in the deep lungs by alveolar macrophages, while larger particles tend to deposit in the upper respiratory tract. A new type of inhalation aerosol has recently been introduced and identified that may help to solve this problem (120). This aerosol is formed by considering the aerodynamic diameter window of 1 to 3  $\mu\text{m}$  as a lower limit, because it was demonstrated that particles of mean aerodynamic diameter of 1 to 3  $\mu\text{m}$  deposit maximally in the deep-lung region, whereas particles with an aerodynamic diameter smaller than 1  $\mu\text{m}$  are mostly exhaled, and particles larger than 10  $\mu\text{m}$  deposit maximally in the mouth and throat. Particles with low mass density (porous) and larger geometric diameter (about 10–15  $\mu\text{m}$ ) have been used and gave excellent results. The advantage of this new aerosol is a decrease in the tendency to aggregate while minimizing clearance by alveolar macrophages. Biodegradable polymers or lipophilic carriers can also be used to protect drug from metabolism. Therefore these systems are potentially good for long-acting therapeutic delivery following inhalation (120,121).

There are no cilia or mucus blankets in the alveoli, but insoluble substances will be engulfed by alveolar macrophages, which are then carried to the ciliated epithelium and cleared through the mucociliary clearance pathway (122). Systemic absorption of inhaled substances may also be inhibited by pulmonary metabolism. The lungs contain a variety of drug-metabolizing enzymes, including microsomal mixed function, amine oxidase, monoamine oxidase, reductases, esterases, a variety of conjugates, and proteolytic enzymes (123,124).

### 3. Examples

Drug administration to the lungs has been employed for many years for local treatment of pulmonary diseases

(110,125). For example, bronchodilators, corticosteroids, anticholinergics, and antiallergic drugs are administered by means of oral inhalation (110). The advantages are a decrease in systemic side effects and rapid onset of action. In recent years, the systemic effect of the drugs delivered via this route has been studied. Patton et al. (126) reviewed the potential of using the pulmonary area as a route for the delivery of insulin. By comparing the data from several studies, they concluded that aerosol insulin has a potential advantage over subcutaneous injection because it is more rapidly absorbed (serum peak at 5–60 min) and cleared than a subcutaneous injection (serum peak at 60–150 min). However, aerosol delivery involves some losses, including loss from the device, loss from exhaling or deposits in the mouth and throat, and loss from lung metabolism. These problems can be largely overcome by proper dosage form design, which accurately delivers drug to a specific site, the lungs, and prevents lung metabolism. Moreover, delivery devices are also a crucial factor. It is interesting to note that the same delivery devices as nasal delivery are used for pulmonary delivery; however, the aims of pulmonary delivery are achieving a high deposition in the lower airways and a minimum deposition in the upper airways. Most of the drugs are administered to the lungs as aerosols, and their delivery is to a great extent dependent on particle size distribution. Different aerosol size distributions may be expected to deposit preferentially in different regions of the respiratory tract, and aerosols inhaled intranasally also have different deposition patterns from those inhaled orally (127). For further information about delivery devices a number of interesting reviews are recommended (110–112,128–130); this report will concentrate on the development of formulations.

Sanders et al. (131) compared the pulmonary deposition of aerosols generated from two formulations in healthy volunteers and asthmatic subjects. The two formulations were a teflon particulate suspension with a mean particle diameter of 5.76  $\mu\text{m}$ , and a solution that generated aerosol particles of 2.13  $\mu\text{m}$  mean diameter. Both formulations were radiolabeled with  $^{99\text{m}}\text{Tc}$  and delivered by standard metered dose inhaler. The results showed that the aerosol generated from the solution produced a significantly greater total lung deposition than the suspension aerosol. Adjai and Garren (132) studied the effect of particle size on bioavailability of leuprolide acetate from a solution and suspension formulation. By using impaction and light scattering methods, they demonstrated that the solution aerosol consisted largely of coarse particles, and they lost most of the drug at the actuator, while the suspension aerosol had greater fractions of particles within the respiratory range (<5  $\mu\text{m}$ ) and delivered about 40–50% to the lungs. The

bioavailability of each aerosol formulation based on intravenous control was compared. The bioavailability results from the suspension aerosol were significantly more than for the solution aerosol, which correlated with the particle size distribution results. However, when the correct bioavailabilities were used to compare the effect of the type of formulation to the absorption of drug from the lungs, there were no differences between these two formulations. Note that the correct bioavailability was calculated from the effective dose, which equals the amount of the drug reaching the lungs.

Emulsion is another liquid formulation that could be used as a pulmonary delivery system, for example, water in fluorocarbon emulsions (133). These emulsions are stabilized by perfluoroalkylated surfactants with a dimorpholinophosphate head group. Fluorocarbons, such as perfluorooctyl bromide and perfluorooctyl ethane, were used as the external phase of reverse emulsions. Significantly slower release of 5,6-carboxyfluorescein entrapped in the water droplets was found compared to using hydrocarbon oils as the external phase. This can be explained by the extremely hydrophobic character of fluorocarbons, which act as a physical barrier to diffusion of encapsulated hydrophilic compounds.

The ban of chlorofluorocarbon propellants has spurred the development of alternative pulmonary drug delivery systems for metered dose inhalers. One possibility is the use of dry powders in the inhalation device. Many trials to develop an ideal dry powder formulation that can deliver the drug accurately to the lungs have been conducted by designing powders and constructing inhalers (134–139). Kawashima et al. (135) presented a new powder design method to improve inhalation efficacy of hydrophobic drug powders such as Pranlukast hydrate. They modified the surface of powders by using hydroxypropylmethylcellulose phthalate, a pH-dependent cellulose derivative (soluble at pH > 5.5). Dramatically improved inhalation properties of the surface modified powders were found in vitro compared with the original unmodified powder. The improvements were attributed to the increased surface roughness, the hydrophilicity of the surface-modified powders (at pH > 5.5), and the resultant increased dispersibility in air and emission from a device. As described before, a large and porous particle with biodegradable polymers or lipophilic carriers can be aerosolized from a dry powder inhaler more efficiently than smaller nonporous particles, resulting in higher respiratory fractions of inhaled drug (120,121). In addition, these formulations can be particularly useful for controlled release purposes. For example, insulin was encapsulated into porous and nonporous particles of poly(lactic acid-co-glycolic acid). Inhalation of

large porous insulin particles resulted in suppressed systemic glucose levels in rats for 96 hours, whereas only 4 hours was the result from small nonporous insulin particles. The bioavailabilities relative to subcutaneous injection were 87.5% and 12% for large porous and small nonporous particles, respectively. High systemic bioavailability of testosterone was also achieved by inhalation of large porous particles. Note that both porous and nonporous particles have similar aerodynamic diameter. Ben-Jebria et al (121) used dipalmitoyl phosphatidylcholine as a lipophilic carrier for sustaining the action of the bronchodilator, albuterol sulfate, in the lungs. They found that inhalation of large porous particles produced a significant inhibition of carbochol-induced bronchoconstriction for at least 16 hours, while inhalation of small nonporous particles protected from carbochol-induced bronchoconstriction for up to 5 hours.

Drug entrapment in liposomes has been most extensively investigated, and evidence has been presented both in animals and in humans that liposomes may enhance drug efficacy by greater intrapulmonary retention (125, 140–146). Taylor et al. (140) studied the pharmacokinetics of sodium cromoglycolate in healthy volunteers. It was inhaled as a solution and encapsulated in dipalmitoylphosphatidylcholine/cholesterol (1:1) liposomes. The data indicated that encapsulation of this drug can prolong drug retention within the lungs and alter its pharmacokinetics as compared to a solution formulation. The antitumor drug cytosine arabinoside was administered to the lungs of rats via intratracheal instillation as free or liposome encapsulated form (141). It was demonstrated that prolonged action of this drug could be confined to the lungs through the use of a liposomal formulation. This formulation also showed a reduction in extrapulmonary side effects. A similar clearance study was done by Lambros et al. (144). They evaluated the clearance kinetics and organ distribution of inhaled liposomal Amphotericin B in mice. Amphotericin B was not detected in the serum and other organs, such as kidney, liver, and brain. Surface charge of the liposome also affects lung clearance kinetics, where the positively charged and neutral liposomes exhibited a longer half-life than the negatively charged liposome. Saari et al. (147) used gamma scintigraphy to study the pulmonary distribution and clearance of  $^{99m}\text{Tc}$ -labeled beclomethasone dipropionate liposome formulations in healthy volunteers. The liposome formulations contained dilauroylphosphatidylcholine or dipalmitoylphosphatidylcholine. By using an Aerotech jet nebulizer, both liposome aerosols had a suitable droplet size (mass median aerodynamic diameter about 1.3  $\mu\text{m}$ ). The remaining liposomes in the lung after 24 hours were 79% and 83% for dilauroyl-

phosphatidylcholine and dipalmitoylphosphatidylcholine liposomes, respectively. These results indicate that liposomal formulations delivered to the lungs have the potential to sustain drug release, prolong drug action, and minimize side effects.

### C. Oral Cavity

#### 1. Relevant Anatomy and Physiology

The oral cavity is lined by a relatively thick, dense, and multilayered highly vascularized mucosa. The total surface area is about 100–160 cm<sup>2</sup> (148,149) and can be divided into three general areas according to functional demands. First, the masticatory mucosa consists of stratified squamous epithelium, which is generally keratinized, and presents on the gingival and hard palate. Second, a specialized mucosa is present on the borders of the lips and the dorsal surface of the tongue with its highly selective keratinization. Third, the lining mucosa is found on the lips, cheeks, floor of the mouth, ventral surface of the tongue, alveolar, and soft palate. This mucosa consists of nonkeratinized stratified squamous epithelium (148,150). Transport of drugs via the oral mucosa most likely occurs through the nonkeratinized areas (151), so we will discuss this pathway by emphasizing sublingual and buccal delivery. Sublingual delivery is drug administration through the mucosa of the floor of the mouth and the ventral surface of the tongue, while buccal delivery is drug administration through the mucosa lining the inside of the cheeks. The thickness of the oral epithelium varies depending on location and species. In humans, dogs, and rabbits, the thickness of the buccal epithelium is about 500 to 800  $\mu\text{m}$ , whereas the sublingual area measures about 100 to 200  $\mu\text{m}$ . This is because the buccal epithelium is composed of about 40 to 50 cell layers, while the sublingual epithelium contains considerably fewer cell layers (152,153). Separately, the buccal and sublingual mucosae of the human have a surface area about 50 and 26.5 cm<sup>2</sup>, respectively (149). The surface of the mucosa is continuously washed by a stream of about 0.5 to 2 liters of saliva daily and is cleared by swallowing. Saliva also functions as a moistening liquid for the mucosa with a pH between 5.8 to 7.2. The thickness of the coating of saliva on the mucosa throughout the mouth is about 70  $\mu\text{m}$ .

#### 2. Major Biological Barriers and Appropriate Strategies

The permeability of the oral mucosa in general is probably intermediate between that of the skin and the intestinal mucosa. The sublingual mucosa is relatively permeable, giving relatively rapid absorption and acceptable bioavail-

ability for many drugs, while the buccal mucosa is considerably less permeable and is generally not able to provide rapid absorption (154). The permeability barrier of the oral mucosa is thought to reside within the superficial layers, constituting about one-fourth to one-third, of the epithelium (155), as shown by using horseradish peroxidase (156) and lanthanum salts (157), which are both water-soluble markers. In these studies, they found that both markers did not penetrate beyond the top three cellular layers when applied topically. When applied subepithelially, markers can penetrate through the lower area of the mucosa but they did not penetrate outward to the upper epithelium. Dowty et al. (158) showed that the upper 50  $\mu\text{m}$  of the epithelial tissue was a barrier to transport of thyrotropin-releasing hormone in rabbit buccal mucosa *in vitro*. A possible explanation of this behavior is the presence of membrane coating granules or Odland bodies, which are spherical or oval organelles, 100 to 300 nm in diameter (152–154). This barrier is apparently an accumulation of neutral lipids and glycolipids in the intercellular spaces of the superficial cell layers and is derived from the extrusion of the contents of the membrane coating granules as the epithelial cells move superficially (155).

Besides membrane coating granules as a barrier for permeation, one must also consider enzymatic activity in the oral mucosa. The presence of hydrolytic enzymes, esterases, and peptidases has been reported in the buccal mucosa. The small available surface area and short residence time are also factors to be considered for designing an appropriate dosage form.

#### 3. Examples

Oral cavity drug delivery systems have been employed to obtain local or systemic effects (159,160). Despite some limitations in the oral cavity, such as low permeability, short retention time, and small surface area, the delivery systems can be optimized to provide desired drug concentration in the oral cavity (local) or in the blood (systemic). Several dosage forms have been used in the oral cavity including solutions, tablets, patches, films, and semisolid systems.

Buccal tablets, incorporating active ingredients and bioadhesives, have been studied extensively. The purpose of using a bioadhesive is to increase contact time and sustain drug release. Several studies showed promising results for the delivery of local-acting drugs. Nagai (161) used two-layered tablets to deliver triamcinolone acetonide, which proved to be effective in the treatment of aphthous stomatitis, an infection of the mouth. The tablet consisted of a bioadhesive and a non-adhesive layer. The bioadhesive layer contained the drug Carbopol 934 and hydroxypropyl-

cellulose, while the nonadhesive layer contained lactose. Bouckaert et al. (162,163) prepared a buccal bioadhesive miconazole slow-release tablet by mixing miconazole, an antifungal drug, with thermally modified starch and 5% polyacrylic acid (Carbopol 934, 910, or 907). The *in vivo* data of release characteristics and adhesion time showed that no significant difference could be seen among the formulations (163). For the Carbopol 934 formulation, mean adhesion time was  $586 \pm 133$  minutes (range 360–870 minutes), and the salivary miconazole concentration remained constant at an effective level for more than 10 hours (162). Recently, buccal bioadhesive tablets of metronidazole were prepared by using Carbopol 934P, hydroxypropylmethylcellulose, and sodium carboxymethylcellulose as bioadhesives (164). *In situ* release studies using the bovine cheek pouch membrane in a flow through cell demonstrated that the concentration of metronidazole was maintained at an effective level for a period of 6 hours, the time for which it was held in the buccal cavity.

Buccal tablets are also used as a drug delivery system for systemic delivery. Ishida et al. (165) examined the possibility of buccal delivery of insulin using a bioadhesive dosage form. Insulin was incorporated into core materials of cocoa butter and sodium glycocholate, and then a mixture of hydroxypropylcellulose and Carbopol 934 (1:2) was compressed around the core. Subsequent studies in beagles revealed that the tablet adhered for up to 6 hours; however, the percentage of insulin absorbed was about 0.5% compared to an intramuscular injection. There has been interest in buccal administration of morphine; however, studies of buccal tablets have indicated poor bioavailability and clinical efficacy (166,167). Bioadhesive tablets seem to be the answer to these problems. Anlar et al. (168) prepared a bioadhesive tablet of morphine sulfate by compression with bioadhesives, hydroxypropylmethylcellulose, and Carbopol 910, in various amounts. This tablet showed significant bioadhesive characteristics in contact with bovine sublingual mucus. The release behavior was found to be non-Fickian, suggesting that the release of morphine sulfate was controlled by a combination of diffusion of morphine sulfate in the matrix and swelling of the matrix. The average percentage of morphine sulfate absorbed in healthy volunteers was  $30 \pm 5\%$  of the drug load within 8 hours. The current comparison study between three formulations, a 30 mg oral controlled-release tablet, a 20 mg aqueous solution retained in the mouth for 10 minutes, and a 60 mg bioadhesive buccal tablet, showed that morphine absorption from the solution was very low, while a sustained-release pattern was found in the case of other formulations (169). However, information about excipients in the formulations was not available. Yukimatsu et al (170) developed a bioadhesive tablet consisting of two

layers, a fast-release layer and a sustained-release layer. It was designed for gingival application. The fast-release layer contained 20% isosorbide dinitrate dispersed in the solid matrix of D-mannitol and low molecular weight polyvinylpyrrolidone, while the sustained-release layer consisted of 80% isosorbide dinitrate in the polymer matrix of high molecular weight polyvinylpyrrolidone and polyacrylic acid. The release profile of drug from this tablet indicated that the fast-release fraction was released within 15 minutes, contributing to a rapid absorption, and the sustained-release fraction was released gradually over a period of 12 hours, contributing to a prolonged duration of drug plasma concentration. This tablet of isosorbide dinitrate was confirmed to achieve a desired pharmacokinetics profile, such as a rapid onset and long duration of therapeutic effect in both beagles and humans. Moreover, it showed a better bioavailability than a marketed oral sustained-release tablet and the same bioavailability as a sublingual tablet. Han et al. (171) used a manual single-punch tableting machine to prepare a disk with diameter and thickness of 8 mm and 1 mm, respectively. Various amounts of Carbopol 934, hydroxypropylcellulose, and drug were mixed to prepare different formulations of buccal disks. The impermeable backing layer of ethylcellulose was cast on one side of the disks. By varying the drug hydrophilicity and the amount of solubility enhancer ( $\beta$ -cyclodextrin) inside the disks, the results demonstrated that drug solubility was an important factor in controlling drug release. Moreover, *in vitro* studies showed that the disks can attach to porcine buccal tissues for at least 48 hours.

Oral mucosal patches for drug delivery systems have been developed extensively (172,173). These patches may show unidirectional (releasing the drug only into the mucosa) or bidirectional (releasing the drug into the mouth as well) drug release. Depending on its size and shape, the patch may be applied at different sites, including the buccal, sublingual, and gingival mucosa. For optimum patient compliance, high flexibility and appropriate size of the patch need to be considered. Buccal patches may have a size of up to 12–15 cm<sup>2</sup>, while sublingual or gingival patches should be in the range of 1–3 cm<sup>2</sup> (160,174). Veillard et al (175) developed a three-layer buccal patch consisting of a bioadhesive basement membrane, a rate-limiting center membrane, and an impermeable facing membrane, which permitted unidirectional drug release into the mucosa. Polycarbophil was used as a bioadhesive in the bottom layer. This patch can remain in place for approximately 17 hours regardless of eating or drinking. However, the study did not incorporate drugs into the patch. Buccal adhesive patches, consisting of two-ply laminates of an impermeable backing layer and a bioadhesive layer containing drugs, were developed (174). The poly-

mers used were hydroxyethylcellulose, hydroxypropylcellulose, polyvinylpyrrolidone, and polyvinylalcohol. It was found that the duration of mucosal adhesion *in vivo* was affected by the type of polymer, their viscosity grades, polymer content, and the drying procedure for preparation. Biolaminated films, consisting of a drug-containing bioadhesive layer and a drug-free backing layer, were produced by a casting/solvent evaporation technique (176). The bioadhesive layer consisted of a mixture of drug and chitosan, with or without an anionic polymer such as polycarboxylic acid, sodium alginate, and gellan gum. The backing layer was made of ethylcellulose to avoid loss of drug due to washout with saliva. This patch was also expected to provide drug release in a unidirectional fashion to the mucosa.

Several ointment bases for oral mucosa administration have been developed. Ishida et al. (177) mixed Carbopol 934 with three kinds of ointment bases including white petrolatum, hydrophilic petrolatum, and absorptive ointment. They found that Carbopol 934 could improve the physical properties of the ointments and the release profiles of the model drug, prednisolone. Bremecker et al. (178) explored the possibility of using a neutralized polymethacrylic acid methyl ester as an adhesive ointment base. Sveinsson and Holbrook (179) used a copolymer of methacrylic acid and methacrylic acid methyl ester to produce an oral bioadhesive ointment containing liposomes with triamcinolone acetonide. Gelatin was also added to the formulation to improve its adhesive property. Recently, Petelin et al. (180) studied the properties of bioadhesive ointment for delivery of liposomes containing drugs. Polymethyl methacrylate, Carbopol 934P, and Orabase were used as the bioadhesive ointment bases. The results showed that polymethyl methacrylate was the most appropriate bioadhesive ointment base for local application in the oral cavity because the liposomes were most stable in this base. Sublingual gel formulation of leuprolide was developed by using hydroxypropylcellulose as a bioadhesive (181). A prolonged absorption of up to 6 hours after sublingual dosing in the human was observed. This observation may be attributed to an increase in residence time at the site of absorption.

Recently, high-velocity powder injection, namely PowderJect, has been introduced as a new drug delivery technology to overcome the barrier limitation of skin and mucosal sites (182). This new technology was developed based on the direct injection of solid powder through the stratum corneum or into mucosal membranes without using a needle. The oral PowderJect delivery system used a gas-pressure pulse to accelerate and deliver fine particles 20 to 100  $\mu\text{m}$  diameter into oral mucosal tissue. This device proved useful for delivery of testosterone and lido-

caine hydrochloride through the oral mucosal, showing promising pharmacokinetic results.

## D. Gastrointestinal Tract

### 1. Relevant Anatomy and Physiology

The GI tract comprises the stomach, small intestine, and large intestine. It is responsible for the major digestion of food, absorption of the end products of digestion, absorption of ingested fluids and reabsorption of secreted fluids, and excretion of some digestive end products. Table 4 lists the specific functions of different regions of the GI tract.

The human stomach is usually described as a J-shaped sac with a maximum length of 25 cm and a width of 15 cm. The average adult stomach has a capacity of about 1.5 L. It is divided into the cardia, the fundus, the body, the antrum, and the pylorus, and the function of each region is described in Table 4. The surface of the gastric mucosa is covered by simple columnar epithelium. Its surface is increased by downgrowths, which are variously called foveolae, pits, or crypts. The major function of the gastric epithelium is the secretion of acid and digestive enzymes. It also secretes mucus to lubricate ingested food and to protect itself from autodigestion by acid and pepsin. The glands in the area of the cardia and the pylorus only produce mucus, while the glands in the body and the fundus produce mucus, hydrochloric acid, and proteolytic enzymes (184). The stomach is emptied by vigorous peristaltic contractions that begin in the antral region, or perhaps in the esophagus, with simultaneous opening of the pylorus. The pylorus is immediately closed after chyme (the mixture of food with gastric secretions) has left the stomach. Emptying is most intensive immediately after a meal and then becomes weaker. Gastric emptying time depends on the amount, the composition, and the particle size and shape of the food. A carbohydrate-rich food is emptied after a relatively short time, while the poorly chewed or fat-rich foods can prolong the emptying time up to 5 hours. In the fasting state, the stomach displays a minimum secretion (5–15 mL/h). This secretion is free of hydrochloric acid and pepsin and therefore shows a neutral to slightly alkaline pH. After ingestion of a meal, the rate of gastric secretion increases rapidly. The three phases of gastric secretion in response to food are the cephalic phase, the gastric phase, and the intestinal phase (185). The cephalic phase takes place under the influence of nervous impulses from the central nervous system such as the sight, smell, and taste of food. The acid secretion rate during this phase can be as much as 40% of the maximum rate. The gastric phase is initiated when food reaches the stomach. The principal stimuli include distension of the stomach and the re-

**Table 40.4** Regions of the Gastrointestinal Tract and Their Primary Functions

Organ	Region	Function
Stomach	Fundus	Initial storage of food
	Body	Storage/secretion
	Antrum	Vigorous mixing of food with secretions to form a semisolid chyme
	Pylorus	Separate the stomach from the duodenum
Small intestine	Duodenum	Segment receiving liver and pancreatic secretions Important site for the regulation and overall coordination of GI function
	Jejunum	Absorption of the majority of the end products of digestion
	Ileum	Fluid reabsorption; junction with the large intestine is termed the ileocecal sphincter
Large intestine	Ascending colon	Fluid reabsorption
	Transverse colon	Fluid reabsorption
	Descending colon	Fluid reabsorption
	Sigmoid colon	Storage of feces
	Rectum	Storage and elimination of feces

Source: Ref. 183.

lease of gastrin. The intestinal phase is the final phase of secretion, which is initiated by the passage of chyme into the duodenum. The presence of chyme in the duodenum results in both stimulation and inhibition of acid secretion in the stomach. The stimulatory influence dominates when the pH of gastric chyme is above 3. This is probably based on the release of gastrin. However, when the pH falls below 3, the inhibitory influence dominates by the release of secretin, which inhibits acid secretion.

The small intestine is the major site for both digestion and absorption of food (Table 4). It is 6 to 7 meters long with an average diameter of 4 cm. It is divided into the duodenum, the jejunum, and the ileum (182,185). The duodenum is a 20 to 30 cm long segment connected to the pylorus. This region is the place where secretions of the liver and pancreas enter the small intestine. The jejunum is 250 to 300 cm long, while the length of the ileum is about 300 to 400 cm. The small intestinal mucosa is covered by a simple columnar epithelium and is characterized by a large surface area. The first stage of the surface enlargement results from circular mucosal folds called the plicae circularis or Kerckring's folds. In this fold, the epithelium consists of an enormous number of small finger-like villi, roughly 1 mm high. These two factors increase the luminal area 30-fold over that of a smooth cylinder of the same external diameter. A further increase in the surface area can be produced by the presence of microvilli or brush border which are about 1  $\mu\text{m}$  long and 0.1  $\mu\text{m}$  in width. The microvilli can enlarge the surface area of the lumen by a factor of 600. This makes a total absorptive surface area of the small intestine up to 200  $\text{m}^2$ . The transport of chyme through the small intestine varies but can

be estimated as 5 minutes in the duodenum, 2 hours in the jejunum, and 3 to 6 hours in the ileum (186).

The large intestine is the terminal part of the intestinal tract and is composed of the cecum, the colon, and the rectum (182,185). It is about 150 cm long, and connects to the small intestine at the ileocecal valve, where the small intestine contents are released into the large intestine. The colon has a total length of about 130 cm and a lumen diameter of 6 to 8 cm. It is divided into an ascending, a transverse, a descending, and a sigmoid colon. The function of each region is shown in Table 4. Even though the large intestine has a larger diameter and length than the small intestine, it has a smaller surface area than the small intestine because of the lack of villi in its entire region. The surface area of the large intestine can be increased by the presence of crypts. The epithelium of the crypts consists of goblet cells, which produce mucus. The peristaltic movement starting from the caecum and moving to the sigmoid colon is superimposed two to three times a day. Therefore a colonic transit time of 35 hours or longer is typical (187).

The rectum is the dilated distal portion of the alimentary canal. Its upper part is distinguished from the rest of the colon by the presence of transverse folds (188). The rectal epithelium is the same as other regions of the large intestine and is covered by simple columnar cells, consisting of numerous goblet cells. There are no villi or microvilli on the rectal mucosa, and only a limited surface area of 200 to 400  $\text{cm}^2$  is available for drug absorption. The human rectum is approximately 15 to 19 cm long and 1.5 to 3.5 cm in diameter. The rectum contains 1 to 3 mL of mucus fluid with a pH of 7 to 8 (189).

The GI tract is richly supplied by a blood-capillary network that is associated with the splanchnic circulation. All venous drainage from the GI tract is via the mesenteric veins, which empty into the portal vein, and passes through the liver before entering the systemic circulation. In addition to the blood supply, the lymphatic vessels that drain to the thoracic duct extensively supply the GI tract. As shown in Fig. 2, absorption of drug by the lymphatic system will then enter directly into the venous system of the systemic circulation without passing through the liver.

Both blood and lymphatic vessels are also abundant in the submucosal region of the rectal mucosa. Blood supply is delivered by the superior rectal artery and is drained by a superior, a middle, and an inferior hemorrhoidal vein. The superior veins drain into the portal circulation, while the middle and inferior veins drain into the inferior vena cava. However, there are extensive anastomoses among these veins (189,190).

## 2. Major Biological Barriers and Appropriate Strategies

The oral route is the most popular and convenient route of drug administration; however, several factors can influence absorption of drugs through the GI tract. These include the pH of the luminal content, the presence of enzymes, motility and transit time, the complexity of the absorbing surface, blood and lymph flow, and colonic microflora.

Variation of pH in different regions was found throughout the entire GI tract, as shown in Table 5. The small intestine has the largest absorptive surface area in the GI tract (Table 5) and therefore is the primary region responsible for drug absorption. However, the stomach controls the rate at which oral drug delivery systems reach the small intestine. In addition, the acidic environment and presence of pepsin in the stomach can influence drug stability and solubility. A number of factors influence the rate of gastric emptying, including stomach content volume, pH, caloric content, osmolarity, viscosity, and calcium sequestrant ca-

capacity (194). Davis et al. (195) studied the transit of pharmaceutical dosage forms through the small intestine in normal subjects using gamma scintigraphy. They found that solutions and pellets (<2 mm in size) were emptied rapidly (<1 h) even when the stomach was in the digestive mode, while matrix tablets and osmotic pumps were retained for longer periods of time, depending on the size of the meal. Small intestinal transit times were found constant (3 to 4 h) for all dosage forms and in different states. They concluded that the nature of the dosage form and the presence of food in the stomach affected gastric emptying, while small intestinal transit times were independent of the dosage form and fed state. Since small intestinal transit time does not vary, the arrival of an oral dosage form to the colon is determined mostly by the rate of gastric emptying. When the dosage form reaches the colon, the transit time depends on size, not density, especially in the proximal area of the colon. Small units pass through the colon slower than large units. Segmental transit measured by radioopaque markers gave values of 35 hours for the whole colon. Men had slightly shorter transit times than women, and this was significantly apparent in the proximal area of the colon (187). There is no experimental evidence for the existence of carrier or receptor mediated drug transport through the colon mucosa. Since the intercellular spaces are considerably smaller in the colon than in the duodenum and ileum, the principal route for colonic absorption appears to be transcellular rather than paracellular.

Exterior to the small intestinal lining, the microvilli are covered by a mucus layer about 300  $\mu\text{m}$  thick. This layer is bound to a 0.1  $\mu\text{m}$  thick glycocalyx, which is covalently linked to the microvilli. The negatively charged glycoprotein of the glycocalyx is balanced by positively charged counterions resulting in an acidic microclimate at the surface of the microvilli. It also has an unstirred water layer present at the surface. This layer can be the rate-limiting step in absorption of lipophilic drugs (196). However, studies in dogs and humans showed that the unstirred water layer has a maximal apparent thickness of only about 40  $\mu\text{m}$  (197). With this thin layer, the barrier property of this layer is still questionable.

A recently recognized factor, which may play an important role in drug absorption through the small intestine, is the presence of P-glycoprotein, which is a membrane-associated transport protein. P-glycoproteins that are located in the apical membrane of enterocytes can actively transport a broad range of drugs out of the cell into the intestinal lumen. This results in a low total absorption of drugs. Examples of drugs that are P-glycoprotein substrates are anthracyclines, digoxin, verapamil, phenytoin, erythromycin, cyclosporin A, quinine, and dexamethasone (198).

**Table 40.5** pH and Absorbing Surface Area in the Gastrointestinal Tract

Region	pH	Absorbing surface area ( $\text{m}^2$ )
Stomach	1–3.5	~0.11
Duodenum	5–7	~0.09
Jejunum	6.1–7.1	~60
Ileum	7–8	~60
Colon	5.8–7.7	~0.25
Rectum	7–8	~0.03

The GI tract presents the largest metabolic barrier to the absorption of drugs, especially proteins and peptides, because the GI tract contains several enzymes, i.e., trypsin, chymotrypsin, elastase, carboxypeptidase, and aminopeptidase (80,199,200). The metabolism of many drugs occurs either in the lumen or in the wall of the GI tract, which can reduce the overall bioavailability and hence the pharmacological activity of a wide range of drugs. When such metabolism occurs within the lumen of the intestine, it simply reduces the amount of drug available for absorption. In the GI wall, metabolism can occur during the absorptive process, so the amount of active drug available within the body can be further decreased (201). Note that huge inter-individual and interspecies differences in these processes have been recorded (202,203). Since venous drainage from the GI tract enters the portal circulation, first-pass metabolism in the liver will be a problem for many drugs. This problem can be avoided if a drug molecule is absorbed through the lymphatic circulation. However, the flow rate of lymphatic fluid (1 to 2 mL/min) compared with blood (2 L/min) is significantly lower. This may be one of the main reasons for the lower extent of absorption through the lymphatics (204). The activities of various proteases in the small intestine were generally higher than those in the large intestine. This tendency was more remarkable in the case of endopeptidases such as trypsin, chymotrypsin, and elastases (205). Once a drug is released into the colonic lumen, it is subjected to possible metabolism by host enzymes in the enterocytes and by microbial enzymes from the colon flora. A large number of aerobic and anaerobic bacteria are present throughout the entire length of the human GI tract, especially in the colon. The concentration of bacteria in the human colon is about  $10^{11}$  to  $10^{12}$  colony-forming units/mL and is dominated by anaerobic bacteria. Hence microbial metabolism proceeds primarily by reduction and hydrolysis without oxidation (206,207).

As in the colon, drug absorption from rectal administration may occur via the transcellular and/or paracellular pathways. Hence passive transport seems to be the main mechanism for rectal drug absorption (208). The fate of a drug absorbed from the rectum depends on its position in the rectum. The chance of a drug avoiding hepatic first-pass metabolism increases as the absorption site distance from the colon increases (189). Ritschel et al. (209) studied the first-pass elimination of lidocaine in the rabbit after peroral and rectal administration. The result indicated that about 30 percent of the rectally administered dose bypassed the liver after rectal absorption. This indicates that absorption from the rectum is partly via the portal route and partly via direct systemic delivery. This is similar to the finding in man, which was studied by de Boer et al. (210). However, the presence of extensive anastomoses

may attenuate this effect. Absorption from the rectum is also accomplished by the lymphatics, which are located all along the gastrointestinal tract. This pathway can circumvent hepatic first-pass metabolism; however, it should be noted that the total amount of drug absorbed through the lymphatic appears to be quite small compared with the blood circulation (189,211).

According to metabolic studies, the rectal mucosa had consistently high activities of aminopeptidase and esterase (26,27,212). This coupled with the other disadvantages, i.e., interruption of absorption by defecation, lack of acceptability by patients, limited area, and local irritation, make this route less desirable than other routes. However, this route can be useful for the delivery of drugs to patients with difficulty using the oral or other routes, such as children (213–215) and psychiatric patients (216).

### 3. Examples

Despite several barriers to drug delivery that exist within the GI tract, drug administration through the GI tract continues to be the most popular route. To be able to maintain the successful therapeutic effect of a drug, the correct amount should be released and maintained during a specific time. Moreover, the drug should be delivered or targeted to a specific region in the GI tract. There are a number of developments relative to the GI tract that have been reported. This report will review some of these, including bioadhesive systems, enteric-coated systems, and rectal delivery systems.

The original idea of using bioadhesives as platforms for oral controlled drug delivery was to use these polymers to control and prolong the gastrointestinal transit of the systems (217–219). However, *in vivo* results obtained in humans did not show that bioadhesive systems were able to control or slow down significantly the gastrointestinal transit time of dosage forms (220). Possible explanations of this failure are overhydration of the bioadhesive, inactivation of the bioadhesive by soluble mucin, and fast turnover rate of mucus (221). Microspheres prepared by using a combination of polyglycerol esters of fatty acid (PGEF) and Carbopol 934P have been demonstrated to be good candidates for increasing the gastrointestinal residence time, especially in the stomach and upper small intestine (222). Akiyama et al. (222) prepared three types of microsphere based on this combination including Carbopol-coated microspheres, PGEF-based microspheres, and Carbopol dispersion in PGEF microspheres. Only the dispersion type microspheres, referred as an Adhesive Micro-matrix System, showed a promising result. They claimed that this system prolonged gastrointestinal transit time by adhering to the gastric or intestinal mucosae in the rat.

Studies in man, using furosemide and riboflavin as markers, were done to confirm this conclusion (223). Since furosemide and riboflavin are compounds that are absorbed in the upper small intestine, drug absorption after administration of bioadhesive microspheres should be higher than that of nonadhesive microspheres, if the gastrointestinal transit time of bioadhesive microspheres is prolonged. Results from humans confirm the former conclusion. Therefore this system may be useful for drugs with low bioavailability and drugs expecting a local action. In fact, Nagahara et al. (224) tried to use this system for increasing the anti-*Helicobacter pylori* effect of amoxicillin. This idea was done following the publication by Kimura et al. (225), who demonstrated that 1-hour topical treatment with the infused solution of high concentration of antimicrobial agents provided more complete eradication of *H. pylori* than conventional therapy due to the extended gastric residence times of the drugs. The percentage of amoxicillin remaining in the stomach after oral administration of the bioadhesive microspheres to Mongolian gerbils under fed conditions was about three times higher than that of a 0.5% methylcellulose suspension. Moreover, the required dose of amoxicillin to eradicate *H. pylori* was effectively reduced by a factor of ten when the bioadhesive microspheres were used (224). Chickering et al. (226) demonstrated that polymeric microspheres made of poly(fumaric-co-sebacic), a bioerodible polyanhydride, displayed good adhesion. In vivo gastrointestinal studies using barium as a marker showed that these microspheres had a residence time of 24 to 36 hours. Optical microscopy was used to explore the absorption efficacy of these microspheres. After 24 hours, large amount of microspheres were observed in the enterocytes, the Payer's patches, and also in the spleen and liver tissues (227). Further studies were performed to determine whether these microspheres could be used as oral drug carriers. Microspheres composed of poly(fumaric-co-sebacic) in a 20:80 molar ratio were used to encapsulate dicumarol and plasmid DNA. Oral administration of these drug-containing microspheres to rats showed an improvement in the oral bioavailability of these drugs. In the same study, insulin was encapsulated in a blend of poly(fumaric anhydride) and poly(lactide-co-glycolide), and the microspheres were administered to the group of fasted rats that were injected subcutaneously with an initial glucose load. The results showed that this preparation was better able to regulate the glucose load than the controls, soluble insulin in saline (227). Coating liposomes with bioadhesive also showed a good relationship with prolonged the residence time. Takeuchi et al. (228) evaluated the adhesive property of the bioadhesive-coated liposomes in vitro using rat intestine. Multilamellar liposomes of dipalmitoyl phosphatidyl-

choline and dicetyl phosphate in a molar ratio of 8:2 were coated with three different types of bioadhesives including chitosan, polyvinyl alcohol, and poly(acrylic acid). They found that chitosan-coated liposomes had the highest adhesive property. An in vivo study was carried out using insulin as a model drug. A marked reduction in basal blood glucose level was observed within 30 minutes after administration of the chitosan-coated liposomes containing insulin and was prolonged for up to 12 hours. This prolonging effect could be attributed to the bioadhesive property. It is interesting to note that the relative effectiveness of this system was only 10% compared to the case of a 5 International Unit (IU) subcutaneous injection. An oil-in-water bioadhesive submicron emulsion was used as a carrier for desmopressin acetate (229). Oral administration of these formulations using Carbopol 940 as a bioadhesive showed substantial enhancement, up to 12-fold, of the rat oral bioavailability of desmopressin acetate with regard to a simple saline solution of the drug.

These examples are based on the use of a nonspecific bioadhesive interaction as a tool for localizing drug delivery systems to the surface of the GI tract and hence increasing bioavailability of the drugs. However, targeting to a specific area of the mucosa is still difficult. To deal with this problem, specific bioadhesion using ligand-receptor interactions was investigated. Lectin is an interesting ligand that can bind specifically to biological surfaces bearing sugar residues located at the surface of epithelial cells (221,230-233). It was demonstrated that tomato lectin will bind to the small intestinal epithelium surface in vitro (232,234). This binding was shown to be specific and mediated through N-acetylglucosamine-containing glycoconjugates. The uptake in vitro study of tomato lectin was shown to be taken up by enterocytes via specific adsorptive endocytosis (235). Note that an in vivo study did not show a significant difference in the transit time of tomato lectin and polyvinylpyrrolidone (236). Specific bioadhesion particulate systems for oral delivery purposes can be designed by grafting lectin onto the surface of particulate carriers such as microspheres, nanoparticles, and liposomes. Irache et al. (237) proved this idea through lectin-latex conjugates by covalent coupling of different lectins (tomato, asparagus, pea, and mycoplasma) to polystyrene latexes. In vitro interaction between lectin-latex conjugates and pig gastric mucin was tested. The results showed that the lectin-latex conjugates still had the properties of free lectin such as high binding affinity and high specificity for carbohydrate moieties of mucus glycoproteins. These results support the former publication, in which Lehr et al. (232) found that tomato lectin-coated polystyrene microspheres showed specific binding to enterocytes in vitro.

Hussain et al. (238) investigated the oral uptake of tomato lectin-conjugated nanoparticles in rat intestine. They found the enhancement of intestinal transcytosis at the site where these nanoparticles were bound. Another example is lectin-bearing polymerized liposomes. Lectins can be incorporated into a liposome membrane by modifying them with a hydrophobic anchor, N-glutaryl-phosphatidylethanolamine. Chen et al. (239) incorporated modified lectins into liposome bilayers, and then the liposomes were stabilized via polymerization. Studies in mice established that these systems had the potential to be used as vehicles for an oral vaccine because they can promote binding to Peyer's patches.

Enterio-coated systems are those that remain intact in the stomach but will dissolve and release drugs once they reach the intestinal tract (240,241). The traditional purposes of using these systems are preventing destruction of the drug by gastric enzymes or by the acidity of the gastric fluid, preventing nausea and vomiting caused by the drug's irritation, and delivering the drug to the primary absorption site. Recently, such coatings have been used as a controlled-release dosage form. In principle, the action of enteric coating results from a difference in pH and enzymatic properties in the stomach and intestinal tract. pH-sensitive polymers used as enteric coating are undissociated in the low-pH environment of the stomach and dissolve when the pH rises to appropriate values (Table 6). For example, CAP will dissolve when the pH of the environment increases to 6, while CAT will dissolve at a lower pH (4.8). Since the variation of pH in the GI tract is obvious and is changed by foods or drugs, enteric coated systems for the distal area of the GI tract are still unpredictable (243).

Coatings subject to enzymatic breakdown are consid-

ered as potential colonic drug delivery systems because of the presence of bacteria in the colon. Saffran et al. (244) developed a copolymer of styrene and 2-hydroxyethyl methacrylate cross-linked with divinylazobenzene to coat oral dosage forms. They showed the success of delivering insulin to rats and dogs via oral administration. The coating polymer is degraded by bacterial azoreductase, and the drug is subsequently released. Later, Van den Mooter et al. (245,246) studied the influence of hydrophilicity on the degradation of azopolymers. They found that degradation of the azo polymers was strongly affected by hydrophilicity of the polymers. The hydrophilic moiety ensures a good availability of the azo group for bacterial reduction, while the hydrophobic moiety provides resistance to degradation by the gastric and small intestinal fluids. Therefore, a balance between hydrophilic and hydrophobic moieties in the polymer must be considered. Kopecek et al. (247) introduced two new ideas to develop a polymeric carrier for site-specific drug delivery to the colon. The first system is based on the concept of binding polymeric carriers to the colonic mucosa followed by the degrading action of microbial enzymes. One example of these polymers is N-(2-hydroxypropyl)methacrylamide copolymers containing high amounts of both bioadhesive moiety (fucosylamine) and 5-aminosalicylic acid (a drug for the treatment of ulcerative colitis). Fucosylamine will bind to the colonic mucosa, and the system will release drug by the degrading action of azoreductase (248). The second system, a biodegradable pH-sensitive hydrogel, is based on the swelling properties of the polymer at different pH and an enzymatically degradable azoaromatic cross-link. This polymer has a low degree of swelling in the low-pH environment of the stomach, and thus the drug is protected against digestion

**Table 40.6** Commonly Used Enteric Coating Materials

Polymer	Dissolved pH
Cellulose acetate trimellitate (CAT)	4.8
Polyvinyl acetate phthalate (PVAP)	5.0
Carboxymethylethylcellulose (CMEC)	5.0
HPMCP 50	5.2
HPMCP 55, HPMCP 55S	5.4
Hydroxypropylmethylcellulose acetate succinate (HPMCAS)	5.0, 5.5, 7.0 (three grades)
Eudragit L30D	5.6
Cellulose acetate phthalate (CAP)	6.0

by enzymes. The degree of swelling increases as the polymer passes down the GI tract according to an increase in pH. In the colon, the polymer has a high degree of swelling that makes the cross-links accessible to azoreductase. When the polymer is degraded, drug is released (249,250).

Rectally administered drugs can be given by several dosage forms such as suppositories, enemas, and foams. The spread of the rectal formulations within the distal colon is dependent on both type and volume of the formulations. Studies using scintigraphy have shown that the spread of both enemas and foams was more extensive than that of suppositories (251–253). In fact, the spread of suppositories was limited to the rectal vault (252,253), while enemas and foams can spread as far as the transverse colon (253,254). Therefore suppository dosage forms should be more appropriate for systemic absorption of drugs to minimize first-pass metabolism. Enemas and foams, however, are appropriate for local activity in the colon.

Ulcerative colitis is a primary disease of nonsmokers, for which nicotine is a therapeutic agent. However, long-term transdermal nicotine treatment is likely to be limited by side effects (255,256). Pharmacokinetic studies in humans demonstrated that administration of nicotine as a liquid enema resulted in less systemic absorption and thus decreased side effects (257,258). Moreover, Sandborn et al. (256) observed the clinical improvement in patients with mild to moderately active left-sided ulcerative colitis as nicotine tartrate liquid enema was administered at a dose of 3 mg nicotine base per day for 1 week and then 6 mg per day for 3 weeks. Otten et al. (259) compared two products containing 5-aminosalicylic acid, which is widely used as a topical treatment in distal inflammatory bowel disease. These products had different properties such as viscosity and particle size. They found that the product with a larger volume and smaller particle size reached a substantially larger proportion of the colon. Furthermore, with higher viscosity, this product also produced a significantly higher retention time in the proximal parts of the large intestine.

In an attempt to restrict drug absorption from suppositories to only the lower rectum, several approaches have been explored. These included the use of hydrogel, bioadhesive, or thermoreversible polymer systems as vehicles. The formulations with sustained-release properties have been designed using the hydrogel as a vehicle. Polyvinyl alcohol hydrogel suppositories containing indomethacin were prepared and tested in rats and dogs (260). The plasma concentration of indomethacin showed a sustained-release profile, and formulations with higher pH showed higher plasma concentration. Propranolol HCl was also used as a model drug in this vehicle. By adding phospholipid into the formulations, Morimoto et al. (261) found

better bioavailability than that with a conventional suppository (Witepsol H15). Cole et al. (262) used a cross-linked polyethylene glycol 4000 to prepare a sustained-release formulation of morphine sulfate that was administered to human volunteers. The plasma morphine concentrations in these subjects increased to approximately steady values within 2 to 4 hours after administration and were maintained for at least 12 hours. Bioadhesives have been incorporated into suppository formulations to improve bioavailability of the drugs. Recently, Hosny (263) prepared an insulin suppository by adding deoxycholic acid, sodium taurocholate, and/or polycarbophil to the formulations. Using the rabbit as an animal model, the greatest relative hypoglycemia was obtained from the suppository formulation containing all three materials. This formulation showed a relative bioavailability of 56.4% compared with subcutaneous injection. Another example was by Yahagi et al. (264). They prepared bioadhesive lidocaine suppositories using Witepsol H15 as a base, and Carbopol 934P and white beeswax as additives. Carbopol has a bioadhesive property, while white beeswax was added to increase the melting point of the suppositories. Suppositories containing 10% Carbopol and 20 to 30% white beeswax were retained in the lower rectum for at least 2 hours, but adding white beeswax reduced drug release. Therefore double-phased suppositories consisting of a bioadhesive front layer containing 10% Carbopol and 20% white beeswax, and a second layer containing Carbopol and lidocaine, were designed. The double-phased formulation, with the addition of 5% Carbopol in the second layer, exhibited the lowest metabolites/lidocaine area under the curve ratio. This can be explained in that the bioadhesive front layer containing white beeswax prevented movement of the second layer toward the upper rectum and limited the absorption region to the lower rectum, and hence reduced first-pass metabolism. A new approach employed a bioadhesive liquid suppository composed of a thermoreversible polymer and bioadhesives. These systems exist as liquids at room temperature and form gels at body temperature, so they can be easily applied into the rectum as liquids and remain in the rectum without leakage as gels. Choi et al. (265) developed acetaminophen liquid suppositories composed of Poloxamer 188, 407, and polycarbophil as a vehicle. Pharmacokinetic studies in rats showed good bioavailability and did not cause damage to the rectal tissues. Insulin was also incorporated into these formulations (266). The pharmacodynamic studies and quantitative histological assessment of rectal mucosa of rats were carried out. The optimum result was found for the formulation of insulin: P407: P188: polycarbophil: sodium salicylate (100 IU/g: 15: 20: 0.5: 10%). From these studies, one can con-

clude that thermoreversible liquid suppositories may be more convenient, safe, and effective rectal delivery systems.

**E. Vaginal**

1. Relevant Anatomy and Physiology

The vagina is a fibromuscular tube that extends to the lower part of the uterine cervix (267–269). In adult premenopausal women, the vagina is approximately 7 to 8 cm in length and 2 cm wide, and shrinks to approximately 4.5 to 6 cm in length and 1 to 1.5 cm in width in postmenopausal women (270). The vaginal wall consists of three layers: an epithelial layer, the muscular coat, and the tunica adventitia. The epithelium is a nonkeratinized stratified squamous type with thickness about 200 to 300 μm. The thickness of the vaginal epithelium varies with age and menstrual cycle. In postmenopausal women and ovariectomized animals, the vaginal epithelium becomes extremely thin and porous, leading to a substantial increase in permeability of this tissue. The menstrual cycle is the human female reproductive cycle. In most women, this cycle lasts about 28 days (21 to 35 days). The first menstrual day is numbered as day 1. At day 14, ovulation occurs, and splits the ovarian cycle into the follicular and luteal phase. These phases represent different hormone levels as described in Table 7.

The vaginal epithelium consists of five different cell layers: basal, parabasal, intermediate, transitional, and superficial layers. The cyclical variations of the vaginal epi-

thelium generally involve proliferation, differentiation, and desquamation. The intermediate, transitional, and superficial layers are strongly affected by the cycle and become thickest at ovulation. During the luteal phase, desquamation occurs on the superficial epithelial layer extending as far as the intermediate cells. Loosening of intercellular grooves and a porelike widening of intercellular crevices following ovulation precedes this cyclic desquamation. The intercellular channels are narrow during the early follicular phase but become wide at ovulation and during the luteal phase. This can be explained by the change of estrogen and progesterone hormone level during the menstrual cycle. Estrogen causes an increase in mucosal thickness and the amount of endocervical fluid, while progesterone causes an increase in fluid secretion from the epithelial layers and an increase in glycogen, which is metabolized to decrease pH. Estrogen also decreases fluid viscosity, but progesterone increases viscosity. A related physiological event associated with a decline in estrogen levels is a substantial reduction in vaginal blood flow with concomitant drying of vaginal tissue (270). The surface area of the vagina is increased by numerous foldings and by microridges, which run either longitudinally or in circles.

Although the vaginal epithelium lacks specific moisturizing glands, the surface is usually covered with a film of moisture exuded from the vascular bed of the lamina propria and the cervix. The origin and composition of vaginal fluid is complex and its volume varies with age, menstrual phase, and degree of sexual excitement (272). pH of the

**Table 40.7** Phases of the Human Menstrual Cycle

Days	Phase	Hormone	Numbers of cell layers
1 to 4	Follicular phase begins	Estradiol, progesterone, FSH <sup>B</sup> and LH <sup>C</sup> : low	18
5 to 13	Follicular phase continues	Estradiol: rising Progesterone, FSH and LH: low	22
14	Ovulatory phase	Estradiol: falls after follicle ovulation Progesterone: rising FSH and LH: sharply increase (peak)	45
15 to 28	Luteal phase	Estradiol and progesterone: high FSH and LH: low	23 to 33

vagina varies between 4 to 5 in adult premenopausal women depending on the menstrual cycle and location, whereas in the postmenopausal women neutral or alkaline values are typical (273). Blood supply to the vagina is via the uterine and pudendal arteries, which arise from the internal iliac arteries. The vagina is drained by a rich venous plexus, which empties into the internal iliac veins.

## 2. Major Biological Barriers and Appropriate Strategies

The transcellular and paracellular pathways for drug absorption through the vaginal mucosa are apparently the same as those found in other mucosae (269,274). It was proposed that the absorption barriers of the vagina consisted of two barriers in series, which are an effective aqueous barrier and a membrane barrier (275). The membrane barrier consists of a lipoidal pathway (transcellular) and aqueous pore pathway (paracellular). In addition, Hwang et al. (276) found that the permeability coefficient of the aqueous pore for 1-alkanoic acids was significantly smaller than that for alcohols. Therefore they concluded that the aqueous pore might be semipolar in character or negatively charged, so that aqueous anions had more difficulty being transported via this pathway.

Cyclic changes in the thickness and porosity of the vaginal epithelium can also affect absorption; however, different results have been reported. For example, the effect of the estrus cycle on the permeability of Vidarabine in mice vaginal mucosa has been demonstrated. The results revealed that the permeability coefficients during the diestrus phase were 10 to 100 times higher than those obtained in the estrus phase (277). Okada et al. (278) showed the effect of estrus cyclic changes on vaginal absorption of insulin, phenolsulfonphthalein, and salicylic acid in rats. They concluded that the permeability for hydrophobic compounds, which are transported mainly through the transcellular pathway, is less affected by the estrus cycle; whereas the permeability for hydrophilic compounds, which are transported mainly through intercellular channels, is highly dependent on the estrus cycle. Note that the estrus cycle of the rat is completed in 4 to 5 days, and during this cycle, changes in the vaginal mucosal membrane, the ovaries, and the uterus occur. These changes are similar to the vaginal mucosa changes in women during the menstrual cycle. In contrast to these results, the vaginal absorption of methanol, octanol, progesterone, and estrone in monkeys showed no relationship between the menstrual cycle and the vaginal membrane permeability. The result is also the same as the case of prostaglandin E<sub>1</sub> in humans (268).

Regarding the metabolic barrier, several enzymes have

been found in the vaginal mucosa. The outer cell layers of the vagina contain varying amounts of  $\beta$ -glucuronidase, acid phosphatase, phosphoamidase, succinic dehydrogenase, and diphosphopyridine nucleotide diaphorase (279). The protease enzyme activities could also potentially be an important barrier in the delivery of protein and peptide drugs through the vaginal route (24,269). The enzymatic activity can be changed with hormonal fluctuation in premenopausal and postmenopausal women (279–281). Acarturk and Robinson (281) studied the vaginal permeability and enzymatic activity in intact and ovariectomized rabbits. The ovariectomized rabbits showed a thinner mucosal epithelium and a higher vaginal permeability to enkephalin. In addition, the activity of aminopeptidase N was significantly decreased in these rabbits, while the activity of leucine aminopeptidase, aminopeptidase A, and aminopeptidase B remained unchanged in both cases. They suggested that the ovariectomized rabbit might be useful as an animal model for postmenopausal vaginal studies. Since the activity of several vaginal enzymes was found to vary with the menstrual cycle and postmenopausally, variation in enzyme activity with hormonal changes should be added to the consideration of drug delivery design.

## 3. Examples

Typical vaginal delivery systems include solutions, gels, foams, and suppositories. Each of these systems suffers from a short residence time in the vaginal region. Therefore formulations that can provide a prolonged contact time will be discussed.

Robinson and Bologna (270) described a vaginal delivery system using the bioadhesive polycarbophil. This system can remain on vaginal tissues for 3 to 4 days. Moreover, intrinsic properties of polycarbophil can alter the local pH and hydration level of the tissue. A gel product was an emulsion gel of approximately 60,000 to 80,000 cps, containing 1 to 3% polycarbophil plus humectants and lipid lubricants in an aqueous base. In postmenopausal women, this gel showed a reduction in pH from about 6 to 4 and maintenance in this pH for about 3 to 4 days after the last dose. It also created a significant increase in blood flow, which then provided hydration of the vaginal tissues. Therefore a low viscosity gel of this polymer can be used as an effective treating agent for dry vagina in postmenopausal women and those female cancer patients on estrogen blockers. In contrast to this report, Brown et al. (282) used the  $\gamma$ -scintigraphy method to study the spreading and retention of this formulation in postmenopausal women. They found a lack of significant retention time and considerable intersubject variability.

Bioadhesive gel formulation also has a capacity to serve as a platform for drug delivery (270). For example, vaginally delivered progesterone containing polycarbophil allowed a prolonged delivery of progesterone to achieve clinical effect with low side effects. In another case, a combination of this polymer with nonoxynol 9, a spermicidal/antiviral agent, offered suitable potential benefit in the area of contraception and prophylaxis against sexually transmitted diseases. Lee and Chien (283) used Carbopol 934P as a gel base for a combination of nonoxynol 9 and chelating agent (EDTA). This system showed longer contact time and greater surface contact with the vaginal mucosa, so the effective drug concentration could be maintained for a prolonged period of time. These results confirmed that a bioadhesive gel formulation is suitable for controlled release of nonoxynol 9 and enhances fertility control by providing prolonged spermicidal action.

Another formulation for nonoxynol 9 was prepared by coprecipitation with polyvinylpyrrolidone with or without iodine to produce powders, and then incorporated into bilayer tablets or hard gelatin capsules (284). Bilayer tablets consisted of fast and slow releasing compartments, while hard gelatin capsules were composed of fast, intermediate, and slow releasing compartments. After intravaginal administration in rabbits, these systems released their nonoxynol 9 and iodine content rapidly, reaching spermicidal levels within 3 minutes and that lasted for at least 4 hours.

Richardson et al. (285) prepared vaginal delivery systems for calcitonin using the microspheres of hyaluronane esters. The vaginal absorption of calcitonin was compared after administration of these microspheres and calcitonin solution to rats. The results from the microspheres showed more rapid pronounced hypocalcaemic effects than a simple calcitonin solution. This enhancement of absorption may be due to intimate contact between the microspheres and the vaginal mucosa, as shown by microscopic examination. In addition, the distribution and retention time of these formulations were evaluated in sheep by using  $\gamma$ -scintigraphy (286). They found that about 68 to 80% of the radioactive remained within the vagina, and there was no indication of movement of the microspheres to the upper levels of the genital tract. Note that the microspheres in dry powder form showed slightly longer retention time than the vaginal pessary form. These results demonstrated the potential of using the microspheres as a sustained-release intravaginal delivery system.

Liposomes containing progesterone were developed and evaluated for use as an intravaginal contraceptive system (287). These liposomes were incorporated into polyacrylamide gel and progestational activity determined. It was observed that the formation of functioning corpora lu-

tea was decreased in treated animals. Moreover, the effect of liposomal preparation was found to be greater and more prolonged as compared to a control gel.

## V. CONCLUSION

In this chapter, several areas have been reviewed including relevant anatomy and physiology of mucosae in different areas, major biological barriers, and some examples of drug delivery systems through these routes. However, our knowledge of these areas is still insufficient to warrant optimism about the routine delivery of drugs.

Drug delivery via the mucosal routes offers many advantages, which support these routes as alternatives to the injection route. However, the presence of several barriers creates some difficulties in the design of promising drug delivery systems. Each of these barriers can be overcome by one or more possible solutions. At present, there is no universal solution to all problems. Therefore it is reasonable to conclude that there remains a need for properly designed drug delivery systems, and careful consideration of the relevant anatomy and physiology of mucosae will help pharmaceutical scientists in the development of more efficient and safe drug delivery systems.

## Bioadhesive Drug Delivery Systems

A. David Woolfson, R. Karl Malcolm, Paul A. McCarron, and David S. Jones  
*The Queen's University of Belfast, Belfast, Northern Ireland*

### I. BIOADHESION AND MUCOADHESION

Bioadhesion, the adherence of two phases, at least one of which is biological in nature, is a topic of increasing interest to the pharmaceutical scientist. Bioadhesion can be regarded as a useful phenomenon, facilitating the design of novel polymeric drug delivery systems. However, it can also be a clinically unhelpful or potentially dangerous problem, responsible, in part, for the formation of microbial biofilm on medical devices, a primary cause of clinical infection in, for example, intensive care situations.

Bioadhesive drug delivery systems may be prepared as flexible films, solid compacts, gels, and viscoelastic semi-solids. Applied advanced rheological methods, notably texture profile analysis and oscillatory rheometry, may be employed in the study of bioadhesive systems in order to obtain a fundamental understanding of their adhesive, cohesive, and flow properties. Sites for application of bioadhesive drug delivery systems are primarily topical and include ocular, nasal buccal, urogenital, and anal applications. A number of excellent reviews have been published on the general area of bioadhesion (1–10).

Bioadhesion, in the context of drug delivery, is the molecular force that resists separation across the interface between a biological surface and a carrier, usually polymeric in nature. The primary aim of bioadhesive drug delivery systems is to provide prolonged residence time, improved contact, and hence improved absorption at a given applica-

tion site. Most frequently, bioadhesive drug delivery systems operate in an environment in which a mucus gel layer acts as an interface between adherent and epithelial surfaces. This three-phase system is therefore a special case of the phenomenon of bioadhesion.

Mucosal epithelial sites are rich in a viscous secretion, mucus, which adheres to the adjacent epithelium, protecting it from mechanical, bacterial, viral, and chemical attack. Mucus consists of water (up to 95% by weight), glycoproteins (0.5 to 5%), low proportions of lipids, mineral salts (1%) and 0.5 to 1% of free proteins (11). The rheological properties of mucus, together with its adhesive and cohesive properties, are primarily attributable to the glycoprotein fraction.

### II. NONSPECIFIC AND SPECIFIC BIOADHESION

Bioadhesive drug delivery systems may offer certain advantages over more traditional dosage forms, including:

- Enhanced absorption rates by minimizing diffusion barriers
- Increased residence time leading to enhanced adsorption
- Improved intimacy of contact with various biological membranes

Improved bioavailability through the protection of bioactive molecules from physical and chemical degradation

The process of bioadhesion can result either from non-specific interactions with the mucosal tissue, which are governed by the physicochemical properties of the bioadhesive material and the surface, or from specific interactions when a ligand attached to a specific site is used for the recognition and attachment to a specific site at the mucosal surface.

The first generation of bioadhesive drug delivery systems were based on mucoadhesive polymers, e.g., natural or synthetic macromolecules, often already well accepted and used as pharmaceutical excipients for other purposes. These agents had the interesting ability to adhere to humid or wet mucosal tissue surfaces. Certain mucoadhesive polymers were also found to have other, possibly more significant, biological activities, namely, to inhibit proteolytic enzymes and/or to modulate the permeability of tight epithelial tissue barriers. Such features may be particularly useful in the context of peptide and protein drug delivery.

As an alternative to the nonspecific binding to tissue achieved with mucoadhesive polymers, interest has increasingly turned to molecules with specific cell-binding affinities. In particular, specific bioadhesives such as plant or bacterial lectins, adhesion molecules that specifically bind to sugar moieties of the epithelial cell membrane, have been extensively studied, notably for drug targeting applications (12,13). These second-generation bioadhesives provide not only for cellular binding but also for subsequent endo- and transcytosis. However, lectins have yet to deliver on their initial promise as specific bioadhesive drug delivery systems, as the literature to date indicate the general variability in drug absorption associated with their use (14).

### III. MECHANISMS OF BIOADHESION

There is no unified theory to explain the process of bioadhesion. The mechanism responsible for the process depends on the tissue substrate, the environment, and, critically, the design of the dosage form. The mechanical or wetting theory is perhaps the oldest available adhesion theory and explains adhesion as an embedding process. Adhesive molecules penetrate into surface irregularities and ultimately harden, producing numerous anchors (15). For the adhesive to move freely into such pores, it must overcome any surface tension effects present at the interface. The wetting theory is most applicable to liquid bioadhesives. It describes the interactions between the bioadhesive polymer, and its angle of contact with the substrate, to thermo-

dynamic work of adhesion. Such liquid bioadhesives are, in practice, only weakly adherent.

The formation of an electrical double layer is the basis of the electrostatic theory (16). This theory, applicable to mucoadhesion, assumes that, upon contact, the mucin glycoproteins and polymer material transfer electrons across the interface. This movement of coulombic charge sets up an electrical double layer and, subsequently, a system of attractive forces that maintains the contact.

The interpenetration or diffusion theory is perhaps the most widely accepted physical theory and the most relevant to bioadhesive hydrogel systems. In the mucoadhesive context, polymeric chains, from both bioadhesive and mucus, intermingle and reach a sufficient depth within the opposite matrix to allow formation of a semipermanent bond. The process can be visualized from the point of initial contact. The bioadhesive concentration gradient will drive polymeric chains into the mucous network until an equilibrium penetration depth is achieved. Once intimate contact occurs, the mucin and polymer chains move along their concentration gradients into the opposing phase. The depth of penetration into this phase depends on their respective diffusion coefficients. Reinhart and Peppas found that the diffusion coefficient depended on the molecular weight of the polymer strand and that it decreased with increasing cross-linking density (17). This process of simple physical entanglement has been described as analogous to forcing two pieces of steel wool to intermingle upon contact (18). In the context of bioadhesive drug delivery systems, the formation of permanent ionic or covalent bonds, by contrast, is not required. Bioadhesive delivery systems require a defined residence time at the target site, after which they are removed or rendered inactive. Adhesives that form permanent covalent bonds with the tissue substrate, such as those used in dentistry and orthopaedics, are too strong for this purpose (19,20).

The adsorption theory of adhesion involves surface forces (21,22). Adherence to tissue is due to the establishment of weak attractive forces between substrate and polymer, primarily via van der Waal's forces and hydrogen bonding (21,22). Once intimate contact has been established between polymer and substrate, these may be considered to be the strongest contributors to bioadhesion (23).

A study of the formation of fractures or cracks at the polymer mucin interface (in the case of mucoadhesion) leads to the fracture theory of adhesion (24). The mechanical deformation during the separation process between bioadhesive polymer system and tissue substrate dissipates heat at, or into, the immediate area of the interface, thereby raising the temperature at the fracture area. In an interface, microcracks will always exist. The temperature rise, espe-

cially in the region of the crack tip, will increase the plasticity of polymer chains and accelerate the crack propagation. Thus the process of interface fracture is determined by crack formation and crack propagation. This theory is dependent upon fracture occurring exactly at the polymer–mucin interface. Experience, however, has shown that this cannot always be guaranteed (25).

The surface microstructure of any tissue is an important parameter for considering those bioadhesives that achieve their bonding mostly through physical attachment. Such surfaces often contain undulations and crevices that provide both attachment points and a key for the deposition and inclusion of the polymeric adhesive. Mucoadhesion, involving polymeric carrier adherence to a mucin-coated epithelium, can be considered a “wet-stick” adhesion process, in which polymer chains are released from restraining dry lattice forces by hydration. These chains then move and entangle into the matrix of the substance. Once entangled, opposing chemical groupings become aligned, increasing the probability of van der Waals attraction or hydrogen bonding. As this liberation of polymer chains is hydration dependent, the amount of water present in the bond site is decisive in determining its strength. Overhydration will form a wet slippery mucilage with no adhesive strength.

Overall, bioadhesion can be understood as a two-step process, in which the first adsorptive contact is governed by surface energy effects and a spreading process. In the latter phase, the diffusion of polymer chains across the interface may enhance the final bond (26). Water plays an important role in mucoadhesion, the invading water molecules liberating polymer chains from their twisted and entangled state and thus exposing reactive sites that can bond to tissue macromolecules. The adhesion of dried hydrogels to moist tissue can be quite substantial, with water uptake from the tissue surface facilitating surface dehydration and exposing surface depressions that may act as anchoring locations (27). Thus the use of strongly mucoadhesive polymeric drug delivery systems in the oral cavity can, for example, produce a profound and, for some individuals, unpleasant dryness at the site of attachment.

#### IV. DETERMINATION OF BIOADHESIVE FORCE OF ATTACHMENT

The evaluation of bioadhesive properties is fundamental to the development of novel bioadhesive delivery systems. Measurement of the mechanical properties of a bioadhesive material after interaction with a substrate is one of the most direct ways to quantify the bioadhesive performance. To measure the force of bioadhesive attachment to tissue

involves the application of a stress to the bonding interface. Numerous designs of apparatus have been proposed for this purpose (11,28,29). Since no standard apparatus is available for testing bioadhesive strength, an inevitable lack of uniformity between test methods has arisen. Nevertheless, three main testing modes are recognized: tensile, shear, and peel tests.

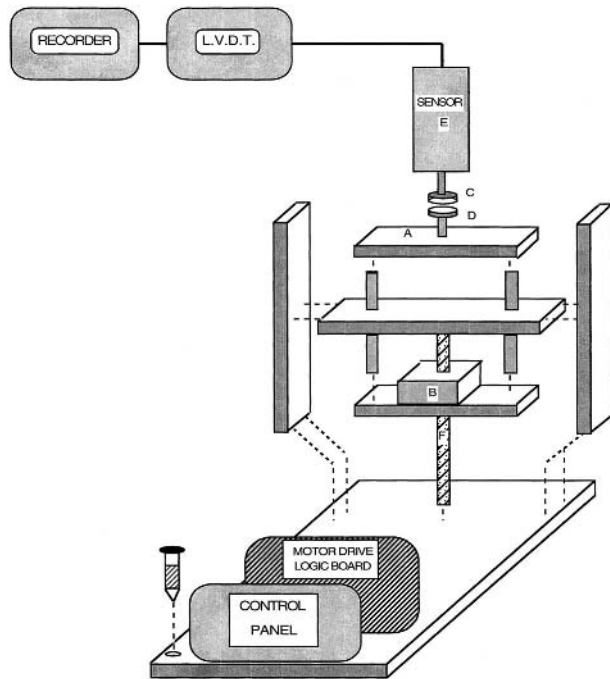

When the force of separation is applied perpendicularly to the tissue/adhesive interface, a state of tensile stress is set up. This is perhaps the most common configuration used in bioadhesive testing. During shear stress the direction of the forces is reoriented so that it acts along the joint interface. In both tensile and shear modes, an equal pressure is distributed over the contact area (29).

The peel test is more applicable to systems involving adhesive tape where removal of the device is an important parameter. By pulling the two interfaces apart at an acute angle, the force is focused along a single line of contact. This effectively concentrates the applied force at the point of separation and removal of the tape can be achieved easily. The peel test is of limited use in bioadhesive systems, being better suited to transdermal patch technology or the evaluation of adhesive dressing systems.

Once formed, the interface of the bioadhesive bond is likely to exist in a microenvironment that will inevitably influence its further performance. Factors such as pH, temperature, ionic strength, and water content will all affect bond durability. Experimental rigs have been devised to investigate these important considerations. Although the force used to break the bond can be applied in one of three fashions, as described, the majority of researchers prefer to use the tensile stress method. Irrespective of which configuration is used to apply the force, the measurement of the performance of the bioadhesive bond is generally performed in one of three environments:

Most in-vitro methods involve measurement of shear or tensile stress. Smart et al. described a method to study bioadhesion whereby a polymer-coated glass slide was withdrawn from a mucus solution (30). The force required to accomplish this was equated to mucoadhesion. A fluorescence probe technique was developed by Park and Robinson to determine bonding between epithelial cells and a test polymer (31). Other methods have involved measurement of the force required to detach polymeric materials from excised rabbit corneal endothelium. Mikos and Peppas described a method whereby a polymer particle was blown across a mucus filled channel (25). The motion, recorded photographically, gave details regarding the adhesion process. Woolfson et al. described the in vitro measurement of bioadhesive strength via a linear variable differential transformer (32). The apparatus (Fig. 1), constructed from Perspex, consists of a movable platform

**Figure 41.1** Design of a tensile test device for bioadhesion using a linear variable displacement transformer. (A) Platform. (B) Stepping motor. (C) Upper pedestal (tissue mount). (D) Lower pedestal (bioadhesive mount). (E) Sensor housing. (F) Screw-threaded shaft.

with a pedestal to which the bioadhesive formulation is attached. Tissue was secured to a second, upper pedestal linked to the LVDT via a sensor. During the test procedure the platform was moved downwards at a predetermined rate controlled by the motor drive logic board. As movement occurs to the upper pedestal this was detected by the output from the LVDT, which is recorded potentiometrically. The force generated was measured by a previously calibrated spring contained within the sensor housing. Different calibrated springs were used to increase or decrease the sensitivity of the apparatus. Initial evaluation of the testing device was performed on a range of candidate bioadhesive film formulations. Jones et al. have reported on the use of a commercial apparatus, in the form of a Texture Profile Analyser (Fig. 2) operating in bioadhesive test mode, to perform similar functions (33–35).

The ultimate destination for successful bioadhesive devices is a tissue surface such as the gastrointestinal tract or the buccal cavity. Some investigators have used previous results obtained from their own *in vitro* work to predict and subsequently test for *in vivo* performance. Examples of *in vivo* studies in the literature are not as plentiful as

**Figure 41.2** Texture profile analyzer in bioadhesion test mode.

*in vitro* work because of the amount and expense of animal trials and the difficulty in maintaining experimental consistency. Commonly measured variables include gastrointestinal transit times of bioadhesive-coated particles and drug release from *in situ* bioadhesive devices.

Ch'ng et al. studied the *in vivo* transit time for bioadhesive beads in the rat (36). A radiolabeled bioadhesive (using  $^{51}\text{Cr}$ ) was carefully introduced into the stomach. At selected time intervals, the gastrointestinal tracts were removed and cut into 20 equal segments, and the radioactivity in each was measured.

Reich et al. described an instrument for measuring the force of adhesion between intraocular lens materials and the endothelium of excised rabbit corneas (37). It used a metal or glass fiber deflection technique for measuring pressures that were usually lower than  $1 \text{ g cm}^{-2}$ . The contacting surfaces were submerged in saline to eliminate surface tension effects. In contrast to many bioadhesive testing situations, the authors were attempting to find a polymer with a lower adhesion than poly(methylmethacrylate) (PMMA), the material most commonly used to make intraocular lenses. A direct relationship had been shown between the adhesive forces of a polymer to the endothelium and the extent of cell damage. Poly(hydroxyethylmethacrylate) and Duragel®, both hydrophilic materials used to make soft lenses, gave less adhesion and subsequently less cell damage than the hydrophobic PMMA.

Davis (1985) described a method to study gastric-controlled release systems (38). It can be advantageous in certain diseased states for a single dosage unit to be retained in the stomach. This enables released drug to empty from the stomach and have the length of the small intestine available for absorption. Mucoadhesives can help achieve

this objective. Therefore, as an alternative to using invasive in vivo techniques, a formulation was used containing a gamma emitting radionuclide. The release characteristics and the position of the device could be monitored using gamma scintigraphy. This technique could measure two different radionuclides simultaneously, so that a subject could be given two different formulations together, with their release and transit times then being studied in a single-occasion cross-over study.

## V. CHARACTERIZATION METHODS FOR BIOADHESIVE DRUG DELIVERY SYSTEMS

A range of techniques are available for the study of bioadhesive delivery systems; the choice is influenced by the site of attachment and the substrate tissue, together with the design of the dosage form. Most viable bioadhesive drug delivery applications involve mucoadhesion to accessible (topical) epithelia. Certain tests will be required for regulatory purposes, while others, though optional, often constitute an important part of the development of a pharmaceutical package for a novel bioadhesive carrier. Bioadhesive (mucoadhesive) dosage forms vary in bioadhesive performance, water content being a primary determinant of bioadhesion. Delivery platforms include liquids and gels (low adhesion), viscoelastic semisolids (moderate adhesion), flexible hydrogel films, particulates, and compacts (strong adhesion). Applicable characterization methodologies include

- Drug release studies
- Drug diffusion (membrane penetration) studies
- Examination of mechanical and textural properties
- Examination of continuous shear properties
- Examination of structural (viscoelastic) properties at defined temperatures
- Evaluation of adhesion to model substrates
- Examination of product/packaging interactions

Texture profile analysis can be used to determine the following characteristics of semisolid bioadhesive delivery systems (39).

- Hardness/compressibility—a measure of the resistance of the formulation to probe depression, which can be used to characterize product spreadability
- Cohesiveness—a measure of the effects of successive deformations on the structural properties of a product

Adhesiveness—a measure of the work required to remove the probe from the sample, a property related to bioadhesion

Flow rheometry can be used to obtain the following information on bioadhesive semisolids.

- Effects of successive shearing stresses on the rate of deformation of a product
- Information concerning product viscosity, which in turn affects drug release and ease of application at the site
- Information concerning the rate of structural recovery following deformation (thixotropy), which in turn affects product retention at the application site
- Drug release
- Manufacture

Oscillatory rheometry, a nondestructive test (unlike flow rheometry) can be used to obtain the information on bioadhesive semisolids used at sites subjected to variable stresses, for example, in the oral cavity, where chewing, swallowing, and talking all affect the structural rheology of bioadhesive systems (35,40). Oscillatory rheometry determines strain in the system, resolved into two components: the storage modulus ( $G'$ ) is the part of the strain that is in phase with the stress and is a measure of the solid character, and the loss modulus ( $G''$ ) is the part of the strain that lags the stress by  $90^\circ$  and is a measure of the liquid character.

Dielectric spectroscopy is an analytical technique that involves the application of an oscillating electric field to a sample and the measurement of the corresponding response over a range of frequencies, from which information on sample structure and behavior can be extrapolated. Craig and Tamburic described studies on sodium alginate gels whereby a model was proposed in order to relate the low-frequency response to the gel structure (41). They also reported on the application of dielectric spectroscopy to the study of cross-linked polyacrylic acids with respect to the effects of additives such as propylene glycol and chlorhexidine gluconate, the influence of the choice of neutralizing agent, and the effects of aging on the gel structure.

## VI. BIOADHESIVE (MUCOADHESIVE) POLYMERS FOR PHARMACEUTICAL APPLICATIONS

Mucoadhesives may be defined as natural or synthetic materials that adhere to mucosal surfaces for prolonged periods of time. Mucoadhesion is the specific form of bioadhesion most relevant to drug delivery applications. Mucoadhesive character is almost exclusively displayed

by hydrophilic polymers whose large molecular size and ability to form intermolecular bonds provides them with the necessary interpenetrative and retentive properties required to adhere to the mucus layer. The chemical structures of some of the more common mucoadhesive polymers are presented in Fig. 3. Others include gelatin, pectin, agarose, polystyrene graft copolymers, and glyceryl oleates.

Mucoadhesive polymers can be distinguished into two main categories: polysaccharides and vinyl polymers. The polysaccharides, exemplified by the cellulose derivatives, chitosan, starch, and alginic acid, are simple sugars joined by glycosidic linkages and are of natural origin, although chemical modification of the side chains allows polymers having different physicochemical properties to be produced. For example, chitosan is prepared by the deacetylation of chitin, the principal component of the exoskeleton of crustaceans. The vinyl polymers are of synthetic origin, commonly formed by the free-radical polymerization of the corresponding vinyl monomer.

In order to function as mucoadhesives, polymer molecules must achieve intimate and prolonged contact with the mucosal substrate. This may be facilitated by more than one adhesion mechanism. Certain structural features and physicochemical properties are known to contribute to or improve bio(muco)adhesion. Thus by careful selection and modification of the appropriate polymer, bioadhesive systems can be tailored for a wide range of drug delivery applications.

### A. Hydrophilic Functional Groups

The presence of hydrophilic functionalities, typically ether, carboxyl, hydroxyl, amine, and sulphate groups, are a prerequisite for good mucoadhesion. These groups allow interaction with and attachment to the mucosal tissue, predominantly via hydrogen and dipole–dipole bonding. Where the polymers have been rendered water-insoluble by cross-linking, the hydrophilic moieties also take up water, causing the networks to swell. The swelling increases the conformational mobility of the polymer chains and enhances mucoadhesive strength due to a concomitant increase in chain diffusivity and degree of entanglement. Swelling also exposes a greater number of hydrophilic functionalities to the mucosal surface.

Additional hydrophilic groups can be incorporated into polymers to enhance their bioadhesion. For example, Matsuda et al. have reported that the *in vitro* bonding strength of gelatin films is enhanced up to sixfold by grafting free-dangling aldehyde groups (42). When the aldehyde groups were reacted with either glycine or sodium borohydride to form the corresponding imine and alcohol, respectively,

the bonding strengths subsequently decreased, suggesting that the Schiff bases formed between the aldehyde groups in the gelatin film and the amino groups of the porcine skin test material strongly contributed to enhanced bioadhesion.

If the addition of hydrophilic moieties increases the bioadhesive strength of polymers, the converse should also hold true. Pritchard et al. have demonstrated that esterification of the carboxylic acid groups of hyaluronic acid caused a decrease in the mean detachment force from rat epithelia (43). However, additional factors, including the degree of hydrophilicity and swelling of the esterified polymers, were also considered to be factors.

Bioerodible copolymers of fumaric and sebacic acid have been reported whose bioadhesion is attributed to hydrogen bonding between the copolymer and mucus glycoproteins (44). Interestingly, the continuous degradation of these materials enhanced their bioadhesive properties by changing surface energy, increasing surface roughness, and increasing the number of carboxylic acid moieties available for binding.

Some proteins have been shown to possess bioadhesive character. The strong mucoadhesive properties of the mussel adhesive protein produced by the blue mussel, *Mytilus edulis*, have been attributed to hydroxylated amino acid residues and the presence of 10–20% dopa residues (45). However, the presence of hydrophilic functions does not necessarily ensure good bioadhesion. In certain bioadhesive formulations the ability of the hydrophilic groups to bind with mucin may be significantly reduced by interactions or complex formation with other excipients. Also, certain coiled-chain configurations can hide the functionalities within the coil structure, thereby decreasing the possibility of interactions with a substrate.

### B. Cross-linking

Linear bioadhesive polymers, such as those in Fig. 3, may be cross-linked according to their type. For vinyl polymers, this is most readily achieved by including a divinyl molecule into the polymerization reaction, typically at concentrations of between 0.1 and 1.0%. Both polysaccharides and vinyl polymers can be cross-linked postpolymerization by the addition of a difunctional molecule capable of reacting with functional groups in the polymer. The addition of divalent cations, such as  $\text{Ca}^{2+}$ , to poly(acrylic acid) will also cause cross-linking. While the linear polymers are generally soluble in water, cross-linking causes them to become water insoluble, although they will swell in aqueous environments. Although cross-linking tends to improve the retentive character of the bioadhesive at a biological site, the restricted chain mobility and loss of

Figure 41.3 Chemical structures of some bioadhesive polymers.

functionality may to some degree counteract this advantage. Optimal bioadhesive properties can be achieved by controlling the degree of cross-linking.

Much of the work on cross-linked mucoadhesive polymers has focused on poly(acrylic acid) derivatives. Several studies have shown that the degree of bioadhesion observed decreases with increasing cross-linking concentration (46–48). Cross-linking, however, need not be limited to modifying the mechanical and dissolution properties of bioadhesive systems. Kakoulides et al. reported on the performance of poly(acrylic acid) networks where the azo groups of the divinylazobenzene cross-links are designed to be cleaved in the reductive environment of the colon, causing biodegradation of the network and the simultaneous formation of bioadhesive amine groups (49).

### C. Degree of Hydration/Polymer Concentration

Mucoadhesive polymers display different adhesive properties at different hydration levels, but maximum adhesion will exist at an optimum hydration level. If excess water is present, adhesiveness may be lost due to the formation of a slippery mucilage. The amount of solvent present during the initial phase of bioadhesion is also vital. For interpenetration of the polymer chains, they must first be mobilized with sufficient solvent to allow exposure of the functional groups on the chains. Many studies have shown that the bioadhesive character of mucoadhesive drug delivery formulations decreases with increasing formulation water content (47,50,51). In some cases, the greatest bioadhesion on wet mucosal tissue was observed for hydrophobic formulations, i.e., where water is absent (50). Needleman et al. reported that the differences in bioadhesive strength and degree of retention for chitosan, xanthan gum, and poly(ethylene oxide) aqueous formulations could be attributed to their different rates of hydration (52).

### D. Polymer Molecular Weight

The relationship between polymer molecular weight and bioadhesive properties is not as simple as might first be imagined, as evidenced by many conflicting results in the literature. The problem is exacerbated in that there is no standard test of bioadhesive strength (force of detachment from substrate). Differences in testing procedures and biological substrates further complicate intersystem comparisons. A standardized and more comprehensive evaluation of the influence of molecular weight is required.

Early studies reported that adhesive strength increased as the molecular weight of the adhesive polymer increased

up to approximately 100,000, after which there was little effect (22). Although a critical molecular weight may be necessary to produce the interpenetration and entanglement of adhesive and substrate, others factors must also be considered. For example, the linear chain configurations in poly(ethylene oxide)s and the subsequent increase in penetration length are reported to be responsible for increasing adhesive strength up to a molecular weight of  $4 \times 10^6$  (20). Polymers with coiled configurations, such as dextrans, displayed similar bioadhesive strengths at both low and high molecular weights, owing to “shielding” of the hydrophilic functional groups and intra- rather than intermolecular hydrogen bonding.

Pritchard et al. found that low molecular weight hyaluronic acids performed better than higher molecular weights in detachment tests, although their effect on mucociliary transport was similar (43). This contrasts with the work of Saettone et al. (53) and Durrani et al. (54) who reported opposite findings. The differences may be attributed to differences in hydration rates and/or testing methodologies. The bioadhesive properties of N-(2-hydroxypropyl)methacrylamide copolymers with different amounts of pendant saccharide moieties were also found to decrease with increasing molecular weight (55).

Poly(acrylic acid)s have also been extensively studied with regard to the effect of molecular weight on bioadhesive strength. In general, higher molecular weights were reported to produce better bioadhesion (56–58), although the opposite trend has also been reported (47).

### E. Segment Mobility/Flexibility

For mucin and polymer chains to interpenetrate, they must be able to diffuse. Interdiffusion will increase with increasing chain segment mobility in the bioadhesive, which is intrinsically related to the degree of hydration and the cross-linking density. Gu et al. have shown the importance of the expanded nature of both mucin and the bioadhesive polymer on the subsequent strength of mucoadhesion (59). A series of 0.2% cross-linked copolymers were synthesized from varying ratios of acrylic acid and methyl methacrylate monomers. The amount of water a polymer absorbed was determined as the difference between the dried weight of polymer particles and the equilibrium weight after hydration in a buffer solution. Dried, unswollen particles were shown to possess no bioadhesion, but when swollen, adhesion was significant. As the percentage of acrylic acid in the copolymer increased, the number of available charged carboxyl groups also increased and bioadhesion likewise increased. Increased charge density

drives water molecules into the polymer network and expands its structure. Solvent uptake, polymer network openness, and polymer bioadhesion are all interdependent properties. The addition of a plasticizer to poly(methyl vinyl ether-co-maleic anhydride) bioadhesive formulations increased mechanical flexibility but did not significantly effect *in vitro* bioadhesion (60).

#### F. Charge/pH

Polyelectrolytes, i.e., polymers having ionizable groups along the chain, are often excellent mucoadhesives (30,61). Examples include poly(acrylic acid) and chitosan, which possess a carboxylic acid and an amine function, respectively. The zeta potential and extent of hydration of 0.3% cross-linked poly(acrylic acid)s were examined in the presence of isotonic saline, simulated gastric fluid, and simulated intestinal fluid (62). The relationship between the zeta potential and the bioadhesive strength showed that bioadhesion was linked to the extent of ionization that occurred during the interaction of the polymer with the mucin/epithelial cell surface. A suitable extent of ionization was required for the initial adhesion of polymer to the biological tissue. However, extensive ionization and swelling could lead to the formation of very loose particles or dissolution and therefore to difficulty in interacting with the animal tissue. Thus the degree of neutralization of poly(acrylic acid) influences its mucoadhesions to pig gastric tissue (48).

Ch'ng et al. demonstrated that a neutral polymer, such as poly(2-hydroxyethyl methacrylate), required a much lower force for detachment than charged polymers based on acrylic acid (36). The poly(acrylic acid) derivative polycarbophil was tested in buffers of increasing pH values; bioadhesion to rabbit stomach increased correspondingly until, at pH 7, bioadhesion unexpectedly and suddenly dropped. The authors explained this phenomenon as an imbalance between repulsive and swelling forces. Pendant groups on the mucus backbone are fully ionized at pH 2.6. The pKa of polycarbophil is 4.75, and above this pH value, electrostatic repulsion between the two negatively charged polymer and mucin chains will increase. However, above pH 4, the polycarbophil network becomes highly swollen, which favors the interpenetration of polymeric chains across the interface. At pH 7, the authors believed that the repulsion was so great that bioadhesion was no longer feasible.

Changes in pH of the substrate can also affect bioadhesion. Anionic polymers were found to strengthen the mucus gel more than a neutral or cationic polymer, with a consequent potential increase in chain entanglement with

mucoadhesive polymers (57). Positively charged lysine residues are implicated in the bioadhesive character of mussel adhesive protein (45).

#### G. Drug/Excipient Concentration

BlancoFuentes et al. showed that the addition of propranolol hydrochloride to Carbopol (a lightly cross-linked poly(acrylic acid) polymer) hydrogels increased adhesion when water was limited in the system, due to an increase in the elasticity caused by complex formation between drug and polymer (47). However, when large quantities of water were present, the complex precipitated out, leading to a slight decrease in adhesive character. By contrast, miconazole nitrate did not influence bioadhesion up to a concentration of 30% in poly(acrylic acid)-based tablets (56). Voorspoels et al. demonstrated that increasing concentrations of testosterone and its esters produced a decrease in adhesive characteristics of buccal tablets (63).

For ionic bioadhesive polymers, dissolved salts can have a significant effect on bioadhesion by a variety of mechanisms, including salting out of polymeric components and charge neutralization, preventing expansion of coiled polymer chains and thus entanglement with epithelial mucin. Woolfson et al. added sodium chloride to polymer blends containing Gantrez and found no effect on bioadhesive character, indicating that the sensitivity of bioadhesive polymers to the presence of dissolved salts varies considerably, depending on structure (51). However sodium chloride can affect bioadhesion through a direct action on the substrate. Thus sodium chloride, when added to several mucoadhesive polymers, was observed to reduce the stiffness of mucus gel (57).

#### H. Polymer Combinations

Although individual polymers may display mucoadhesive properties, combinations of mucoadhesives and nonmucoadhesive polymers have been used advantageously to tailor the physicochemical properties (56,64–68).

When several polymers are included in mucoadhesive drug delivery devices, interactions between the polymers can cause either a decrease or an increase in the degree of mucoadhesion observed. Hydrogen bond-accepting polymers, such as poly(vinyl pyrrolidone) and poly(ethylene oxide), can form interpolymer complexes with hydrogen bond donating polymers, such as poly(acrylic acid), thereby reducing the strength of the bond between the mucoadhesive and mucin (69). In the same study, the incorporation of starch or poly(vinyl alcohol), which cannot form

strong intermolecular forces with poly(acrylic acid), did not significantly reduce mucoadhesion.

### I. Comparison of Bioadhesive Strength of Mucoadhesive Polymers

Despite the difficulties in comparing bioadhesive strengths of individual polymers, polymer combinations, and formulated bioadhesive or mucoadhesive delivery systems, a number of "ranking orders" have been published. Wong et al. used an *in vitro* chicken pouch model to simulate conditions for buccal drug delivery and reported decreasing bioadhesive strength in the order Carbopols > gelatin > NaCMC > HPMC > alginic acid, Eudragits, chitosan (65). Needleman et al., using an *in vivo* periodontal model, produced the ranking xanthan gum > poly(ethylene oxide) > chitosan (70). An *in vitro* modified intestinal perfusion technique reported by Cvetkovic et al. ranked poly(acrylic acid) > sodium carboxymethylcellulose > hydroxypropylcellulose (71).

The variability among the literature reports strongly suggests a cautious interpretation of comparative bioadhesion among polymers. Of more profound significance is likely to be the delivery platform itself into which the polymeric components are formulated, together with the extent of water in the delivery system, the amount of water (or biological fluid) at the site, and the capacity of the delivery system to swell in the presence of water and to retain water without forming a slippery mucilage. In general, polycations and polyanions provide the strongest bioadhesion if correctly formulated. Arguably, highly hydrated systems such as liquids and light gels are at best capable of tack but not significant bioadhesion/mucoadhesion. Solid systems with low water contents, or semisolids formulated with a low water content/high polymer content, are most likely to optimize the bioadhesion or mucoadhesion of a given polymer or polymeric combination.

## VII. BIOADHESIVE AND MUCOADHESIVE DRUG DELIVERY APPLICATIONS

### A. Bioadhesive Devices for the Oral Cavity

The oral cavity is a convenient and accessible area, ideally suited to bioadhesive drug delivery. The most commonly used areas are the buccal and sublingual areas. The nonkeratinized regions in the oral cavity, such as the soft palate, the mouth floor, the ventral side of the tongue, and the buccal mucosa also offer least resistance to drug absorption (72). In many instances, these areas are most suitable for locating bioadhesives. Molecular transport across the barrier membrane is achieved by simple diffusion along a

concentration gradient from carrier to tissue, possibly aided by some form of penetration enhancement. Larger, hydrophilic molecules encounter greater resistance to diffusion and are believed to cross the oral epithelium by intercellular pathways. The advantages of drug delivery through the oral mucosa have been detailed by Veillard et al. (73) and include bypassing hepatic first-pass metabolism, excellent accessibility, unidirectional drug flux, and improved barrier permeability compared, for example, to intact skin.

Many drugs, such as glyceryl trinitrate, testosterone, and buprenorphine (74), have been delivered via the buccal route. Absorption is rapid and drains into the reticulated vein. This avoids hepatic first-pass metabolism and intestinal enzymatic attack on the drug species. Because of its accessibility, the buccal area offers excellent patient compliance in comparison to epithelial routes that involve insertion of oleaginous devices, as sometimes found in rectal and vaginal delivery.

The process of drug absorption from conventional oral delivery systems normally occurs from saliva after dissolution from the formulation. Bioadhesive devices differ in that drug diffuses directly through the swollen polymer and then into the membrane. The intimacy of contact concentrates the drug on the epithelial surface. At other mucosal surfaces, the activity of goblet cells builds up a diffusion-limiting mucus layer that can impede drug absorption. This potential problem does not manifest itself at the oral mucosa, which contains no goblet cells, the mouth receiving its mucus primarily from the parotid, submaxillary, and sublingual salivary glands (73).

Ponchel et al. described the delivery of metronidazole from a bioadhesive tablet containing hydroxypropylmethylcellulose and poly(acrylic acid) (75). The tablets contained a compressed mixture of 50% drug and 50% of various blends of the two polymers. Using a method described by Ponchel et al., the work of adhesion required to remove the tablets from bovine sublingual mucus was measured and found to plateau to a maximum force (76). This maximum adhesion was produced from a tablet containing 25% poly(acrylic acid), and further increases in poly(acrylic acid) content did not increase bioadhesion. Drug release was found to be non-Fickian, controlled by a combination of diffusion and polymer chain relaxation.

The buccal route may be an attractive site for peptide delivery because it is deficient in enzymatic degradation pathways. The cavity is lined with a relatively thick mucous membrane that is highly vascularized and approximately 100 cm<sup>2</sup> in area (72). Prompted by studies showing rectal absorption of insulin in oleaginous vehicles, various workers tried to achieve systemic blood levels of insulin using a bioadhesive buccal patch (74,77–80). Insulin was

mixed with sodium glycocholate (used to enhance penetration) in an oil-based core and encapsulated with a bioadhesive cap. Once located, the overlapping outer layer stuck to the membrane and swelled into a gelled mass that kept the molten inner core intact. Unfortunately, concentrations of peptide in the blood only achieved 0.5% bioavailability compared with an intramuscular administration of insulin. The poor bioavailability of insulin from this device was explained as a combination of several factors. The center core was made from cocoa butter, which is poorly soluble in saliva, and the area of the core in contact with the mucosa was quite small.

Oral mucosal ulceration is a common condition: up to 50% of healthy adults suffer from recurrent minor aphthous ulcers. A bioadhesive compound, Zilactin®, has provided a novel way to alleviate symptoms of this oral mucosal ulceration. It is based on hydroxypropylcellulose complexed with tannic, boric, and salicylic acids. Rodu et al. applied portions of gel to oral mucosa *in vivo* and found that its adhesion was not affected by food or drink intake (81).

Eversole has compared the mucosal binding properties of Orabase® and Zilactin® and evaluated their temporary pain relief and protective properties (82). Samples of ointment were placed on the labial mucosa and allowed to dry. Zilactin® formed a resilient film that did not adhere to the opposite gingiva, whereas Orabase® formed a sticky, inconvenient mass that readily adhered to teeth and gingiva. Zilactin® was shown to give significant symptomatic relief of pain and protected the ulcerated area from irritants present in the oral cavity. On the principle that low-water-content solid systems offer better mucoadhesion than semisolids, a novel bioadhesive patch for the treatment of recurrent aphthous ulceration has been reported (83). The patch provided passive protection to the site, allowing healing and resisting *in vivo* challenge by acidic citrus juice.

The formulation and *in vitro/in vivo* evaluation of buccal bioadhesive captopril tablets was reported by Iscan et al. (66). The objectives were to elucidate factors affecting the bioadhesion property of compressed tablet consisting of hydroxypropylmethylcellulose and carbomer and to evaluate the bioavailability and pharmacokinetics of the formulated buccal adhesive captopril tablets. Buccal adhesive controlled-release systems for the delivery of captopril were prepared by compression of hydroxypropylmethylcellulose with carbomer, which served as the bioactive adhesive compound. The mean pharmacokinetic parameters after use of the buccal adhesive tablet were C-max, 310.7 ng/mL; t(max), 1.2 h; AUC(0–8), 890.1 ng h/mL. This study demonstrated that the formulated buccoadhesive therapeutic system was suitable for buccal administration of captopril.

Wong et al. reported the formulation and evaluation of controlled release Eudragit buccal patches (65). Controlled release buccal patches were fabricated using Eudragit NE40D. Various bioadhesive polymers, namely hydroxypropylmethylcellulose, sodium carboxymethylcellulose, and Carbopol of different grades, were incorporated into the patches, using metoprolol tartrate as the model drug. The *in vitro* drug release was determined using the USP 23 dissolution test apparatus 5 with slight modification, while the bioadhesive properties were evaluated using texture analyser equipment with chicken pouch as the model tissue. The incorporation of hydrophilic polymers was found to affect the drug release as well as enhance the bioadhesiveness. Although high-viscosity polymers can enhance the bioadhesiveness of the patches, they also tend to cause nonhomogeneous distribution of the polymers and drug, resulting in nonpredictable drug-release rates. Of the various bioadhesive polymers studied, Cokol 700 appeared to be the most satisfactory in terms of modifying the drug release and enhancement of the bioadhesive properties.

The design and evaluation of chitosan/ethylcellulose mucoadhesive bilayered devices for buccal drug delivery has recently been described (84). Buccal bilayered devices comprise a drug-containing mucoadhesive layer and a drug-free backing layer. Bilaminated films were produced by a casting/solvent evaporation technique, and bilayered tablets were obtained by direct compression. The mucoadhesive layer was composed of a mixture of drug and chitosan, with or without an anionic cross-linking polymer (polycarbophil, sodium alginate, gellan gum), and the backing layer was made of ethylcellulose. The double-layered structure design was expected to provide drug delivery in a unidirectional fashion to the mucosa and avoid loss of drug due to washout with saliva. Using nifedipine and propranolol hydrochloride as slightly and highly water-soluble model drugs, respectively, it was demonstrated that the devices show promising potential for use in controlled delivery of drugs to the oral cavity. The uncross-linked chitosan-containing devices absorbed a large amount of water, gelled, and then eroded, allowing drug release. Bilaminated films showed a sustained drug release in a phosphate buffer (pH 6.4).

Diseases of the oral cavity can be broadly differentiated into two categories, namely inflammatory and infective conditions. In many cases, the demarcation between these two categories is unclear, as some inflammatory diseases may be microbiological in origin (85). Most frequently, therapeutic agents are delivered into the oral cavity in the form of solutions and gels, as this ensures direct access of the specific agent to the required site in concentrations that vastly exceed those that can be achieved using systemic administration (34,85). However, the retention of such for-

mulations within the oral cavity is poor, due primarily to their inability to interact with the hard and soft tissues and additionally to overcome the flushing actions of saliva. Therefore the use of bioadhesive formulations has been promoted by several authors to overcome these problems and hence improve the clinical resolution of superficial diseases of the oral cavity (33,86). In particular, within the oral cavity, bioadhesive formulations have been reported for the treatment of periodontal diseases and superficial oral infection, in which specific interactions between the bioadhesive formulations and the oral mucosa may be utilized to "anchor" the formulations to the site of application.

Periodontitis is an inflammatory disease of the oral cavity that results in the destruction of the supporting structures of the teeth (87). It is characterized by the formation of pockets between the soft tissue of the gingiva and the tooth; if untreated it may result in tooth loss (33,87). Drug delivery problems associated with the periodontal pocket may be overcome by the use of novel, bioadhesive, syringeable semisolid systems (33,34). Such systems can be formulated to exhibit requisitory flow properties (and hence may be easily administered into the periodontal pocket using a syringe), mucoadhesive properties (ensuring prolonged retention within the pocket), and sustained release of therapeutic agent within this environment. In a series of papers, Jones et al. (28,33,34,40) described the formulation and physicochemical characterization of semisolid bioadhesive networks (containing tetracycline or metronidazole), in which the physical state of the bioadhesive component, polycarbophil, i.e., neutralized (swollen) or unneutralized (particulate), was controlled by the amount of available water in the formulations. Increasing the concentrations of the other hydrophilic polymeric components reduced the amount of available water for the swelling of polycarbophil following its incorporation into the gel matrix, which, in turn, decreased the swelling of this component. Upon contact with mucus, water diffuses into the formulation and controls swelling of the bioadhesive polymer, which in turn allows interpenetration of the fluidized polymer chains with mucus and hence ensures physical and chemical adhesion. The authors concluded that, when used in combination with mechanical treatments, tetracycline-containing bioadhesive semisolid systems described in the study would augment periodontal therapy by improving the removal of pathogens and hence improving periodontal health.

## **B. Bioadhesive Devices for the Gastrointestinal Tract**

Bioadhesive polymers may provide useful delivery systems for drugs that have limited bioavailability from more

conventional dosage forms. To attain a once-daily dosing strategy using peroral bioadhesion, it is desirable for a dosage form to attach itself to the mucosa of the gastrointestinal tract (GIT). If attachment is successful in the gastric region, then a steady supply of drug is available to the intestinal tract for absorption. However, gastric motility and muscular contractions will tend to dislodge any such device. Motility in the GIT during the fasted state is known as the interdigestive migrating motor complex (IMMC) (72). During certain phases of the IMMC, a "housekeeper wave" migrates from the foregut to the terminal ileum and is intended to clear all nondigestible items from the gut. The strength of this "housekeeper wave" is such that poorly adhered dosage forms are easily removed, and only strong bioadhesives will be of any practical use.

In addition to physical abrasion and erosion exerted on a bioadhesive dosage form, the mucin to which it is attached turns over quickly, especially in the gastric region. Any device that has lodged to surface mucus will be dislodged as newly synthesized mucus displaces the older surface layers. The acid environment will also affect bioadhesion, especially with polyacid polymers, such as poly(acrylic acid), where the mechanism of bond formation is thought to occur chiefly through hydrogen bonding and electrostatic interactions.

Longer et al. described the formulation of a bioadhesive sustained release system containing polycarbophil and drug incorporated in albumin beads, all enclosed in a hard gelatin capsule (88). Once swallowed, the capsule wall disintegrated and the exposed polymer swelled to bind the beads together. The drug studied was chlorthalidide, which showed saturable, or site-specific, absorption from the human GIT. High doses (500 mg) were 16% bioavailable, whereas lower doses (50 mg) were 56% bioavailable. In vitro release studies showed that the albumin beads controlled drug release, and the presence of polycarbophil did not affect this release significantly. However, in the rat intestine, after 6 hours, 90% of the beads remained in the stomach encapsulated in a gelled polymer mass. In contrast, polycarbophil bound the beads together, the majority located halfway along the gut; only a few beads were detected in the stomach.

Any swallowed dosage form will be subjected to shear forces as the intestinal contents move. This motility will either prevent the attachment of the bioadhesive or attempt to remove it if bonding to the gut wall has occurred. Previous attempts to reduce the GIT transit time of normal dosage forms have included devices that swelled and floated on the stomach contents, their increasing size preventing them from passing through the pylorus. Harris et al. studied the GIT transit time of formulations containing potential bioadhesive agents (89). Of the agents investigated in animal studies, the acrylic acid polymers were most likely

to delay GIT transit time. The study was extended to human subjects, and the transit times of test devices were monitored using gamma scintigraphy. The materials under study were of four types, large and small resin particles, both coated and uncoated with bioadhesive polymers. Bioadhesives were unable to slow significantly the GIT transit of radiolabeled large resin beads (size range 750–1000  $\mu\text{m}$ ) when compared to uncoated controls. However, when the smaller beads were used (size range 5–50  $\mu\text{m}$ ), bioadhesives increased the oro-caecal transit times by 30% when compared to uncoated controls. It was further observed that the transit speed for the smaller nonbioadhesive particulate material was significantly quicker than for larger nonbioadhesive particles. Thus the action of a bioadhesive coating was to extend the transit time of the smaller particles to levels comparable with larger bioadhesive particles. Images from the gamma camera revealed that uncoated controls dispersed readily, releasing the beads, whereas the bioadhesives transformed the beads into a gelled cluster in the stomach. Overall, it was concluded that the results did not necessarily confirm the potential of bioadhesive materials for either delaying GIT transit or improving bioavailability.

The *in vitro* controlled release and bioadhesive properties of furosemide formulations were evaluated with standard dissolution tests and with a specially developed model using rabbit intestine (90). The results showed that the controlled release properties were not affected by the application of the bioadhesive polymer but that the bioadhesive properties were substantially different. In order to assess the gastrointestinal transit time *in vivo*, a gamma-scintigraphy study was performed in six volunteers testing the same controlled-release formulation with and without bioadhesive polymer. Plasma levels of furosemide, evaluation of urinary flux, and measures of urinary excretion of furosemide in the six volunteers allowed correlations to be made between gastrointestinal transit and furosemide absorption.

The oral route constitutes the preferred route for drug delivery. However, numerous drugs remain poorly available when administered orally. Drugs associated with bioadhesive polymeric nanoparticulates or small particles in the micrometer size range may be advantageous in this respect due to their ability to interact with the mucosal surface. Targeting applications are possible by this method if there are specific interactions occurring when a ligand attached to the particle is used for the recognition and attachment to a specific site at the mucosal surface (91).

Drug delivery particulates of alginate, polylysine, and pectin have been reported (92). Theophylline, chlorothiazide, and indomethacin were used as the model drugs for *in vitro* assessments, and mannitol was the model for assessing paracellular drug absorption across Caco-2 cell monolayers. Alginate and pectin served as the core poly-

mers, and polylysine helped to strengthen the particulates. Use of pectin specially helped in forming a more robust particulate that was more resistant in acidic pH and modulated the release profiles of the encapsulated model drugs in alkaline pH. Alginate and pectin were also found to enhance the paracellular absorption of mannitol across Caco-2 cell monolayers by about three times. The release rate could be described as a first-order or square-root time process depending on the drug load. Use of alginate–polylysine–pectin particulates is expected to combine the advantages of bioadhesion, absorption enhancement, and sustained release. This particulate system may have use as a carrier for drugs that are poorly absorbed after oral administration.

Alginate–chitosan microcapsules have been investigated as a bioadhesive drug delivery system (93). Calcium alginate gel beads uncoated and coated with chitosan were tested for adhesive properties, using novel techniques, with negatively charged chromatography particles and *in vitro* with pig oesophagus and stomach mucosa. The addition of a chitosan coating increased the adhesive properties significantly. The adherence of both coated and uncoated beads was much greater to the stomach mucosa than to oesophageal mucosa. The difference in adhesive properties between the coated and uncoated microcapsules was also found considerably larger for the stomach mucosa.

In general, oral applications of bioadhesive technology have been less successful than where the delivery system can be applied directly to an accessible site. Issues such as overhydration, attachment to gastrointestinal mucus and subsequent shedding, and poor resistance to mechanical forces in the gastrointestinal tract have tended to limit the utility of bioadhesive gastric-retentive systems to date.

### C. Bioadhesive Devices for Rectal Drug Delivery

The function of the rectum is mostly concerned with removing water. It is only 10 cm in length, with no villi, giving it a relatively small surface area for drug absorption (72). Drug permeability differs from that found in both the oral cavity and the intestinal regions. Most rectal absorption of drugs is achieved by a simple diffusion process through the lipid membrane. However, the rectal route is readily accessible, penetration enhancers can be used, and there is access to the lymphatic system. In contrast, drugs absorbed via the small intestine are transported mostly to the blood, and only a small proportion enters the lymphatic system.

Drugs that are liable to extensive first-pass metabolism can benefit greatly if delivered to the rectal area, especially if they are targeted to areas close to the anus. This is because the blood from the lower rectum drains directly into

the systemic circulation, whereas blood from the upper regions drains into the portal systems via the superior hemorrhoidal vein and the inferior mesenteric vein. Drug absorbed from this upper site is subjected to liver metabolism. A bioadhesive suppository will attach to the lower rectal area and once inserted will reduce the tendency for migration upwards to the upper rectum; this migration can occur with conventional suppositories.

Morimoto et al. recognized that high molecular weight hormones, such as insulin, were not readily absorbed through rectal mucosa (94). Emulsions containing surfactants have been employed to promote the absorption of this peptide, but their long-term administration was associated with irritation and toxicity. To overcome these problems, insulin was formulated in a poly(acrylic acid) gel comprising long-chain fatty acids as absorption enhancers. The absorption rate of insulin was encouraging, and consequently a simple and painless dosage form in the long-term therapy of diabetics may be a possibility in the future. However, bioadhesives have not been extensively employed for rectal delivery.

#### D. Bioadhesive Devices for Cervical Drug Delivery

Nagai has investigated various bioadhesive forms to treat uterine and cervical cancers (78). Uterine cancers comprise about 25% of all malignant tumors in Japan, among which *carcinoma colli* accounts for 95% of this figure (95). The target cells remain at, or near, the cervical epithelium and can be readily targeted with an appropriate dosage form. Pessaries have been of limited use because drug release is rapid and leakage into the surrounding tissue causes inflammation of vaginal mucosa. In order to meet three important criteria, drug release, swelling of the preparation, and adhesion to the diseased tissue, a bioadhesive disc was prepared. Bleomycin was incorporated into a hydroxypropylcellulose/Carbopol® mix and molded into a suitable shape. This could be placed on or into the cervical canal, where it adhered and released the cytotoxic drug. After treatment and following colposcopic examination, areas of necrosis on the lesion were observed, with surrounding normal mucosal cells unaffected. With pessaries, however, this was not the case. In approximately 33% of cases, cancerous foci had completely disappeared.

Woolfson et al. described a novel bioadhesive cervical patch containing 5-fluorouracil for the treatment of cervical intraepithelial neoplasia (CIN) (96). The patch was of bilaminar design (Fig. 4), with a drug-loaded bioadhesive film cast from a gel containing 2% w/w Carbopol® 981 plasticized with 1% w/w glycerin. The casting solvent was ethanol:water 30:70, chosen to give a nonfissuring film

Figure 41.4 Bioadhesive cervical drug delivery system.

with an even particle size distribution. The film, which was mechanically stable on storage under ambient conditions, was bonded directly to a backing layer formed from thermally cured poly(vinyl chloride) emulsion. Bioadhesive strength was independent of drug loading in the bioadhesive matrix over the range investigated but was influenced by both the plasticizer concentration in the casting gel and the thickness of the final film. Release of 5-fluorouracil from the bioadhesive layer into an aqueous sink was rapid but was controlled down to an undetectable level through the backing layer. The latter characteristic was desirable to prevent drug spill from the device onto vaginal epithelium in vivo. Despite the relatively hydrophilic nature of 5-fluorouracil, substantial drug release through human cervical tissue samples was observed over approximately 20 hours. Drug release, which was clearly tissue dependent rather than device dependent, may have been aided by a shunt diffusion route through aqueous pores in the tissue. The bioadhesive and drug release characteristics of the 5-fluorouracil cervical patch indicated that it would be suitable for further clinical investigation as a drug treatment for CIN (97).

#### E. Bioadhesive Devices for Vaginal Drug Delivery

Bioadhesives can control the rate of drug release from, and extend the residence time of, vaginal formulations. These formulations may contain drug or quite simply act in conjunction with moisturizing agents as a control for vaginal

dryness. Gursoy and Bayhan described the formulation of a vaginal tablet comprising sodium carboxymethylcellulose and poly(acrylic acid) with zinc sulphate as a model drug (98). Gursoy et al. recognized that no *in vitro* dissolution apparatus was available to quantify drug release from such formulations (99). A mechanical device was designed and built and compared to the dissolution apparatus described in the BP and USP. The *in situ* drug released was also determined using freshly obtained bovine vaginal tissue. Tablets were placed into the tissue and removed at specified time intervals. The drug remaining in the tablet following removal was then quantified. The release behavior in the new apparatus correlated well to *in situ* data, whereas the BP and USP grossly exaggerated the release profiles.

Spreading and retention (and consequent “messiness”) of semisolid vaginal bioadhesive systems, such as gels, are major issues in intravaginal drug delivery. Brown et al. reported a scintigraphic evaluation of vaginal dosage forms in postmenopausal women (100). The vaginal spreading and clearance of a radiolabeled pessary formulation and a commercial polycarboxiphil gel was assessed in six healthy postmenopausal female volunteers over a 6 hour period by gamma scintigraphy. In five out of the six subjects studied, clearance of the two formulations exhibited very little intrasubject variation. However, there was considerable intersubject variability in clearance. Importantly, there was no evidence to suggest that either of the formulations dispersed material beyond the cervix, into the uterus, in any of the subjects studied. The authors concluded that the lack of significant retention of these products in most of the volunteers had obvious implications for the delivery of therapeutic agents.

#### F. Bioadhesive Devices for Nasal Drug Delivery

The area of the normal human nasal mucosa is approximately 150 cm<sup>2</sup>. The nasal mucosa and submucosa are liberally populated with goblet cells along with numerous mucous and serous glands. These keep the nasal mucosal surfaces moist. Drug administration to this region is normally reserved for local treatment, such as nasal allergy or inflammation. The nasal mucosa is thin and incorporates a dense vascular network, indicating that drug absorption may be good from this site (101). Absorbed drugs avoid first-pass metabolism and luminal degradation associated with the oral route (72). The nasal mucosa itself is sensitive to drug molecules and to surfactants, which are often used to enhance drug absorption. Moreover, the mucociliary escalator travels at 5 mm min<sup>-1</sup> as it drags mucous fluid backwards toward the throat. Therefore if a drug is applied in either a simple powder or a liquid formulation it will be quickly cleared from this site of absorption. Thus any use-

ful dosage form must be nonirritant to the nasal mucosa and be retained for extended periods of time.

Nagai et al. reported the low bioavailability of insulin across the oral epithelia and attempted to enhance its absorption using the nasal route (102). He prepared a powder containing freeze-dried bovine insulin and powdered bioadhesive excipients. The powder was puffed into the nostrils of beagles, and blood-glucose levels were then determined. The bioavailability of insulin was enhanced when given in a bioadhesive powder. Indeed, a powder of freeze dried Carbopol® and insulin produced a hypoglycemia to an extent of one-third that achieved by an equivalent dose given intravenously.

Nasal delivery of protein therapeutics can be compromised by the brief residence time at this mucosal surface. Some bioadhesive polymers have been suggested to extend residence time and improve protein uptake across the nasal mucosa. Witschi and Mrsny examined several potential polymer platforms, in the form of starch, alginate, chitosan, or Carbopol microparticles, for their *in vitro* protein (bovine serum albumin) release, relative bioadhesive properties, and induction of cytokine release from respiratory epithelium (103). Carbopol gels and chitosan microparticles provided the most desirable characteristics for protein therapeutic and protein antigen delivery, respectively, of the formulations examined.

An erythrocyte-based bioadhesive system has been reported for controlled systemic delivery of propranolol hydrochloride through the nasal route (104). Rat erythrocytes were loaded with propranolol HCl by a method based on hypotonic swelling, isotonic resealing, and reannealing. The loaded erythrocytes were cross-linked by treating with glutaraldehyde and were characterized *in vitro* for drug payload efficiency, propranolol release, drug diffusion through rat intestine, bioadhesion, and morphological characteristics. Loaded erythrocytes were found to release propranolol HCl slowly, the release being dependent on the degree of cross-linking. The system was found to possess good bioadhesive properties. *In vivo* studies conducted on rats revealed that the developed system maintained constant plasma levels of propranolol for up to 10 hours.

Overall, the nasal route remains highly promising, particularly for macromolecular absorption, but there are problems regarding effects of bioadhesive delivery systems on nasal ciliary beat.

#### G. Bioadhesive Devices for Ocular Drug Delivery

Extended drug delivery to the eye is difficult for several reasons. Systemically administered drugs must cross the blood–aqueous humor barrier, and to achieve local thera-

peutic concentrations of drug, high levels of drug in the blood are needed. In addition, lacrimation, blinking, and tear turnover will all reduce the bioavailability of topically administered drug to approximately 1–10% (18). Conventional delivery methods are not ideal. Solutions and suspensions are readily washed from the cornea, and ointments alter the tear refractive index and blur vision.

Hui and Robinson have described the synthesis of cross-linked acrylic acid and evaluated their potential for ocular drug delivery of progesterone (105). The aqueous humor levels in the rabbit obtained after dosing with 50  $\mu$ L of 0.3% progesterone suspension and 50  $\mu$ L of the 0.3% progesterone suspension in the bioadhesive polymer showed a 4.2 times increase in bioavailability from the bioadhesive suspension. Further, drug levels in the aqueous humor declined at a slower rate when given in the latter suspension.

Saettone and Chiellini investigated the release of pilocarpine from poly(acrylic acid) and hydroxypropylcellulose discs and found that the solubility of the discs could be controlled by the addition of high molecular weight poly(vinyl alcohol) (PVA) (106). Once added, PVA improved in vivo bioavailability when compared to simple nonbioadhesive pilocarpine drops, as demonstrated by the miotic activity in rabbits. Ünlü et al. described the acrylic polymers and their hydrogels as good adhering agents for ocular drug therapy (107). They were nonirritant, well tolerated, and, according to the polymer type, presented no interference to visibility when in situ. The viscosity of Carbopol vehicles significantly decreased when subjected to a simulated lacrimal fluid, but the mucoadhesive properties of the polymer were still retained. More recently, Lebourlais et al. have reviewed the applications of bioadhesion in the development of novel ocular drug delivery systems (9).

## VIII. CONCLUSIONS

Bioadhesive drug delivery systems have been widely studied in the past decade, and a number of interesting, novel drug delivery systems incorporating the use of bioadhesive polymers have been described. Primarily, the application of bioadhesion to drug delivery involves the process of mucoadhesion, a “wet-stick” adhesion requiring, primarily, spreading of the mucoadhesive on a mucin-coated epithelium, followed by interpenetration of polymer chains between the hydrated delivery system and mucin. An alternative mechanism can involve the use of specific bioadhesive molecules, notably lectins, primarily for oral drug delivery applications. Results, however, remain variable by this specific method, as with the use of bioadhesives, generally, for oral systemic drug delivery. The most notable

applications of mucoadhesive systems to date remain those involving accessible epithelia, such as in ocular, nasal, buccal, rectal, or intravaginal drug delivery systems. The ancillary effects of certain mucoadhesive polymers, such as polycations, on promoting drug penetration of epithelial tissues, may be increasingly important in the future, particularly for the transmucosal delivery of therapeutic peptides and other biomolecules.

## Recent Developments in Drug Delivery to the Nervous System

Dusica Maysinger, Radoslav Savic, Joseph Tam, Christine Allen, and Adi Eisenberg  
*McGill University, Montreal, Quebec, Canada*

### I. NEUROACTIVE AGENTS AND THEIR DELIVERY TO THE CNS AND PNS

In the past decade, the contribution of the material sciences to drug delivery to the brain was realized mainly through the use of nonbiodegradable cylinders for intracerebral implantation of genetically engineered cells, or through the use of polymeric matrices that contained drugs. More recently, further progress has been made in the arena of prodrugs or conjugates that can exploit existing transport systems. An understanding of the basic mechanisms of the blood–brain barrier (BBB) transport biology provides a broad platform for current and future nervous system drug targeting strategies. In general, current approaches are either invasive (e.g., neurosurgical), pharmacological (e.g., by applying lipid carriers, liposomes, or different kinds of nanoparticles), or physiological (e.g., by taking advantage of normal endogenous pathways of carrier-mediated transport or receptor-mediated transport). Lipid-soluble molecules that have molecular mass under 500 daltons access the brain via lipid-mediated transport, but hydrophilic molecules such as peptides are mainly transported via receptor-mediated endocytosis. The main concepts of and underlying strategies for the administration of clinically relevant growth factors to the PNS, (1), and to overcome the BBB in the CNS, are summarized in several reviews (2–6).

#### A. Problems with Hydrophilic Agents

Although the surface area of the BBB in the human brain is large [approximately 20 m<sup>2</sup> (7)], small hydrophilic molecules cannot access the brain in pharmacologically adequate amounts when administered systemically or orally. This applies also to small peptidomimetic agents such as nerve growth factor (NGF)-mimetics (8) or neurotensine mimetics (9); hence effective delivery of these agents will require a drug delivery and targeting vehicle, or they should be conjugated to a BBB-targeting system. Development of novel drug delivery strategies requires adequate biological models to test their suitability. In vitro models include (i) primary cultures, (ii) immortalized neuronal, glial, and cerebromicrovascular endothelial cultures, (iii) hippocampal immortalized neuronal cultures (10,11), (iv) human cerebromicrovascular endothelial cell lines as a model of the BBB (12), and (v) more complex cocultures of neuronal and glial cells (13). In addition to these in vitro models, a number of in vivo model systems have been employed for testing neuroactive agents and their delivery systems. Rodent models, although indispensable and most commonly used to investigate neurological diseases, have limitations: (i) In general, they show some, but rarely all, of the pathological features of human neurological diseases; (ii) the time course of the progression of the disease is limited due to the difference in life span between two

species; and (iii) tests for verbal communication skills cannot be applied. A number of neurological disorders are associated with either a lack of neuroactive peptides (e.g., growth factors, neurotrophins) or malfunctioning of their receptors (defective binding between receptor and ligand, impaired internalization and transport of the receptor–ligand complex, or impaired signaling pathways downstream from the receptor site) (14–20). For example, abnormal growth factor levels in the CNS and/or PNS have been associated with Alzheimer's disease, Parkinson's disease, Huntington's disease, and diabetic neuropathy (21–24). Results from preclinical studies employing both *in vitro* and *in vivo* models discussed above suggest that individual growth factors (as representatives of hydrophilic molecules) can indeed correct, prevent, or delay some of the pathological features characteristic of diabetic neuropathy, Alzheimer's, Parkinson's, and Huntington's diseases. However, due to the complexities involved in these pathologies, a simple replacement therapy employing drug delivery systems containing individual hydrophilic neurotherapeutics will most likely be used in conjunction with gene therapy and/or stem-cell therapies.

### **B. Problems with Lipophilic Agents**

In general, lipophilic agents have little difficulty in penetrating cell membranes, including those of the BBB. The more lipophilic a drug is, the more readily it will cross the BBB and reach the brain. Thus the main problem with these agents lies not in their permeability but rather with aspects of (i) specificity and selectivity of action in the brain, (ii) neurotoxicity, and (iii) poor solubility and unfavorable pharmacokinetic properties. Some of these problems can be solved, at least partially, by incorporating the drug into a carrier polymer so that the release is slower and the toxicity is reduced. An attempt to increase the specificity and selectivity of neuroactive lipophilic drugs has been made by conjugation of the drug either with a specific ligand or with an antibody toward a protein specifically expressed at the cell surface (3). More recently, a class of lipophilic compounds, neurosteroids, *i.e.*, steroids known to be particularly effective in the nervous system, were found to influence the brain's functions significantly, memory in particular. These agents do not have a problem in crossing the BBB or in specifically binding to their receptors. Studies by Toran-Allerand and colleagues showed that estrogen receptors are localized in central cholinergic neurons, and that signaling pathways activated by growth factors can be also activated by estrogens (25,26). Neurosteroids have been tested in several models (27), and numerous studies are currently underway to provide a proof of concept for neurosteroids as potential therapeutics in neurodegenerative diseases (27).

## **II. NONVIRAL DELIVERY SYSTEMS TO DELIVER AGENTS TO THE NERVOUS SYSTEM**

Although the expression of specific proteins by transfection with viral vectors has been a commonly used technique, this method of drug delivery has certain disadvantages (28–30). A number of nonviral approaches to drug delivery to the nervous system have been developed, including (i) intraventricular infusion of neuroactive agents, (ii) injection or implantation of polymeric systems, (iii) implantation of genetically engineered cells or stem cells, and (iv) use of liposomes. These approaches are summarized in the following sections.

### **A. Intraventricular Infusion of Neuroactive Agents**

Poorly soluble agents and unstable peptides are often administered into the lateral ventricles either as single injections or via permanently installed cannulae (31,32). The advantages of these approaches are that the dosage and rate of drug administration can be controlled, and the results resemble a slow intravenous infusion if the drug is readily distributed into the peripheral bloodstream. However, intracerebroventricular (ICV) injection of drug results in distribution to the ependymal surface of only the ipsilateral brain because of the unidirectional flow of cerebrospinal fluid within the brain. The major disadvantage of ICV drug administration is its invasiveness and the possibility of infection at the site of penetration of the BBB.

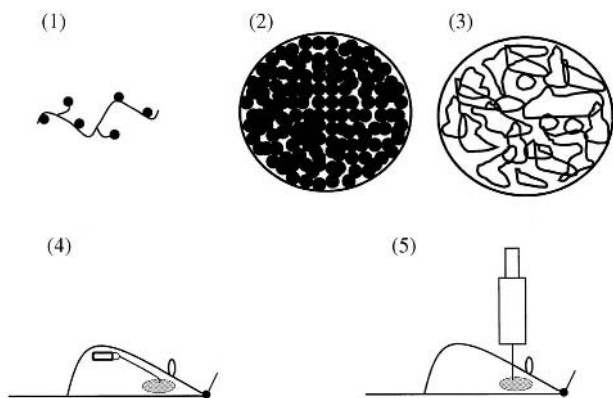

### **B. Injectable and Implantable Polymeric Systems as Drug Carriers**

#### **1. Drug–Polymer Conjugates**

Synthetic polymer materials have been used as drug carriers in several modalities (Fig. 1). Injectable drug–polymer conjugates are produced by covalent binding of water-soluble polymers to a drug. The nature of the covalent bond between the drug and the polymer should be such that the bond is strong enough to be stable in the bloodstream but easily cleaved once the conjugate has reached the target site. This is often difficult to achieve. Moreover, only a relatively small number of biologically active molecules can be attached to the polymer molecule, thus requiring relatively large amounts of drug–polymer conjugate to be injected at the site of action. Approaches overcoming some of these problems are discussed in the following sections.

#### **2. Implants**

Simple replacement therapy with polymeric implants of nerve growth factor have been implemented in animal

**Figure 42.1** Some common approaches to administer neuroactive drugs. 1. Drug covalently bound to the polymer. 2. Microspheres (made of biodegradable polymers) containing neuroactive agents can be injected either systemically, into the lateral ventricle, or into the selected brain structure. 3. Microsponges can be impregnated with neuroactive agent and administered locally. 4. Osmotic pumps allow for steady release of neuroactive agent for a prolonged time period (1–2 weeks). 5. Injections of neuroactive agents directly into the lateral ventricle or parenchyma.

models of central cholinergic deficiencies (33,34) and of peripheral nerve impairment in diabetes (24), in both humans and several animal species (35,36). Recently nerve growth factor (NGF) was delivered locally by implantation of a small polymer pellet providing slow release at a controlled distance from the target site (37). The implants placed 1–2 mm away from the target cholinergic site were effective, whereas the same implants placed 3 mm away from the target site had no detectable effect. These findings strengthen the notion that NGF delivery within a spatially restricted area should be considered a desirable feature if the drug is to be effective. Due to the larger size of the target areas in the human brain than in rodent animal models, the concept of pharmacotechnics has been tested. This strategy involves the creation of an array of local drug-releasing loci to create large but spatially restricted and anatomically defined fields of biological activity. Drug distribution can be more controlled, and moreover this approach lends itself to comparison with mathematical models (38). The geometry and sites of implantations can be determined by noninvasive diagnostic procedures, such as MRI, prior to the surgical procedure. Local delivery, in conjunction with pharmacokinetic modeling (39) and stereotaxic atlases linked to MRI scanners, will eventually allow for customized drug therapy for individual patients. Replacement of other factors such as ciliary neurotrophic factor (CNTF), lymphocyte inhibitory factor (LIF), and brain derived neurotrophic factor (BDNF) has also been

achieved in different ways. However, all of these simple replacement approaches have three major limitations: (i) site-specific delivery, (ii) the amount of drug that can be administered by single administration, and (iii) susceptibility of full-length peptides to enzymatic cleavage due to the presence of various peptidases in the tissue. To solve some of the stability problems, drugs can be incorporated into biodegradable polymers, and an overview of these polymers is given in Chapter 5.

### 3. Osmotic Pumps

Osmotic pumps are also often used in experimental animals. For instance, implantable pumps have been used in primates to deliver dopamine or dopamine agonists (40,41). The pump reservoir is typically installed subcutaneously, and a catheter links a cannula with the pump. There are different sizes of pumps, suitable for small rodents or larger animals (commercially available ‘‘Alzet’’ minipumps); the pumps are refillable, and newer models allow for the adjustment of the delivery rates. The major limitation of pumps is the possibility of a local immune reaction at the site of delivery. In addition, due to the limited diffusion of most peptidergic neurotrophic agents, the majority of the agent is degraded before reaching the intended site of action.

### 4. Micro- and Nanoparticles

These delivery systems were reviewed previously (4,42–48). Controlled release polymer systems not only improve drug safety and efficacy but may also lead to new therapeutics. Some of the frequently used polymers are poly(sebacic acid-*co*-1,3-bis(*p*-carboxyphenoxy)propane), poly(*b*-hydroxybutyrate-hydroxyvalerate), poly(lactide-*co*-glycolide), poly(methyl methacrylate-acrylic acid), poly(acrylamide-*co*-acrylic acid), and poly(fumaric-*co*-sebacic anhydride). Numerous micro- and nanoparticles (some examples of which are shown in Fig. 2) have been designed and tested *in vitro* and *in vivo* to demonstrate superior effectiveness with concomitant reduction in neurotoxicity. Conventional oral or transdermal delivery is inadequate for the delivery of macromolecules such as proteins. Due to the short half-life of macromolecules such as growth factors, micro- and nanocontainers made of different polymers have been investigated as a means of their controlled and prolonged release. Johnson et al. (49) developed biodegradable microspheres composed of lactic glycolic acid polymer in which lyophilized macromolecules (human growth hormone) were complexed with zinc to solve the problem of moisture-induced protein aggregation. The system was tested *in vitro* and in a primate *in vivo* model. A release of the protein for one month was demonstrated, suggesting the possibility that such a system

**Figure 42.2** Some examples of injectable nanoparticles as carriers for neuroactive agents.

may be considered for chronic clinical use. Numerous other nano- and microparticulate biodegradable and biocompatible delivery systems have been developed in the last several years. For instance, rhodium (II) citrate, a recent member of promising antitumor agents, was complexed and encapsulated into poly (D,L-lactic-co-glycolic) acid (PLGA) and poly(anhydride) microspheres (50). Complexation in this case significantly increased the encapsulation efficiency and duration of release in both polymer systems (50). However, problems that need to be dealt with include the limited supply of the neuroactive agent, the invasive aspects of micro- and nanoparticle administration, and release kinetics that were not amenable to regulation by physiological changes at the site or elsewhere. Two interesting and novel approaches have been recently considered and tested: controlled release microchips and neurospheres. Briefly, in contrast to previous methods of controlling drug release from polymeric devices such as pulsatile stimuli by an electric or magnetic field, exposure to ultrasound, light, enzymes, changes in pH or in temperature, new biotechnological approaches have led to the development of a solid-state silicon microchip that can provide controlled release of a single or multiple agents on demand (51). Although it is too early to evaluate its usefulness for the delivery of neuroactive substances, it certainly seems promising. Neurospheres of multipotent and restricted precursors may provide solutions for a longer lasting and more physiological supply of biologically active compounds, either singly or in combination (52–54).

## 5. Liposomes

Cationic liposomes may have a significant potential for clinical applications in gene therapy for the disordered central nervous system (CNS) (55). Recently it has been reported that intracerebroventricular or intrathecal injection of cationic liposome–DNA complexes can produce sig-

nificant levels of expression of biologically and therapeutically relevant genes within the CNS such as nerve growth factor (NGF), granulocyte colony-stimulating factor (G-CSF), and choline acetyltransferase (ChAT) (56). Technical aspects to achieve maximal gene transfer into brain cells using a plasmid DNA–cationic liposome complex have been discussed by Imaoka et al. (57). These authors have administered plasmid DNA–cationic liposome (lipopolyamine of dioctadecylamidoglycyl spermine) complex to 3–6 months old male rats using an osmotic pump. They report an increase of approximately up to two orders of magnitude in transfection efficiency compared to one obtained by a single injection. The authors propose that the continuous injection approach may be safe and effective in increasing the transfection efficiency. Another group led by Yokota (58) examined the effects of a calcium-dependent cysteine protease (calpain) inhibitor entrapped in liposomes in delaying neuronal death in gerbil hippocampal CA1 neurons following a transient forebrain ischemia. Selective neuronal damage induced by forebrain ischemia in the CA1 region of the hippocampus, and calpain-induced proteolysis of neuronal cytoskeleton, were prevented by administration of the inhibitor in a dose-dependent manner (58). Evaluation of transfection efficacy of a plasmid vector complexed with three different cationic liposomes into two experimental rodent and human malignant glioma cell lines and the mouse 3T3 fibroblast were studied by Bell et al. (59). The transfection efficacy and cytotoxicity of the liposomes were reported to vary quantitatively and qualitatively between cell lines. These authors suggest that their results support a potential application of cationic liposomes in both experimental and human malignant glioma gene transduction. Further studies on liposomal transfection of normal and neoplastic cells derived from the CNS will likely be very useful in helping to ascertain the particular merits of liposome-mediated gene transfection (59). Although the emphasis has been on utilizing liposomes in gene delivery to the CNS, this by no means limits their use to gene transfection (60–63).

## C. Therapeutic Approaches Employing Cells

### 1. Genetically Engineered Cells

In order to provide longer term neurotrophin delivery without the need to refill the containers or reduce the frequency of reimplantation of delivery devices, several groups (5,64–66) have developed implantable polymeric devices containing genetically engineered cells that can produce, for example, a missing trophic factor (Fig. 3). This strategy has been tested in animal models, including primates (67). Either primary cultures or genetically engineered cells producing a missing factor can serve as ‘‘long term effective mini-factories,’’ and various cell types used for these pur-

**Figure 42.3** Genetically engineered cells and stem cells. Different cell lines, primary cell cultures, and genetically engineered cells producing a neuroactive agent can be directly injected into the brain as a cell suspension, or prior to administration cells can be microencapsulated in biocompatible polymers. Neural stem cells with the capacity to renew and produce the major cell types of the brain can be used for cell replacement therapy in neurological disorders. (See Section C.3, Stem Cells.)

poses have been reported and reviewed, including pheochromocytoma cells (PC12) (68), fibroblasts, and NIH 3T3 cells genetically altered to produce growth factors (66,69,70). Although fully mature primary cultures or genetically engineered proliferating cells of nonneurological origin can replace missing peptides, they are either (i) deliberately physically separated from the environment at the implantation site to prevent tumor formation (e.g., by encapsulation or by placement of cells within a retractable implantation device) or (ii) in contact with the immediate microenvironment, their phenotype not allowing them to integrate and make functional connections (e.g., PC12 cells, fibroblasts).

### 3. Stem Cells

Replacement strategies using stem cells have recently become an attractive way to overcome the problems of cell integration and of acquisition of normal brain functions (71). Adult CNS stem cells can replace neurons and glia in the adult brain and spinal cord (72) and can also give rise to other cell types such as skin melanocytes and a range of mesenchymal cells in the head and neck (73). Stem cells may integrate appropriately into both the developing and the degenerating central nervous system and may be uniquely responsive to some types of neurodegenerative conditions (74). Neural-derived stem cells are self-renewing under the influence of mitotic agents such as fibroblast growth factor (75), epidermal growth factor (76,77), BDNF (78), and other factors (71,79–82). These cells can differentiate into either neuronal or glial cells and therefore can be used to replace neurons that are damaged or destroyed in defined neuronal structures, such as dopaminergic nigral neurons in Parkinson's disease, or hippo-

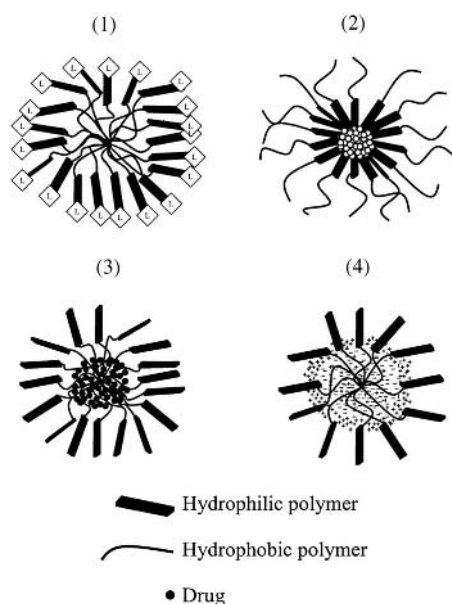

campal neurons (70,76,83–87). Neural stem cells cultured from human embryos can be grown for extended periods of time while retaining the capacity for neuronal and glial differentiation. The ability to generate human neural tissue in vitro allows for screening of neuroactive compounds and provides a source of tissue for testing cellular and genetic therapies for CNS disorders (88). Neurospheres of multipotent and restricted precursors may provide solutions for a longer lasting and more physiological supply of missing biologically active compounds, single or multiple, (52,54,89). Most importantly, stem cells have the advantage of establishing functional connections within the nervous system, a property that cannot be achieved with any polymeric drug delivery system, at least not in cases when a large proportion of neurons is lost. Accounts of the current status of stem cells and their biology and potential in treating neurological disorders are available in recent reviews (70,87,90). Obviously, ethical issues are of importance in implementing stem-cell strategies (84,86).

## III. BLOCK COPOLYMER MICELLES AND VESICLES

Block copolymer micelles (Fig. 4) have a great potential as delivery systems for the administration of neuroactive agents. Previous work (91,92) provided some seminal information in this regard, but much fundamental work relating to physical, morphological, and biological (pharmacological) properties must be done before block copolymer micelles and vesicles can be used either as diagnostics or as therapeutics. Thus far, only spherical micelles have been studied from the physicochemical and biological aspect. Other morphologies were only recently produced and identified using EM (93–95) and some sporadic *in vivo* studies have been reported (cylinder shapes delivered to lungs) without physical-chemical characterization. Our group has been involved in fundamental studies addressing the questions of interrelationships between morphological features (shape, size) and physicochemical properties of tailor-made micelles containing either fluorescent labels (96,97), highly lipophilic radiolabeled agents such as benzopyrene, or poorly soluble bioactive agents such as dihydrotestosterone and FK506 (96,98,99). A recent overview of the physical properties of block copolymer micelles used *in vitro* and *in vivo* in studies by several groups, including ours, is available in (92) and (98).

### A. Biodegradable Block Copolymers for Development of Micellar Delivery Systems

One of the promising biodegradable and biocompatible polymers for micellar delivery systems is polycaprolac-

**Figure 42.4** Representative types of block copolymer micellar delivery systems. 1. Corona forming block has attached ligand to provide site-specific delivery of neuroactive agents. 2. Inverse micelle for the delivery of hydrophilic neuroactive agents. 3. Block copolymer micelle for the delivery of lipophilic neuroactive agents. 4. Block ionomer micelle suitable for the delivery of antisense oligonucleotides and DNA.

tone-*b*-poly(ethylene oxide) (98). The individual components, polycaprolactone and polyethylene oxide, were explored previously for a variety of biomedical applications (110,111). A list of some core forming polymers is given in Table 1. Polycaprolactone, the hydrophobic core-forming block of the micelles, is a biodegradable polymer used as (i) a structural material in the production of medical devices such as implants, sutures, stents, and prosthetics, (ii) a carrier for a variety of drugs (112), (iii) in paste form for drugs (113,114), and (iv) a nanoparticulate ocular delivery system (115). Polyethylene oxide, the hydrophilic shell-forming block of the micelles, imparts blood compatibility to material surfaces (116) and is commonly used in micellar drug delivery systems (91). This polymer lends itself to chemical modifications that can enhance site-directed delivery. Micellar delivery systems for neuroactive agents are described in the following paragraph.

### B. Micelles for the Delivery of Neuroactive Agents

Several types of micelles formed from different polymers and copolymers have been developed (Table 2), some of which could be useful for the delivery of neuroactive

agents. Several considerations arise when considering polymer micelles as drug carriers for CNS-based therapeutics. For instance, a high partitioning of the drug into the micelle is required because otherwise one would have to administer large amounts of micelles. Similarly, the polymer must be biodegradable, biocompatible, and with sufficiently low critical micellar concentration (CMC) to achieve a longer length of time in the bloodstream to allow the drug to reach its site of action. Modifications to optimize polymer-drug interactions and high stability of micelles in the blood have been recently reviewed (127). In order to enhance endocytosis and ultimately transcytosis of micelles containing neuroleptic agents across the BBB, ligands were attached to the polymer micelles. An improved internalization of derivatized pluronic micelles has been demonstrated using primary cultures of brain microvessel endothelial cells (BBMEC) (128–130). Nevertheless, micelle carriers for drug delivery to the brain still have some limitations:

1. Brain endothelial cells take up a relatively small amount of micelles designed so far. Consequently, the amount of drug delivered is relatively small. However, if the drug has a high potency, it should be still possible to obtain the desired biological effects.

2. Drugs to be incorporated into the micelles should have very low capacity to cross the BBB. This is not the case with highly lipophilic agents, but many peptides and oligonucleotides are good candidates for micellar delivery systems to the brain.

In addition to the micelle-based strategies outlined here, there is another strategy that has been explored to a limited extent, namely the exploitation of specific interactions of the polymers themselves with the membrane and membrane transporter proteins found in the brain microvessel endothelial cells that form the BBB. In this case it is not necessary to have micelles, since the monomer itself can modify the BBB permeability. Two proteins within the BBB are targets of such an approach: P-glycoprotein (P-gp) and multidrug resistance-associated protein (MRP) (128,129). Modifications of P-gp and MRP and possibly other transporters in the BBB with polymeric formulations may considerably facilitate the accumulation of neuroactive agents within the brain. Among the polymers tested so far, pluronic polymers seem to be particularly effective in inhibiting P-gp drug efflux in the brain microvessel endothelial cells (106). Some drugs can also change the permeability of the BBB, such as cyclosporin A. Unfortunately, cyclosporin A in equivalent concentrations to Pluronic P85 seriously disrupts the integrity of the brain microvessel endothelial cells (127). Some examples of drugs with effects on the nervous system and of their delivery vehicles are given in Table 3. Polymers as trans-

**Table 42.1** Core-Forming Polymers

Poly(aspartic acid)	Poly(ethylene glycol)–poly(aspartic acid) block copolymer micelles conjugated with adriamycin were prepared, characterized, and tested for anticancer activity. Result in vivo: high anticancer activity of adriamycin micelles in P 388 mouse leukemia and smaller weight loss with adriamycin micelles than with free adriamycin.	100
Poly( $\gamma$ -benzyl-L-glutamate)	Clonazepam containing block copolymer nanoparticles were prepared and tested in vitro. Result: release of clonazepam is dependent on the drug loading contents and PBLG chain length.	101
Polyamines		
Poly(L-lysine)	Supramolecular associates of DNA with PEG-PLL block copolymers increase nuclease resistance of plasmid DNA.	102
	Turbidometric analysis of polyelectrolyte complexes formed between PLL and DNA.	103
	Examination of the use of oligopeptides containing the RGD sequence in promoting the uptake of PLL/DNA complexes in vitro.	104
Polyspermine	Discussion of physicochemical aspects of formation and behavior of interpolyelectrolyte and block ionomer complexes for gene delivery.	105
Others		
Polypropylene oxide	Interactions of pluronic block copolymers with brain microvessel endothelial cells.	106
	Haloperidol's neuroleptic activity increases after its solubilization in surfactant micelles.	107
	Establishment of the structure–property relationship for $E_mP_n$ ( $E$ , oxyethylene; $P$ , oxypropylene) diblock copolymers–micellization and gelation of $E_mP_n$ diblock copolymers in aqueous solution.	108
Polyethylene	New class of synthetic thin-shelled capsules. Polymersomes: tough vesicles made from diblock copolymers.	109

port-modifying agents have both advantages and limitations:

1. Polymers exhibit relative selectivity. However, since P-gp and MRP are also present in liver, the drug could accumulate in this organ, affecting normal functions, in particular metabolic processes.
2. Less damage occurs to the microvessel endothelial cell integrity.
3. Some polymers are effective below the CMC.

### C. Micelles for the Delivery of Antisense Oligonucleotides

#### 1. Problems in the Delivery of Antisense Oligonucleotides

The use of antisense oligonucleotides to control protein expression has received considerable attention due to their relative ease of synthesis and specific use. Commonly, short (between 15 and 20 bases) chemically modified nu-

cleic acids are employed. They hybridize to complementary nucleotide sequences in accessible regions of mRNA molecules, thus blocking expression of the encoded proteins. Two major problems are associated with the use of antisense oligonucleotides: (i) the identification of accessible regions in mRNA to which the oligonucleotides can hybridize, and (ii) the delivery of the oligonucleotides into the cell and to their target (136). The accessibility of an mRNA sequence is determined by the primary nucleotide sequence, its three-dimensional structure, and the presence of associated proteins. This combination of factors has made the design of effective antisense oligonucleotides a difficult task, and experiments involving the use of poorly designed antisense oligonucleotides often produce misleading results. However, once a candidate oligonucleotide has been synthesized, several challenges arise in delivering it effectively to its target. A first consideration is the presence of various endo- and exonucleases in serum that can degrade the oligonucleotides and destroy their biological activity (137). Also, some types of antisense oligonucleotides (e.g., phosphothiorate) are highly charged

**Table 42.2** Types of Micelles

Micelles	Utilization	Reference
Pluronic based micelles	Examination of the solubilization of hydrocarbons by aggregates of Pluronic® block copolymers in water [Pluronic®; symmetric copolymers with poly(ethylene oxide), PEO, as the hydrophilic end blocks and poly(propylene oxide), PPO, as the hydrophobic middle block (PEO-PPO-PEO)].	117
	Stabilization and activation of Pluronic micelles for tumor-targeted drug delivery.	118
	Pluronic based (Pluronic L61 and Pluronic F127) formulation of doxorubicin.	119
Block ionomer complexes	Potential application of polymer–surfactant complexes between block ionomers and oppositely charged surfactants as a drug delivery system.	120
Polyion micelles	Surface charge modulation of poly(ethylene glycol)-poly(D,L-lactide) block copolymer micelles: conjugation of charged peptides.	121
Thermoresponsive micelles	Control of adriamycin cytotoxic activity using thermally responsive polymeric micelles composed of poly(N-isopropylacrylamide-co-N,N-dimethylacrylamide)- <i>b</i> -poly(D,L-lactide).	122
	Gelation behavior of thermosensitive poly(ethylene glycol- <i>b</i> -(D,L-lactic acid-co-glycolic acid)- <i>b</i> -ethylene glycol) triblock copolymers.	123
Polycaprolactone- <i>b</i> -polyethylene oxide micelles	PCL- <i>b</i> -PEO copolymer micelles as a delivery vehicle for lipophilic drugs.	96, 124
Shell-cross linked polymer micelles	Formation of cross-links throughout the shell of polymer micelles reinforces the weak interactions that facilitate micelle existence.	125
Polycation comb-type copolymer	Copolymer-mediated stabilization of DNA duplexes and triplexes.	126

polyanions and bind extensively to serum proteins (138–140). Such oligonucleotides have a very limited ability to cross cellular membranes, and this reduces the amount of oligonucleotides that can reach their nuclear target (141, 142). Furthermore, the binding of serum proteins by oligonucleotides may also alter the protein activity, which may be misinterpreted as an effect of the oligonucleotides on nuclear targets. A second consideration is that the amount of oligonucleotides taken up by different tissues

and cells varies considerably. Studies in rodents have shown that the majority of intravenously injected oligonucleotides distribute to the kidney and liver, where they may be degraded and lose biological activity (143–144). Also, these studies showed that the biodistribution of oligonucleotides is generally much greater in the intestine, bone marrow, skeletal muscle, and skin than in the brain. This presents additional concerns for the delivery of oligonucleotides to targets in the central nervous system.

**Table 42.3** Examples of Drugs with Effects on the Nervous System and Their Delivery Vehicles

Drug	Delivery vehicle	Reference
FK 506	Polycaprolactone- <i>b</i> -poly(ethylene oxide) block copolymer micelles; a novel drug delivery vehicle for FK506 and L-685,818.	96
Paclitaxel	Poly(D,L-lactide)- <i>b</i> -methoxy polyethylene glycol micelles; human plasma distribution of free and micelle incorporated paclitaxel.	131
Neurosteroids	Polycaprolactone- <i>b</i> -poly(ethylene oxide) copolymer micelles; delivery vehicle for dihydrotestosterone.	124
	Poly (D,L-lactic acid) microspheres; evaluation of microspheres' physical properties and their in vivo characteristics for long-acting drug delivery (testosterone).	132
	Caprolactone/lactide block copolymer; delivery kinetics of levonorgestrel and estradiol.	133
	Tricalcium phosphate lysine (TCLP) drug delivery system; the synergistic effect of sustained delivery of steroid hormones on the ventral prostate of adult male rodents.	134
Cyclosporine	Microemulsion formulation; comparison of the steady-state pharmacokinetics and tolerability of the cyclosporine microemulsion formulation with the cyclosporine commercial formulation in clinically stable renal allograft recipients.	135
Clonazepam	Core-shell type nanoparticles; in vitro clonazepam release is dependent on the drug loading contents and poly(γ-benzyl-L-glutamate) chain length.	101

The actual mechanisms by which antisense oligonucleotides enter into cells are currently under debate, but they are thought to involve fluid-phase pinocytosis and/or receptor-mediated endocytosis (145). A third concern is that once the oligonucleotides have successfully entered into a cell, they are subject to degradation. Confocal and electron microscopy studies have shown that the majority of internalized antisense oligonucleotides enter into the cellular endosomal and lysosomal systems (146). These compartments may have acidic pH and contain enzymes that degrade the oligonucleotides and destroy their biological activity. It is clear, however, that a portion of the administered oligonucleotides either escapes from the endosomal/lysosomal systems or bypasses them altogether and enters the cytoplasm to diffuse into the nucleus, by poorly understood mechanisms (141). The cytosolic environment also contains a variety of exo- and endonucleases and proteins, which presents problems similar to those encountered in the serum. An additional concern arising from microscopy studies is the existence of an efflux of oligonucleotides from the nucleus, likely through a passive diffusion mechanism via nuclear pores (146), and from the cell (147–149). These phenomena must also be considered when targeting antisense oligonucleotides to the nucleus.

## 2. Early Approaches in Antisense Oligonucleotide Delivery Systems

Short-term antisense therapy is often marked by the development of two common toxicities, namely activation of the complement system and increase in blood clotting time (150,151). However, clinical studies have shown that these effects are minor due to the relatively short half-life (30–60 minutes) of oligonucleotides in the serum, which may be due to binding of serum proteins to oligonucleotides (145). As well, chronic administration of antisense oligonucleotides in rodent models leads to the induction of immune responses, characterized by lymphoid hyperplasia, splenomegaly, and monocyte recruitment to a number of tissues (151). In consequence, there has been considerable interest in developing delivery methods that can minimize these degradative and immune drawbacks to the use of oligonucleotides. Early approaches focused on improving the cellular uptake of antisense oligonucleotides by coupling them to polycations such as polylysine (152) and polyethyleneimine (153), or, more successfully, to polycationic lipids/lipid formulations (154,155). Other approaches involved targeting antisense oligonucleotides to cell surface receptors such as the folate receptor (156), transferrin receptor (157), and asialoglycoprotein receptor (158), to stimulate receptor-mediated endocytosis. Another strategy involved the coupling of oligonucleotides to typical membrane enti-

ties such as cholesterol (159) or to fusogenic peptides (160). These *in vitro* uptake enhancers have been successful in tissue culture systems, with significant increases in the uptake and nuclear localization of the oligonucleotides. However, it is noteworthy that the internalization profiles of oligonucleotides *in vitro* often differ considerably from their behavior *in vivo* (145). Furthermore, these early approaches did not focus upon minimizing the immunogenicity and instability of the oligonucleotides, which has been addressed by the micellar delivery approach described below.

## 3. Delivery of Antisense Oligonucleotides Employing Copolymers

Although some oligonucleotides are relatively stable following their administration by a variety of routes (intravenous, intraperitoneal, subcutaneous, intracerebroventricular) (161), delivery of antisense oligonucleotides by delivery systems has been proposed in order to reduce the immunogenicity and protect them from the physiological degradative processes referred to above. The major work in this area has been carried out by Kabanov's group, using, first, hydrophilic polymeric vesicles (162), and subsequently, polyion complex micelles with a protein modified corona (163). A hydrophilic polymer, Nanogel, was used to create vesicles with an average particle size of 120 nanometers (162). This polymer is formed from cross-linked polyethyleneimine (PEI) and carbonyldiimidazole-activated poly(ethylene glycol) (PEG), thus building on the PEI-coupling approach of Boussif (153), which focused on enhancement of cellular uptake. Nanogel particles have been employed for the delivery of antisense phosphothiorate oligonucleotides (SODN), targeting the mRNA of the human multidrug resistance gene, *mdr1* (162). These studies have shown that the Nanogel vesicular approach attains a greater cellular localization of SODN in a human carcinoma cell line in comparison to the administration of free SODN. The effectiveness of the Nanogel-incorporated SODN was demonstrated by its ability to inhibit the expression of P-glycoprotein, a major cellular pump involved in the efflux of cytosolic drugs.

A significant reduction in delivery vehicle size was achieved by Kabanov's group with the synthesis of polyion complex micelles incorporating SODN (163). These micelles contain poly(ethylene glycol)-PEI graft copolymer complexes that self-assemble with SODN to form 40 nanometer particles, each consisting of a PEI/SODN neutralized core surrounded by a poly(ethylene glycol) corona. Transferrin molecules attached to the poly(ethylene glycol) corona create polyion complex micelles (75 to 103 nanometers) facilitating the internalization of SODN into

cells. These studies (163) have indicated that SODN incorporated in polyion micelles with a protein modified corona have a significantly greater ability to inhibit the expression of the P-glycoprotein drug efflux transporter in several cancer cell lines.

#### 4. Micelles for the Delivery of DNA

Some of the most frequently applied techniques to transfect cells are (i) precipitation with calcium phosphate (164–170), (ii) polybrene (171), (iii) electroporation (172), (iv) microinjection (173), (v) modified viral vectors (174,175), (vi) microspheres (47), (vii) liposomes (176–178), and (viii) polycation delivery systems (121,179–181). There are several commonly used protocols for cell transfections, the most frequently used being precipitation with calcium phosphate (164,182).

Kabanov's group has contributed greatly to the delivery systems of genetic materials. The methodology is based on formation of soluble interpolyelectrolyte complexes (IPECs). The term IPEC in polymer science relates to the products of reaction of oppositely charged polyions, and in the case referred to here polycation–DNA complexes represent a special kind of IPECs relevant to biological issues. A critical assessment of transfection approaches in mammalian cells using DNA–IPECs and more common methods such as calcium phosphate precipitation and lipofectin is given in several reviews, e.g., Ref. 179. Polycations as building blocks for DNA complexes can be relatively easily conjugated with ligands and undergo receptor-mediated endocytosis (179). Among the most frequently attached ligands are asialoglycoprotein, insulin, and transferrin. Asialoglycoprotein receptors play a critical role in hepatocytes and allow for targeted delivery of DNA to the liver (183,184). Insulin and transferrin receptors are present in many cell types and provide an endocytotic internalization of the delivery system (insulin receptor) or vesicular transport followed by the return to the cell surface (185). Antibody molecules have also been linked to IPECs to achieve cell and tissue specificity (186). Since neural cells express a wide variety of receptors, some of them specific for (sub)classes of neurons (e.g., cholinergic, dopaminergic, gabaergic), IPECs linked to ligands recognizing these receptors offer an attractive approach in drug and gene delivery to the nervous system.

#### IV. FUTURE TRENDS

If a disease is diagnosed early enough, and if significant improvements can result simply from a slowing down of pathological changes, drug administration using suitable

polymeric devices is a viable approach. Moreover, in conjunction with stem cells, drug delivery systems could improve the viability of implanted stem cells, enhance the rate of functional reactivity, and promote neuronal differentiation. Regardless of particular specific needs, localized (site-specific) physiologically controlled drug release is always desirable. These goals are being gradually achieved by the increasing availability of new functionalized biopolymers, and “smart polymers.”

Smart polymers are hydrogels that undergo fast, reversible changes in microstructure from a hydrophilic to a hydrophobic state (187). Triggers that can produce these changes include neutralization of charged groups by a shift in pH, the addition of an oppositely charged polymer, a change in temperature or ionic strength, or the formation of interpenetrating polymer networks (187). Stimulus-responsive or smart polymers have been used mainly for bio-separations but also for the development of drug delivery systems. One of the models based on smart polymers is a glucose-responsive insulin loaded polymer matrix (188). The number of drug delivery systems utilizing smart polymers is very limited, and much work remains to be done in the area of their synthesis and structure–property relationship studies before they can be considered for clinical applications.

In addition to drug release from polymeric devices such as pulsatile stimuli by an electric or magnetic field, exposure to ultrasound, light, enzyme, or change in pH or temperature, new biotechnological approaches have led to the development of solid-state silicon microchips that can provide controlled release of single or multiple agents on demand (51). Although it is too early to say if microchips will supplement or replace classical delivery systems, they represent a significant step forward in biotechnological approaches to administer neuroactive agents in a more controlled manner.

## Glucose-Mediated Insulin Delivery from Implantable Polymers

Larry R. Brown

*Harvard–Massachusetts Institute of Technology, Cambridge, Massachusetts*

### I. INTRODUCTION

In 1976, Langer and Folkman pioneered the sustained release of protein molecules from biocompatible hydrophobic polymers (1). Further work by Rhine et al. refined the techniques for fabricating polymer matrices for the sustained release of very water soluble proteins such as albumin (2). These polymeric delivery systems were ultimately used to deliver therapeutic proteins such as insulin (3–6). However, insulin represented a somewhat different macromolecule from those that had been studied before. Insulin's aqueous solubility was much lower than that of albumin, and its release kinetics were slower than what had been observed for more water soluble proteins like albumin. Thus the research efforts in developing a sustained release insulin delivery system became a study in the solubility properties of insulin.

Ultimately, it became apparent that altering insulin's solubility within the polymer matrix could be used to alter the insulin release in response to glucose concentration changes. It was determined that changes in the solubility of insulin as a function of pH could be used to control and alter the delivery of insulin. The pH dependent solubility properties of insulin were then used to develop a polymeric glucose mediated insulin delivery system. An understanding of the interrelationship between insulin and its solubility properties is necessary to appreciate fully the development of a pH controlled insulin delivery system. Therefore the topics covered in this article include

1. Insulin's role in physiology
2. Insulin's structural and physical-chemical elements
3. Sustained insulin release from ethylene vinyl acetate copolymer matrices
4. A glucose mediated insulin delivery implant

### II. INSULIN'S ROLE IN PHYSIOLOGY

Insulin is a hormone produced by the beta cells of the endocrine pancreas. The hormone plays a major role in the metabolism and absorption of carbohydrate, protein, and fat. It is especially important in enabling the transport of d-glucose by cells for energy and the transport of amino acids for protein synthesis. It also increases glycogen synthase activity, inhibits lipolysis, and inhibits proteolysis. Insulin dependent diabetes mellitus occurs when the beta cells of the pancreas do not make sufficient insulin to meet the needs of the organism. Given these diverse insulin functions, it is not surprising to discover that the secretion of insulin from the beta cell islets varies in response to many metabolic events.

When insulin was first discovered by Frederick Banting and Charles Best in 1921 it was not fully appreciated that insulin needed to be delivered in pulses in response to carbohydrate laden meals, and in an extended release form in order to mimic basal insulin delivery (7). Thus one sees an increase in plasma insulin concentration at meal times, which returns to a lower basal concentration in between

**Figure 43.1** An idealized representation of the relative concentration of circulating insulin is depicted over the course of a day. Pulses of insulin are observed in response to meals, which is superimposed on basal insulin secretion.

meals. The focus in insulin delivery research has been to develop the systems and means that match the physiologic plasma insulin concentration profiles seen in Fig. 1.

### III. INSULIN'S STRUCTURAL AND PHYSICAL-CHEMICAL ELEMENTS

A brief review of the structural, physical, and chemical properties of insulin is presented as a background for the

solubility dependent release properties of the molecule from polymeric matrix implants.

#### A. Insulin Structure

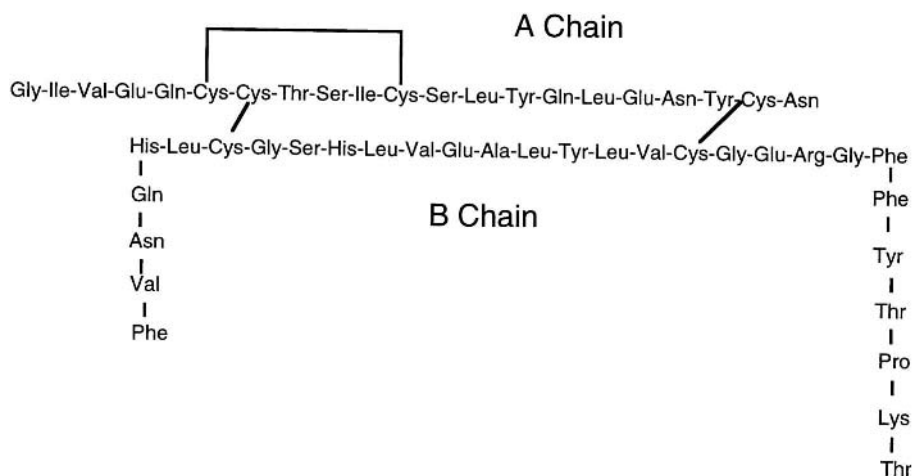

Insulin is a polypeptide hormone produced by cells in the islets of Langerhans in the pancreas. It is synthesized as proinsulin shown in Fig. 2. Proinsulin is composed of 84 amino acids, of which 33 are cleaved as a posttranslational modification of the synthesis of insulin (8–13).

This 33 amino acid peptide that is cleaved is known as the connecting peptide or C-peptide (14). The C-peptide is excreted into the urine, and its presence in the urine can be used to determine if the organism is synthesizing any endogenous insulin.

Two amino acid peptide chains remain after the cleavage of the C-peptide chain shown in Fig. 2. Chain A consists of 21 amino acids, and Chain B consists of 30 amino acids. Fig. 3 shows the primary amino acid structure of human insulin. Insulin is a polypeptide hormone with a molecular weight of approximately 5800 daltons in its monomeric form (17). However, it is often found in its dimeric or hexameric forms. There is remarkable homology between insulin of different species. Historically, insulin for human use was extracted from beef and pork pancreases. Today, recombinant human insulin has largely replaced animal source insulin in the United States and Europe. Table 1 compares the differences between human,

**Figure 43.2** The complete pork proinsulin structure shows the A, B, and C-peptide chains of insulin. There is minimal biological activity associated with proinsulin compared to that of insulin. (From Refs. 15 and 16.) (Reprinted with permission from Lippincott Williams and Wilkins.)

**Figure 43.3** The primary amino acid structure of A and B chains of human insulin is shown along with the two disulfide linkages connecting the A-Cys(7) to B-Cys(7) and A-Cys(20) to B-Cys(19). A third intrachain disulfide linkage is found between A-Cys(6) and A-Cys(11).

beef, and pork insulin. Pork insulin differs from human insulin by one amino acid and from beef insulin by two amino acids. As a result of this homology, there is no appreciable difference in biological activity between insulin forms derived from different species.

**B. Fast Acting Insulin Forms**

Recent developments have led to subtle changes in insulin’s primary structure which yield insulin forms with unique pharmacokinetic properties that do not alter the biological activity of these new insulin forms. For example, on the B-chain of insulin, the number 28 and 29 amino acids are Proline(28) and Lysine(29). Insulin forms have been shown to have greater aqueous solubility when the order of Lysine and Proline in the B-chain is reversed. Insulins have been engineered so that now Lysine is the number 28 amino acid and Proline is the number 29 amino acid. The increase in Lys(28)Pro(29)-insulin’s aqueous solubility has been attributed to a 300-fold inhibition of hexameric insulin unit formation compared to regular insulin. Thus Lys(28)Pro(29)-insulin tends to exist in the monomer form, and this increase in insulin solubility enables

fast absorption from an injection site. This results in a faster onset of insulin action compared to regular insulin (18). Lys(28)Pro(29) insulin is commercially known as Humalog®. There are other insulin analogues that have been developed to exhibit a faster onset of action through the same basic mechanism. These analogues include Asp (B10)Lys(B28)Pro(B29)-human insulin and insulin Aspart [Asp(B28)]-insulin (19). Furthermore, the decreased tendency of these insulin analogues to associate into dimers and hexamers has been attributed to its decreased tendency to be coordinated with divalent zinc ions.

**C. Physical-Chemical Elements**

The solubility of insulin is strongly influenced by its interaction with zinc and the pH of the aqueous solutions in which it is dissolved. These factors and others have been used to develop new insulin forms that either are faster acting or possess extended release properties.

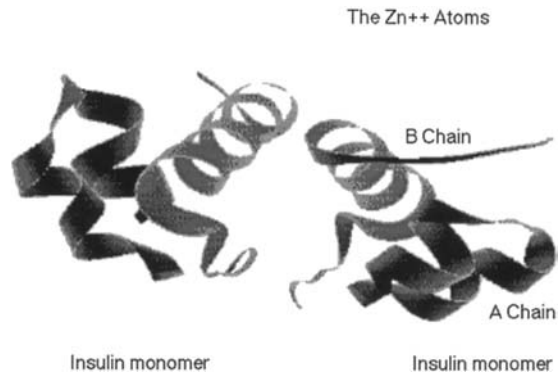

1. The Role of Zinc in Insulin Solubility

As previously described, the A and B chains of insulin are organized in a hexameric structure when in the presence of divalent zinc anions (Zn<sup>++</sup>) and in a pH neutral solution. In this hexameric structure, three insulin dimers are held together by two Zn<sup>++</sup> ions. Figure 4 shows a three-dimensional depiction of the zinc anions in association with an insulin dimer.

The presence of these zinc atoms profoundly affects the pH solubility profile of insulin. Removal of the zinc from the insulin molecule by chelating it with EDTA yields an

**Table 43.1** Primary Structure Amino Acid Variations Between Insulin of Different Species

Insulin source	Chain A—position 8	Chain B—position 30
Human	Thr	Thr
Pork	Thr	Ala
Beef	Ala	Ala

**Figure 43.4** Three-dimensional depiction of an insulin dimer in the presence of zinc. The darker gray chain is the A chain of insulin and the helical chain is the B chain. The A and B chains are chemically bonded with two disulfide linkages. Solutions of bovine insulin have been shown to contain two molecules of zinc ( $Zn^{++}$ ) ions per each six base-molecule of insulin. (From Refs. 23 and 24.)

insulin whose water solubility is approximately 100-fold greater than zinc containing insulin (4).

## 2. pH and Insulin Delivery

There have been numerous efforts to correlate exogenous insulin action with physiologic action and delivery in order to achieve the goal of normalized blood glucose levels. Initially, investigators attempted to prolong the 2–4 hour regular crystalline insulin action so that a 24 hour period could be covered by a single insulin injection. Table 2 outlines several commercial insulin types and their pharmacodynamics in terms of peak action and duration of action.

Regular crystalline insulin has an isoelectric point of approximately 5.3. That is its point of electroneutrality and of lowest solubility in aqueous solution occurs at about pH 5.3. At the physiologic pH of 7.4, insulin's aqueous solubility is high enough to result in a relatively short duration of action due to its complete dissolution and absorption from the site of injection.

**Table 43.2** Insulin Type and Pharmacodynamics

Insulin type	Onset (hours)	Peak action (hours)	Duration (hours)
Humalog®	0.25	0.5–1.5	3–5
Regular	0.5	2–4	6–8
Lantus®	2–4	4–24	24
NPH®	2–4	6–8	12–15
Lente®	1–3	6–12	18–26
UltraLente®	4–8	12–18	22–30

## 3. Early Efforts to Prolong Insulin Action

Soon after the discovery of insulin, researchers tried to increase its half-life by decreasing insulin's solubility in the body. Lewis (23) reported unsuccessful attempts to sustain insulin release by injecting the hormone into oily suspensions, acacia solutions, and lecithin solutions. Other investigators attempted to administer insulin in the presence of epinephrine, posterior pituitary extracts, and astringent metals. These attempts also proved to be unsuccessful. Hagedorn (24) showed that insulin combined with protamine would allow continuous action for 3–12 hours. Protamine insulin actually has an isoelectric point that is near physiologic pH ( $pI \sim 7.3$ ), and therefore it dissolves slowly following subcutaneous injection. This was a significant advance toward a more continuous insulin release. However, protamine insulin proved to be unstable. Scott and Fischer (25) therefore developed protamine zinc insulin, which overcame the instability problem of protamine insulin. It provided a daily requirement of insulin in a single injection. The preparation involved combining 0.20 mg zinc and 1.5 mg protamine per 100 units of insulin. The onset of activity of protamine zinc insulin is 6–8 hours after injection, and it lasts for 24 hours. When used in conjunction with rapidly acting insulin preparations, this provided a more effective method of continuous insulin availability throughout the day for the diabetic (26).

Other insulin preparations include globin zinc insulin, which is an intermediate acting insulin that can normalize glucose levels within 2 hours of injection and maintain them for 16 hours. Isophane zinc insulin is modified protamine zinc insulin consisting of 0.05 mg protamine per 100 units of insulin. Its action is similar to globin insulin with an onset of action within 2 hours and lasting for 20 hours (27).

Lente® insulin was developed in 1952 by Hallas Moller (28). This insulin begins to take advantage of the interaction of zinc and insulin. Lente® insulin is a combination of zinc and insulin in an acetate buffer. The duration of Lente® insulin action can be varied by simply modifying particle size. SemiLente® insulin consists of amorphous insulin particles and has 18 hours activity. UltraLente® is made of large particles with a 30 hour duration of activity. Lente® insulin, which contains 3 parts SemiLente® insulin and 7 parts UltraLente® insulin, lasts 24 hours. Its longevity is due to the large insulin crystals and its neutrality of suspension (pH 7.2), which retard its absorption.

Although these insulin preparations provide an “insulin presence” in the blood of a diabetic for a 24 hour period, their action is neither physiologic nor at a constant basal level when not operating at peak activity. The final 4–6 hours of these 24 hour preparations are often marked by

insufficient insulin concentrations in the blood to maintain normal blood glucose levels throughout the night. Elevated fasting blood glucose levels are often seen in diabetics maintained by this regimen. Complete reduction in plasma glucose levels by a single subcutaneous injection of rapid or intermediate acting insulin is virtually never achieved (29,30), and the long-term complications of the disease remain a serious threat to the normal life of the diabetic.

The Diabetes Control and Complications Trial (DCCT) was a multicenter, randomized, clinical study designed to determine whether an intensive treatment regimen directed at maintaining blood glucose concentrations as close to normal as possible will affect the appearance or progression of early vascular complications in patients with insulin dependent diabetes. As a result of the DCCT study, it was clearly shown that good metabolic control of the insulin dependent diabetic resulted in a significant reduction of the secondary complications of diabetes (31). Improved metabolic control by continuous insulin delivery has been achieved by the use of externally worn miniature infusion pumps (32) and with new genetically engineered insulin forms.

#### 4. A New Insulin Analogue for Longer Term Delivery

Recently a new insulin analogue was approved for use in the United States (33). Lantus® is a sterile solution of insulin glargine for use as an injection. Insulin glargine is a 24 hour long acting recombinant human insulin analogue. Insulin glargine differs from human insulin in that the amino acid asparagine at position A21 is replaced by glycine and two arginines are added to the C-terminus of the B-chain. It has a molecular weight of 6063. Insulin glargine is designed to have a low aqueous solubility at neutral pH. It is injected in a pH 4 injection solution, where it is completely soluble. The acidic solution is neutralized after injection into the subcutaneous tissue, which leads to the formation of microprecipitates from which small amounts of insulin glargine are slowly released. This results in a relatively constant concentration–time profile over 24 hours with no pronounced insulin peak. This profile allows once daily dosing as a patient's basal insulin.

## IV. SUSTAINED INSULIN RELEASE FROM ETHYLENE VINYL ACETATE COPOLYMER MATRICES

The efforts to develop a feedback controlled, sustained release insulin delivery system began with the observations that proteins could be continually released from polymer matrices (1). However, initial attempts to develop a long-

term insulin delivery matrix implant using ethylene vinyl acetate were impeded by two factors. One was the low solubility of insulin which resulted in slow release kinetics (3–5). The second factor was that the polymer matrix geometry employed up to this time resulted in release kinetics that decreased over time (2). Therefore studies were undertaken to address both the marginal solubility of insulin and the nonoptimal insulin release profile from the matrices.

### A. Methods and Materials

The following section describes the experimental techniques used to fabricate insulin releasing ethylene vinyl acetate copolymer matrices.

#### 1. Insulin

Dry powdered zinc insulin from a beef source was the starting material used in the fabrication of the delivery devices. Each mg of insulin contained approximately 26 international units of activity.

#### 2. Conversion of Zinc Insulin to Zinc Free Sodium Insulin

Zinc free insulin is much more soluble than crystalline zinc insulin. Therefore zinc insulin was converted to sodium insulin using the following method. Zinc insulin crystals were dissolved at a concentration of 20 mg/mL in distilled water that was adjusted to pH 3.0 with 0.1 M HCl. Sodium EDTA was added to the insulin solution to achieve a final concentration of 0.02 M, and NaCl was also added to yield a final concentration of 3 M NaCl. This insulin solution was adjusted to pH 8.2 with NaOH. NaCl was then added until the solution turned hazy. Liquefied phenol was added to a final concentration of 0.3%. This suspension was stirred for 3 hours. The suspension was centrifuged, and the supernatant was discarded. The resulting pellet was re-suspended in a 2% NaCl solution. The aqueous solubility of this zinc free insulin preparation was determined to be 120 mg/mL (4). The insulin was then lyophilized to a dry powdered form.

#### 3. Insulin Polymer Matrix Preparation

Zinc insulin powder or sodium insulin powder was sieved to various particle size ranges through U.S. Standards Sieves with mesh sizes of 75, 250, 300, and 425  $\mu\text{m}$ . Flat-slab insulin containing matrices were prepared by a solvent-casting procedure (2). Washed ethylene vinyl acetate copolymer was dissolved in methylene chloride to form a 10% (wt/vol) solution. Various weighed amounts of insulin powder were added to the ethylene vinyl acetate co-

polymer solution. The mixture was vortexed for 15 seconds to give a homogeneous suspension of powdered insulin particles in the polymer solution. The suspension was quickly poured from corner to corner onto a leveled square glass mold ( $5 \times 5 \times 1.5$  cm) that had been precooled on a slab of dry ice for 10 minutes. The frozen slab remained in the mold for 10 minutes. Then the slab was pried loose with a spatula precooled on dry ice, transferred to a nickel-coated wire screen, placed into a  $-20^{\circ}\text{C}$  freezer, and allowed to dry for 2 days. The methylene chloride evaporated without significant migration of the insulin particles within the polymer matrix. The flat slab was dried for an additional 2 days at room temperature under mild vacuum (600 millitorr). Individual disks, 5 mm in diameter and 0.8 mm thick, were excised from the resulting slab with a #3 size cork borer.

#### 4. Release Studies

The insulin polymer slabs were placed in release media that generally consisted of 50 mM Tris-HCl buffer adjusted to pH 7.4. The polymer matrices were placed in a 22 mL glass vial containing the release medium. The matrices were transferred to fresh release medium at appropriate time points. The old release medium was then assayed for insulin by ultraviolet absorption at 220 nm (34).

### B. Results

The following experimental results show the effect of insulin solubility on release and a discussion of the mechanism of insulin release from the polymeric release devices. A near-zero-order releasing polymer matrix implant was investigated, and results both *in vitro* and *in vivo* are reviewed.

#### 1. Effect of Insulin Solubility on Release

The release kinetics of insulin from polymer matrices containing either zinc insulin or sodium insulin are compared in Fig. 5. The weight percent loading of insulin in the matrices was 50% (wt/wt). The insulin particle size was selected to be between 250 and 425  $\mu\text{m}$ . The solubility of the zinc insulin was measured to be 0.33 mg/mL, and the solubility of the sodium insulin was measured to be 120 mg/mL in 50 mM Tris-HCl buffer.

The sodium insulin matrices released 75% of the originally incorporated insulin, whereas the zinc insulin matrices released only 36% over a 36 day period. The initial burst effect of insulin release lasted approximately 100 hours ( $t^{0.5}$ , 10 hours<sup>0.5</sup>) for the zinc insulin matrices and 50 hours ( $t^{0.5}$ , 7.1 hours<sup>0.5</sup>) for the sodium insulin matrices. The second phase of release showed a lower release rate

**Figure 43.5** The cumulative percentage release of insulin versus the square root of time graphed for matrices made with zinc insulin and with sodium insulin. The matrices were released into 50 mM Tris buffer at pH 7.4 and  $23^{\circ}\text{C}$ . The sodium insulin matrices showed greater cumulative percent release than the zinc insulin matrices. Each point represents the mean of seven matrix samples. (Reproduced with permission from John Wiley & Sons.)

than the burst effect and a linear dependence of cumulative percent release on the square root of time. During this second phase of release, an additional 5.5% of the zinc insulin and 41.4% of the sodium insulin was released over the 17 days after the burst effect. These results supported the use of sodium insulin in order to obtain greater cumulative release from these sustained release polymer matrices.

#### 2. Mechanism of Release

Bawa et al. previously showed that the release mechanism of macromolecular drugs from these matrices involved the influx of release medium into the matrix through pores where the drug was dispersed (35). The dissolution of the drug was followed by the slow diffusion of the drug through the complex network of pores to the exterior of the matrix. Figure 5 showed that insulin release from flat-slab solvent cast matrices was divided into two phases. The first phase was an initial burst of insulin release that can be explained as the dissolution of particulate insulin at the surface of the matrix. The second phase of release was the further dissolution and diffusion of insulin through the tortuous porous network. In the second release phase, the cumulative percent release of incorporated insulin was observed to be linear with the square root of time for the flat-slab geometry. This is consistent with the diffusion of molecules through a porous planar matrix as the rate limiting step. An alternate model proposed by Higuchi supports a similar diffusion mechanism through a porous network for drugs like insulin, which possess low solubility

(36). A cross-sectional representation of a typical slab release device is shown in Fig. 6.

A simplified model of release from a matrix slab can be represented by the equation

$$\frac{dQ}{dt} = \frac{C_s D a_i^2}{R}$$

where  $dQ/dt$  = release rate in mg/s,  $C_s$  = drug solubility in mg/mL,  $D$  = diffusion coefficient in  $\text{cm}^2/\text{s}$ ,  $a_i$  = length of the side of the matrix slab in cm, and  $R$  = distance to the releasing surface between the dissolved and dispersed drug in cm.

This equation predicts that release rates will decrease with time as the distance  $R$  increases.

An approach to achieving near constant release rates was then hypothesized by altering the matrix geometry that restricted the releasing surface to a small aperture in the matrix (37). Figure 7 shows a cross section of a hemisphere-shaped matrix that is coated with an impermeable layer of polymer except for a small aperture on the top surface of the matrix.

This geometry restricts release to a small aperture on the surface of the polymer matrix. The increase in  $R$ , which in the slab matrix resulted in decreased release rates over time, now is compensated by an increase in the available

**Figure 43.6** Cross section of a one-sided releasing flat-slab matrix. A  $t = 0$  drug is evenly dispersed throughout the matrix. At some later time  $t$  the distance  $R$  to the releasing surface between the dissolved drug and the dispersed drug increases. Thus  $R$  increases with time and release rates decrease.

**Figure 43.7** Cross section of hemisphere-shaped matrix coated with an impermeable layer of polymer that restricts the release of drug to the aperture. Release rates are predicted to be constant when  $R \gg a_i$  hr. (Reprinted with permission from Harcourt Academic Press.)

drug for release. This geometry predicts that release rates will be near constant when  $R$  is much greater than  $a_i$ . The release rate for the hemisphere-shaped geometry is shown by

$$\frac{dQ}{dt} = 2\pi C_s D a_i \left( \frac{R}{R - a_i} \right)$$

where  $dQ/dt$  = release rate in mg/s,  $C_s$  = drug solubility in mg/mL,  $D$  = diffusion coefficient in  $\text{cm}^2/\text{s}$ ,  $a_i$  = inner aperture radius in cm, and  $R$  = distance of aperture surface to dispersed drug in cm.

### 3. Insulin Release from Coated Hemisphere Matrices

In vitro and in vivo studies demonstrated that indeed near-zero-order release rates are observed when a matrix is formed utilizing the hemisphere geometry (3,4). Matrices designed to release insulin at constant rates were fabricated by coating them with an impermeable layer of ethylene vinyl acetate copolymer and then opening an aperture on the top surface. A 30-gauge needle was inserted into the flat face of the matrix. The frozen matrix was then dipped for 1 second into a solution of pure ethylene vinyl acetate copolymer in methylene chloride. An aperture was drilled in the same location after removal of the needle. The in vitro release kinetics seen in Fig. 8 demonstrated that the cumulative percentage release of insulin from these hemispheric releasing matrices was directly proportional to time. Thus constant release rates in vitro were observed.

### 4. In Vivo Insulin Delivery

The same sodium insulin hemisphere matrices were implanted into streptozotocin induced diabetic rats (38). Figure 9 shows that plasma glucose concentrations among these animals were maintained in the normal range for greater than 3 months. Thus a constant release of insulin was observed both in vitro and in vivo (4,6).

**Figure 43.8** Cumulative percentage release of sodium insulin from an aperture restricted hemisphere matrix design compared to insulin release from an uncoated slab. The hemisphere matrix sustained insulin release at near constant rates of approximately 5 units per day. In contrast, the uncoated slabs released greater than 99% of the incorporated insulin in less than 4 days.

5. Diurnal Glucose Variations

Figure 10 shows the plasma glucose concentrations in normal rats and insulin matrix treated rats over a 26 hour period. It is evident that the control animals remained normoglycemic during the nocturnal time period when the rats are awake and feeding. In contrast, the insulin matrix

**Figure 43.9** Ethylene vinyl acetate copolymer matrix implants using a hemisphere geometry were implanted into 8 diabetic rats. Diabetes was induced by an intravenous injection of streptozotocin on day -9. The insulin matrices were surgically implanted on day 0. The data shows normalization of insulin release for over 100 days by a single implant. (From Refs. 4 and 6.) (Reproduced with permission from the American Diabetes Association.)

**Figure 43.10** Diurnal variation of plasma glucose is graphed over a 26 hour period for normal rats (■) and insulin hemisphere matrix treated diabetic rats (▲). The lights were off for the time period shown in the graph. The rats' feeding period occurred during this nocturnal time frame.

treated rats showed significant plasma glucose elevations during this time period. In this group, plasma glucose concentrations started out below the normal glucose concentrations. Then when the lights were turned off, and the feeding period began, plasma glucose levels rose and exceeded the concentrations of the normal control rats. This data demonstrated that the sustained release of a basal level of insulin from the polymer matrices was incapable of controlling plasma glucose in a completely physiologic manner. This example demonstrated the need to alter insulin delivery rates in response to metabolic changes.

Thus implantable insulin polymer matrices could be effective in delivering consistent basal insulin levels to diabetic rats. However, these implants could not increase insulin release rates in response to feeding periods. Therefore the demonstrated solubility dependent nature of insulin release from the ethylene vinyl acetate copolymer matrices encouraged further studies toward the development of a glucose responsive system.

6. Effect of pH on Insulin Release

The next series of experiments focused on studying the effect of pH on the release and solubility properties of insulin from the insulin polymer matrices. The following experiment was conducted in order to test the hypothesis that the release of insulin could be controlled by the pH of the release medium (4). In this experiment, crystalline zinc insulin loaded matrices were fabricated according to the procedures described previously. These matrices were 50%

by weight insulin sieved to a particle size less than 75  $\mu\text{m}$ . Nine matrices were released in pH 5.9 release medium containing 0.9% NaCl. The matrices released into this medium for 9 days. The release medium buffer was changed to one buffered at pH 7.4. The results of this experiment are shown in Fig. 11.

Figure 11 shows that during the first 9 days of release at pH 5.9, release rates were less than 20  $\mu\text{g/h}$ . However, upon switching the release media to pH 7.4, an immediate burst of insulin was observed. Release rates increased from 10  $\mu\text{g/h}$  to 90  $\mu\text{g/h}$ . During this burst, 13% of the originally incorporated insulin was suddenly released in a 6 hour period, whereas only 5.8% had been released over the previous 9 days. After this burst, release rates fell to 45  $\mu\text{g/h}$  over the next 3 days. This observation was further supported by the pH and solubility profile of crystalline zinc insulin.

### 7. Solubility Profile of Crystalline Zinc Insulin

Figure 12 shows that the aqueous solubility of zinc crystalline insulin is strongly affected by pH. The isoelectric point of this insulin form is approximately 5.3. At pH's above and below the isoelectric point of the protein, its solubility increases significantly. The observations in Fig. 11 show that increasing the pH of the release medium from 5.9 to 7.4 appeared to be a result of the increased dissolution of the insulin incorporated within the polymer matrix. This

**Figure 43.11** The graph shows the release rate of zinc insulin from ethylene vinyl acetate copolymer matrices over an 11.5 day period. The insulin loading was 50% by weight and the particle size of the insulin was less than 75  $\mu\text{m}$ . The first 9 days of release were carried out in pH 5.9 buffer. This buffer was replaced with a pH 7.4 buffered medium at day 9. At this time, a large increase in insulin release rate was observed.

**Figure 43.12** The solubility dependence of crystalline zinc insulin on pH. The graph shows that insulin solubility increases markedly at pH's above and below its isoelectric point of 5.3.

enabled the additional dissolved insulin to be released at much higher release rates.

## V. A GLUCOSE MEDIATED INSULIN DELIVERY IMPLANT

The observations that insulin release could be extended for months with the use of an implantable matrix, and that the release of insulin could be increased by changes in pH, gave rise to the possibility that a feedback controlled insulin delivery system could be developed. The key was to find a way to alter the microenvironmental pH of the polymer matrix in a manner that would produce a burst of insulin release such as the one seen in Fig. 10 in response to changes in glucose concentration. The approach used in these studies was to take advantage of the enzyme glucose oxidase that converts glucose to gluconic acid:

The glucose responsive system was realized by immobilizing glucose oxidase enzyme to sepharose beads, which were incorporated along with zinc insulin into the polymer matrix. When glucose in solution entered the insulin delivery system, gluconic acid was produced, causing a drop in the microenvironmental pH of the matrix. This fall in pH resulted in a rise in insulin solubility and consequently a rise in the insulin release rate from the matrix (39–41).

The following studies review how the observations of the sustained release of insulin from the polymer matrices and the pH dependent solubility properties of insulin were

combined to demonstrate a glucose responsive insulin delivery system.

## A. Methods

The methods and procedures for incorporating the immobilized glucose oxidase enzyme into the ethylene vinyl acetate sustained release matrix are outlined.

### 1. Immobilization of Glucose Oxidase

Glucose oxidase was immobilized to cross-linked sepharose CL-6B or 4B beads using the method of Kohn and Wilchek (42). The sepharose beads were suspended in deionized water, frozen at  $-20^{\circ}\text{C}$ , and lyophilized to yield a fluffy, pale-yellow-colored powder.

### 2. Polymer Matrix Preparation

Ethylene vinyl acetate copolymer matrices for the in vitro and the in vivo studies containing immobilized glucose oxidase and/or insulin were prepared according to published methods described previously. For these experiments the sepharose beads containing the immobilized glucose oxidase were incorporated into the polymer matrix with either regular crystalline zinc insulin or trilycine insulin. Trilycine insulin has an isoelectric point of 7.4 (43).

### 3. In Vitro Release Studies

A flow-through spectrophotometer system was used to examine continuously the feasibility of increasing the insulin release kinetics in response to a glucose stimulus in real time. An insulin loaded matrix with immobilized glucose oxidase was placed inside a filter holder. Distilled water, adjusted to pH 5.3 and containing a glucose concentration of 0 or 10 mg/mL, was delivered with a peristaltic pump past the samples into a 65  $\mu\text{L}$  flow cell of a spectrophotometer. The in vitro experiments were conducted at pH 5.3 as regular crystalline insulin was used in these in vitro experiments.

## B. Results

In vitro and in vivo studies confirm that insulin release can be increased in response to a glucose stimulus.

### 1. Solubility and pH Dependence of Trilycine Insulin

Figure 13 shows the pH solubility profile of trilycine insulin. For the proposed system to work in vivo, an insulin form with a pI at physiologic pH was necessary. In this way, production of gluconic acid by the glucose oxidase

**Figure 43.13** The solubility dependence of trilycine insulin on pH. The graph shows that insulin solubility increases markedly at pH's above and below its isoelectric point of 7.4. Trilycine insulin is appropriate for systems to be tested at physiologic pH.

enzyme would result in an increase in trilycine insulin's solubility. If regular crystalline insulin with a pI of 5.3 were used, one would predict that a decrease in insulin solubility would result, and release rates from the polymer matrix would decrease (see Fig. 12).

### 2. In Vitro Release of Insulin in Response to a Glucose Stimulus

The in vitro results in Fig. 14 demonstrate the kinetic response of the immobilized glucose oxidase-regular crystalline insulin-ethylene vinyl acetate copolymer matrices

**Figure 43.14** Glucose oxidase was immobilized to sepharose beads. The beads were then incorporated with insulin into an ethylene vinyl acetate copolymer matrix. This matrix was tested in a flow-through system. Each insulin peak was preceded by a 35 minute continuous glucose infusion at a concentration of 500 mg/dL through the flow-through apparatus, which monitored the insulin concentration spectrophotometrically. The influx of glucose resulted in a significant increase in insulin release from the polymer matrix.

to a change in glucose concentration. Flow-through release medium containing no glucose was pumped through the flow cell at a rate of 10 mL/hour to establish the baseline insulin release from the system. After the baseline insulin release rate was established, a 500-mg/dL solution of glucose was infused through the system. Peak insulin release from the matrix reached a maximum 35 minutes before the release medium was changed to one containing no glucose. Then the insulin concentrations decreased. Glucose infusion was alternated with nonglucose containing medium eight different times over a 3 hour period. Turning the glucose on and off was shown to stimulate repeatedly the release of insulin from the polymer matrix.

### 3. Refractory Time Interval

Figure 14 showed that each glucose infusion was characterized by a discrete burst of insulin release. The following experiments were conducted to test whether the glucose responsive matrix required a rest or refractory period for maximal response to repeated glucose challenges. The duration between successive glucose stimuli was varied, and the magnitude of the response was measured to determine the amplitude of insulin response. Figure 15 showed that increasing the time between glucose stimuli from 5 to 60 minutes resulted in increasingly greater insulin release from the matrix. Increasing the rest period in between glucose stimuli from 60 to 130 minutes did not result in increased insulin release from the matrix.

**Figure 43.15** The maximum response of the glucose oxidase insulin release is graphed as the concentration of insulin observed in the release media as a function of the time intervals between repeated glucose challenges applied to the insulin–glucose oxidase matrix. The data shows that increasing the time interval between glucose stimuli resulted in greater insulin release until a plateau was reached after a 60 minute interval. (Reproduced by permission from John Wiley & Sons.)

**Table 43.3** Weight Percent Composition of Insulin–Glucose Oxidase Matrices

Matrix No.	Sepharose-GO (wt%)	Sepharose (wt%)	Ethylene vinyl acetate copolymer (wt%)	Insulin (wt%)
1	0	29	48	23
2	9	20	48	23
3	20	0	48	23
4	29	0	48	23

Sepharose-GO matrices contained beads with immobilized glucose oxidase enzyme. Sepharose matrices contained no immobilized enzyme.

### 4. Effect of Glucose Oxidase Concentration

In the following experiment, the effect of increasing the glucose oxidase content on the concentration of insulin released was determined. Four different matrices were tested using increasing percentages of glucose oxidase immobilized sepharose beads in the matrix, as shown in Table 3.

Figure 16 shows that increasing the glucose oxidase concentration resulted in increasing insulin release from the matrix up to a matrix containing 20% by weight of glucose oxidase immobilized to sepharose. Twenty percent glucose oxidase–sepharose appeared to be the optimal content for maximal response to a glucose stimulus.

### C. In Vivo Study Methods

Sixteen female Sprague-Dawley rats weighing  $210 \pm 10$  g were used in this experiment. Diabetes was induced by

**Figure 43.16** The glucose oxidase–insulin response increases with increased glucose oxidase content in the matrix to a maximal response when the polymer matrix contained 20% by weight glucose oxidase. (Reproduced by permission from John Wiley & Sons.)

tail vein injection of streptozotocin (38). A glucose solution at a concentration of 2 M was infused through a catheter to these animals for 30 minutes. Blood samples for glucose and insulin analyses were collected from the tail vein. The glucose oxidase insulin matrices were implanted subcutaneously in each rat. Seven rats received matrices containing trylisine insulin and glucose oxidase-immobilized sepharose beads. Three rats received matrices containing regular insulin and glucose oxidase-immobilized sepharose beads. Three rats received matrices containing regular insulin alone. Three rats were used as diabetic controls with no implants.

### 1. In Vivo Results

The in vivo effect on serum insulin concentrations with this glucose responsive insulin-glucose oxidase matrix is shown in Fig. 17, in which the serum insulin concentrations (ng/mL) are plotted over time for the four groups of rats containing different insulin matrix implants into diabetic rats. The 2 M glucose infusion was begun 15 minutes into the experiment. The rats that received trylisine insulin-glucose oxidase matrices showed a 180% rise in serum insulin concentration that peaked 45 minutes into the experiment. There was a subsequent decrease in plasma insulin concentration 30 minutes after the initiation of the glucose infusion. Those rats that received regular insulin-glucose oxidase matrices exhibited a decrease in serum insulin concentration. Those rats that received matrices containing regular insulin but no glucose oxidase enzyme

**Figure 43.17** Serum insulin concentration is graphed as a function of time among the four treatment groups. 2 M glucose was infused at 15 minutes and was continued for the duration of the experiment. Key (■) trylisine insulin and immobilized glucose oxidase ( $n = 7$  rats); (▲) regular insulin and immobilized glucose oxidase ( $n = 3$  rats); (□) regular insulin and no enzyme ( $n = 3$  rats); (●) diabetic controls, no treatment ( $n = 3$  rats). (Reproduced by permission from John Wiley & Sons.)

or no insulin showed no change in serum insulin concentration. The diabetic control rats showed no change in serum insulin concentration. There was no effect observed in the plasma glucose concentrations in these rats (data not shown). All four groups of rats showed an increase of 500 to 600 mg/dL in plasma glucose in response to the 2 M glucose infusion. The diabetic controls began the experiment with a glucose concentration of 450 mg/dL and at 105 minutes had reached a glucose concentration of 1050 mg/dL. In contrast, the three groups of rats that had received insulin implants exhibited initial plasma glucose concentrations of 50 mg/dL. Their plasma glucose levels rose to 600 to 700 mg/dL in response to the glucose infusion. Normal controls also displayed similar increases in plasma glucose.

## VI. DISCUSSION

The experimental results described helped characterize the release of insulin from ethylene vinyl acetate copolymer matrices in response to glucose (40,41). Glucose oxidase was immobilized on sepharose beads that were incorporated along with one of two different insulin preparations into an ethylene vinyl acetate copolymer matrix. These two insulin preparations had different isoelectric points. The immobilized beads were fixed in the matrix and could not diffuse out of the matrix. Only the insulin could diffuse out of the matrix. The effect of an increase in glucose concentration within the matrix on the immobilized glucose oxidase was to lower the pH in the microenvironment of the matrix by the production of gluconic acid according to the following enzyme catalyzed reaction (44):

The production of gluconic acid caused a decrease in the microenvironmental pH of the matrix and a subsequent increase in the insulin release rates from the ethylene vinyl acetate copolymer matrix. The increased insulin release was a result of the accelerated dissolution and diffusion of the dry powdered insulin from the delivery system (4).

The solubility and dissolution of polypeptides or proteins like insulin is dependent on the pH of the aqueous environment. Proteins and peptides exhibit their lowest solubility at the pI where there is no net charge on the peptide (17). Thus the drug solubility is one important parameter that can be used to alter release rates of drugs from diffusion controlled (36) and dissolution controlled (45) release matrix systems. This system responded in vitro repeatedly, consistently, and in real time to challenges with glucose solutions (Fig. 14).

The insulin used in the in vitro experiments had a pI of

5.3. Peak insulin levels occurred 35 minutes after a 500 mg/mL glucose solution was introduced into the flow-through system. Repeated glucose stimuli were shown to induce a degree of refractory behavior (Fig. 15). It was determined that at least 60 minutes were required between glucose stimuli to observe a maximal response. The rise to a peak in insulin concentration and the ensuing fall to baseline levels following a glucose stimulus (Fig. 14) could be attributed to several factors: (1) the inability of the matrix to secrete insulin because soluble and undissolved insulin might be depleted in the vicinity of the immobilized glucose oxidase; (2) a reequilibration of the pH in the microenvironment of the matrix due to the buffering capacity of dissolved insulin in the pores of the matrix; (3) a decrease in oxygen tension that is necessary to maintain the enzymatic reaction; or (4) the inability of the glucose oxidase enzyme to retain a pH gradient. The maximal system response observed after a 60 minute rest period also suggests that there is only a finite quantity of insulin available for release after any glucose stimulus. This quantity of insulin could be localized near or within the sepharose beads or precipitated along the empty pores of the matrix.

The refractory period may represent the time necessary for the local areas of insulin depletion to be replenished before the next glucose stimulus, which is presumably related to the dissolution rate of insulin, the diffusion coefficient of insulin, and the porosity or the tortuosity of the matrix. A similar finite insulin release observed *in vivo* is shown in Fig. 16. These experiments also supported previous observations that the bioactivity of insulin is preserved in the ethylene vinyl acetate copolymer matrix (5,6). The absence of any effect on the plasma glucose concentrations in the diabetic test animals can be attributed to the large excess of glucose infused into the animals. The high concentration of glucose in these initial studies was used to ensure that the subcutaneously implanted insulin delivery device would be exposed to a sufficient glucose concentration to obtain an insulin response. One can calculate that the quantity of glucose infused in the experiments described here would result in an instantaneous plasma glucose concentration of 1800 mg/dL when distributed in the extracellular fluid compartment of a 200 gram rat if there is no intracellular glucose uptake. Thus it is not surprising that little or no effect on plasma glucose was observed in any experimental animal group. Furthermore, similar large increases in plasma glucose concentrations were also observed in normal control rats. Thus even a physiologically intact pancreas could not respond to the excess glucose load presented to the rats during the time period described in this study.

A maximal insulin response was observed when 20% (w/w) of glucose oxidase immobilized on sepharose beads

was incorporated into the matrix (Fig. 16). The observation that there is an apparent optimal immobilized glucose oxidase concentration may be due to steric hindrance of glucose diffusion into the sepharose beads. A threefold increase in serum insulin concentrations was observed for those rats that received trilycine insulin–glucose oxidase implants. The dependence of regular and trilycine insulin solubility on pH is shown in Fig. 13. These results are consistent with a fall in the microenvironmental pH of the matrix and a rise in trilycine solubility and dissolution rate within the matrix. Trilycine insulin has a pI of 7.4. Thus when the glucose oxidase matrix system operates at physiologic pH, the decrease in microenvironmental pH of the matrix resulted in an increase in insulin solubility and consequently in an increase in insulin release. Regular insulin has a pI of 5.3. Thus the lowering of the pH below pH 5.3 resulted in increased release rates of insulin from the matrix; the matrix was in a release media at pH 5.3. At physiologic pH, those rats treated with regular insulin–glucose oxidase implants experienced a decrease in serum insulin concentrations in response to glucose infusion (Fig. 17). Rats with polymers containing regular insulin but no enzyme, and with no insulin or no enzyme, did not show a serum insulin response to glucose infusion.

## VII. CONCLUSIONS

Indeed, other approaches have been used to develop glucose responsive insulin delivery systems, including microencapsulated islets (46), a lectin bound insulin in which glucose displaces a carbohydrate, such as maltose, to release the insulin (47), and membranes that alter their permeabilities in response to glucose (48). In another system, insulin was esterified with methanol and connected to glucose oxidase with a disulfide compound, 5,5'-dithiobis(2-nitrobenzoic acid). Then adding glucose to an aqueous solution containing the hybrid enzyme resulted in the release of modified insulin (49).

This review has summarized the scientific observations and research efforts that have enabled the development of an alternate approach to achieving a glucose responsive polymeric insulin delivery system. The physiological role of insulin in the treatment of diabetes mellitus was discussed. Scientific and historical efforts resulted in the development of modified insulin forms that are either fast acting or possess extended biological half-lives. The role of zinc in determining insulin's solubility properties proved to be a critical parameter in allowing the long-term release of insulin from ethylene vinyl acetate copolymer matrices. Finally, the solubility properties of insulin were exploited in order to demonstrate a glucose responsive

feedback controlled insulin delivery system. Additional studies are necessary to determine if an optimized system could control the diurnal fluctuations in plasma glucose concentration in diabetic animals. In addition, the in vivo operating duration may be limited by the half-life of the glucose oxidase and the degree of encapsulation of the polymer implant over time (50). Others have observed several months' glucose oxidase activity in implantable glucose biosensors (51). The ability of this system to demonstrate a blood-glucose controlling effect in future experiments might be observed by simply increasing the surface area of the matrix so that more insulin is released in response to a change in glucose concentration. Immobilizing the enzyme on the polymer backbone instead of onto the sepharose beads might also increase the sensitivity of the system and might allow an increased payload of insulin in the matrix with the elimination of the sepharose beads. Other pH-sensitive insulins with greater solubilities might be another possible approach.

The mechanism of an increase in dissolution rate of protein or polypeptide drugs in the microenvironment of a polymer matrix may be a model for use with other pH-sensitive proteins having an appropriate triggering enzyme and substrate. The further development of this feedback controlled release system may find application with the variety of new genetically engineered proteins that are already approved for use or among those that are being researched.

### I. INTRODUCTION

Drug therapy in general has improved greatly during the last century. However, although it is successful in many cases, drug treatment is often hampered by serious side effects. This can be explained in that many drugs do not exert their action at the desired site of action exclusively, but either can perturb physiological processes in other tissues/organs or can produce severe toxicity as well. The occurrence of drug adverse effects can greatly affect the patient's therapeutic compliance.

To solve the problems related to side effects and create more selectively acting drugs, it was already stated in 1906 by Ehrlich that specific targeting of drugs may result in an increased drug accumulation in the cells to be aimed at, relative to nontarget cells. This can lead to a reduction of the required drug dosage and less side effects or toxicity (1). A second application of drug targeting technology lies in the development of pharmacological tools to obtain more insight in the cellular aspects of pathophysiological processes.

The kidneys constitute an important target, since pharmacotherapy of renal disorders is frequently hampered by side effects, e.g., cardiovascular [“Angiotensin I Converting Enzyme” (ACE) inhibitors] or gastrointestinal (nonsteroidal anti-inflammatory drugs, NSAIDs) adverse effects. Although the kidneys receive approximately 25

percent of the cardiac output, and although many drugs are more or less concentrated in the kidney, systemic concentrations are usually so high that extrarenal side effects cannot be prevented.

In this chapter an introduction to renal anatomy and physiology will be given in order to provide a rationale for renal drug targeting. Subsequently, we will focus on the renal targeting strategies applied in our laboratories, considering potentials and limitations of renal targeting with low-molecular-weight proteins (LMWPs) and, in particular, with lysozyme as the drug carrier. The chemical features of LMWP conjugates will be described using ACE inhibitors as model drugs. Furthermore, a number of targetable drugs that can affect kidney functions will be discussed. Finally, we will present data that demonstrate the effectiveness of the drug–lysozyme conjugates. For an extensive overview of various aspects of renal targeting strategies, we recommend other comprehensive reviews (2,3).

### II. THE KIDNEY AS THE TARGET ORGAN

#### A. Anatomy and Functions of the Kidney

The kidneys play a major part in the regulation of the volume and composition of the body fluids through the excretion and retention of a large variety of solutes. It is also an eliminating organ for the excretion of several endoge-

nous and exogenous organic substances. To entertain this function, the kidney exhibits a specific anatomical structure. Each kidney contains several millions of nephrons, the functional urine-producing units in this organ. The nephron consists of glomerular and tubular parts. The latter can be subdivided in the proximal convoluted tubule, the proximal straight tubule, Henle's loop, the distal convoluted tubule, and the collecting duct.

In every nephron blood is supplied to the glomerulus via the afferent arteriole. In the glomerulus, a portion of the blood (approximately 20%) is filtered through the negatively charged glomerular basement membrane. The remaining blood flows through the efferent arterioles and extends in a close network of arterial and venous microcapillaries, the so-called peritubular capillaries, providing a close connection between the blood circulation and the tubular cells.

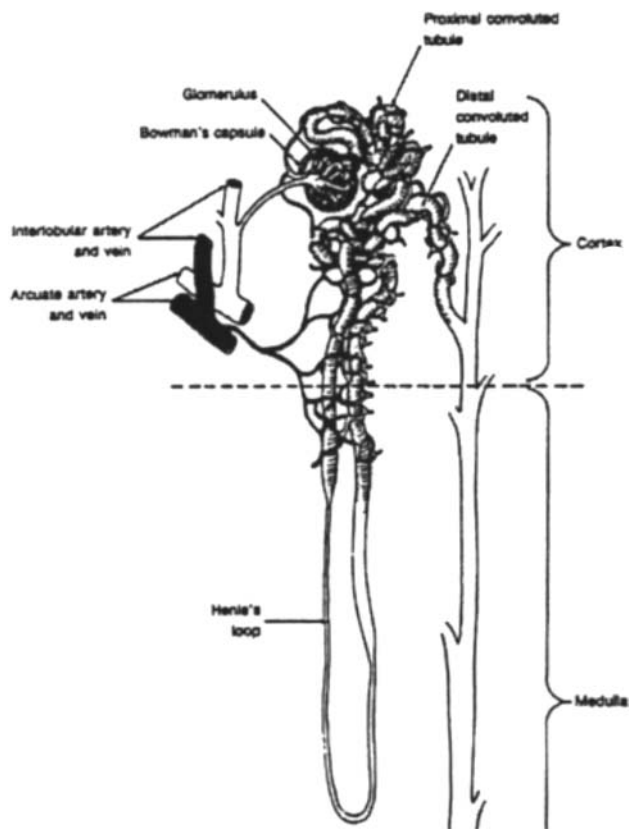

Macroscopically, the kidney can be divided into three major parts. The outer shell, the cortex, consists mainly of glomeruli and the proximal and distal tubuli; it receives more than 80% of the arterial blood delivered to the kidney. The inner part, the medulla, contains predominantly Henle's loops and collecting ducts of several nephrons. Finally, in the papilla, all of the collecting ducts come together and urine is excreted into the urether. A schematic overview of the anatomical structure of the kidney is depicted in Fig. 1.

In the context of drug targeting, the kidney offers several favorable characteristics: a relatively high blood flow, an efficient filtration system, a spectrum of tubular transport systems for inorganic and organic compounds, as well as the presence of a versatile metabolic system.

### B. Blood Flow and Filtration: The Glomerulus

In the glomerulus, the connecting tissue of Bowman's capsule that consists predominantly of endothelial cells, glomerular epithelial cells, and mesangial cells surrounds a capillary network of afferent and efferent arterioles. In the glomerulus, blood components with a size up to approximately 67 kDa can be filtered through the glomerular basement membrane. The latter contains predominantly negatively charged glycoproteins. Consequently, under normal physiological conditions, small molecules will be filtered, whereas large molecules (blood cells, immunoglobulins, and relatively large plasma proteins) will remain in the circulation. Net charge, size, and rigidity of the molecular structure of proteins are important factors in determining the sieving process (4).

In the glomerulus, the mesangial cells represent a suitable target for drug delivery. Not only do these cells play an essential role in the development and progression of

**Figure 44.1** The functional nephron with representative blood supply in the cortical region.

both acute and chronic inflammatory processes, they can also be reached quite easily since a continuous flow of blood plasma flows along the mesangial cells through mesangial fenestrations (5).

### C. Transport Systems: The Tubules

After filtration in the glomerulus, the preurine flows along the proximal tubular cells, a cell group specializing in the transport of sodium, water, glucose, and a variety of other molecules. In the tubule, a monolayer of epithelial cells separates the tubular lumen from the blood. In the tubular cells, three different transport mechanisms can be distinguished, both located at the basolateral membrane and the apical brush border membrane, facing the blood site and the tubular lumen, respectively. Apart from simple passive diffusion across the tubular membrane, the active transport of compounds into and out of the tubular cells is mediated by carrier proteins. In addition, endocytosis and transcytosis occurs at both poles of these cells (6,7). At least three categories of saturable and energy dependent carrier

systems exist in the tubular membranes: for organic cations, for organic anions, and for uncharged compounds (8). In fact, multiple carrier systems contribute to each of these categories. Other basolateral secretory transport systems include the  $\gamma$ -glutamyl transport system and those for glycoproteins (9,10). Finally, certain proteins (insulin, EGF) seem to be transcytosed across the tubular cells via receptor-mediated uptake (11).

On the other hand, valuable endogenous compounds, though freely filtered in the glomeruli, only appear in the urine to a small extent. These compounds are "rescued" during passage through the tubuli. These retention mechanisms consist of a variety of, mostly, carrier-mediated processes at the luminal site of the tubular cell. Substances transported by reabsorptive systems include sugars (12), amino acids (13), dipeptides (14), urate (15), folate (16), nucleosides (17), and certain proteins (18). The tubular reabsorption of low-molecular-weight proteins (LMWPs) as a crucial mechanism in relation to renal drug delivery will be discussed separately (see Section IV.A).

The proximal tubular cell also plays a central role in the regulation of inflammatory processes in the kidney. A wide variety of noxious triggers have been identified, including cytokines, growth factors, hypoxia, ischemia, nephron damage, and luminal obstruction. Finally, tubular protein overload as a result of glomerular proteinuria and high tubular delivery of glucose in the diabetic state is considered to be an important factor causing tubular activation (19,20). The proximal tubular cell therefore is a central target for drug delivery (21).

#### D. The Metabolic Function of the Kidneys

The kidneys are involved in the metabolism of many endogenous and exogenous substances. These compounds are concentrated in the kidney before being eliminated via the urine. Therefore the driving force for metabolic conversion can be high. Within the kidney, various enzymes are involved in the biotransformation of many different compounds. For metabolism of exogenous compounds such as drugs, but also for some endogenous substrates, enzymes involved in both phase I and phase II metabolic routes are present in the kidney, e.g., cytochrome P450, cytochrome b5, glucuronyl transferase, and sulfotransferase (22–26). In addition, renal tubular cells contain various proteases for the degradation of proteins and oligopeptides. These enzymes are either located at the brush border membrane or can be found in the smooth endoplasmic reticulum and the lysosomes of these cells (27). Degradative enzymes include a variety of endopeptidases, exopeptidases, and esterases (28–32). Due to this versatile metabolic apparatus, the kidneys are also able to degrade macromolecular drug

carriers and can regenerate covalently coupled drugs within intracellular compartments, like the lysosomes and the cytoplasm.

### III. LOW-MOLECULAR-WEIGHT PROTEINS AS CARRIERS FOR RENAL DRUG TARGETING

#### A. Renal Handling of Low-Molecular-Weight Proteins

Low-molecular-weight proteins (LMWPs) are small proteins with molecular weights up to approximately 25,000 Da. Their application for renal drug targeting was considered since it was demonstrated that radiolabeled LMWPs accumulated specifically in the kidney (33). Autoradiography of the kidney after administration of labeled probes revealed a specific accumulation within the renal proximal tubular cells. Besides in the kidney, LMWPs do not seem to accumulate to a large extent in tissues elsewhere in the body (Fig. 2). Comparison of the kinetic features of different LMWPs revealed that all of the injected proteins are rapidly cleared from the circulation by the kidney leading to temporary accumulation in this organ. The fraction of the LMWPs that is taken up by the kidney in such studies ranges from 40 to 80% of the injected dose (34–36). In some studies these values are inherently underestimations, since part of the endocytosed protein was degraded during the study, followed by transport of radiolabel out of the kidney.

Within the kidney, the LMWPs are freely filtered in the glomerulus and subsequently reabsorbed by the proximal tubular cells through receptor-mediated endocytosis (37). Christensen et al. have identified the megalin/gp 330 receptor to be responsible for this tubular uptake (38). After endocytosis, an endocytic vesicle (endosome) is formed that is subsequently transported to the lysosomes. The

**Figure 44.2** Gamma-camera imaging after an intravenous injection of a <sup>123</sup>I-radiolabeled LMWP in the rat, showing the predominant uptake of the LMWP by the kidneys.

LMWP is degraded intralysosomally into small peptides and free amino acids by a variety of proteolytic enzymes, such as proteases and hydrolases (39–41).

### B. Low-Molecular-Weight Proteins as Renal Specific Drug Carriers

We considered the possibility that through coupling a drug to an LMWP, an inactive “prodrug” could be formed that could potentially deliver coupled drugs to the kidney. The tissue distribution of the drug could thereby be manipulated in favor of the kidney. This in fact results from the overruling of the physicochemical properties of the linked drug by those of the LMWP. In the kidney, the drug–LMWP conjugate follows the same pathway as endogenous LMWPs and ends up in the lysosomes of the proximal tubular cells. In the lysosomes, the drug is then released from the protein, either by proteolytic or hydrolytic actions, and is excreted from the lysosomes into the cytoplasm of the cells. Subsequently, the released drug can act either within the tubular cell or further downstream after excretion into the urine or back into the renal venous circulation (42). Figure 3 gives a schematic representation of the renal handling of an LMWP–drug conjugate.

A number of essential variables in this concept require closer examination. First, the LMWP carrier must contain

**Figure 44.3** Schematic representation of the concept of renal drug targeting with LMWPs. After filtration in the glomerulus, the conjugate is reabsorbed by the proximal tubular cell and degraded in the lysosomes. The free drug diffuses out of the lysosomes and can diffuse out of the tubular cell at the luminal side into the urine, or at the basolateral side into the renal interstitium. From the interstitium the drug can diffuse into the blood vessel or back into the proximal tubule. For some drugs the transport out of the proximal tubular cell might also be mediated by carrier proteins.

functional groups allowing drug attachment. The chemistry of drug–LMWP conjugates will be described in more detail in Section IV.C, using ACE inhibitors as the model drugs. Second, the physicochemical properties of the LMWP should largely remain intact to ensure tubular uptake and prevent loss of intact conjugate into the urine. Third, the drug conjugate complex must be stable within the circulation to prevent premature systemic side effects of the free drug. Finally, after successful tubular uptake, the drug must be released in the catabolically active lysosomes. For the individual drug targeting constructs, these aspects will be addressed in more detail in Section V.

In addition, the ultimate effectiveness of the targeted drug is also determined by the local redistribution of the drug after endorenal release from the carrier. Transport systems or simple passive reabsorption, described in detail in Section II.B, can relocate the drug into either the primary urine or the systemic circulation. Reabsorption processes therefore may impose limits on the cellular selectivity of drugs released endorenally.

### C. Potentials and Limitations of Low-Molecular-Weight Proteins as Renal Drug Carriers

The processes responsible for the selective tubular reabsorption of LMWP–drug conjugates have been summarized in the previous section. However, to be able to determine the *in vivo* effectiveness of such constructs, the LMWP conjugates have to be administered for a longer period of time in therapeutically appropriate dosages. The required therapeutic drug dosage is governed by the pharmacokinetic properties of the drug targeting preparations as well as the pharmacokinetic and pharmacodynamic features of the targeted drug.

Pharmacokinetic aspects of the free drug are of importance, in particular after the release from the protein carrier in the desired target cell. First, an effective concentration of the drug will only be reached if the drug is retained at the target site after release at least to some extent. This retention is dominated by the physicochemical properties of the drug (diffusion out of the target cell) and its tendency to act as a substrate for excreting carrier proteins (see Sections II.C and III.B). Since the kidney is an organ with a wide variety of carrier systems specialized to transport compounds both into the cell and back into the systemic circulation, it is obvious that these processes will influence renal drug retention. Second, the targeted drug may be inactivated due to metabolizing enzymes, thus influencing the cellular availability and duration of action of the drug. The metabolizing capacity of the kidney for the targeted drug has been described in Section II.D.

The therapeutic response is, apart from delivery to the desired cell type, determined by the intrinsic activity of the drug, often expressed as the concentration in which 50% of the maximal effect is reached ( $EC_{50}$ ). For a drug with a low  $EC_{50}$  relatively long-lasting therapeutic levels have to be attained at the target site. Furthermore, this intrinsic potency of the drug, together with the number of available coupling sites in the carrier molecule, determines and therefore also influences the necessary amount of carrier protein. Thus both pharmacokinetic and pharmacodynamic parameters have to be taken into account when designing an LMWP–drug conjugate.

For the attachment of drugs, the amino groups of 7 lysine moieties are available in the lysozyme molecule for drug coupling. However, these amino acids do also contribute to the solubility of the LMWP and may influence the interaction with the megalin receptor that mediates tubular reabsorption (39,43,44). Therefore only a limited number of amino groups can be substituted to maintain most of the physicochemical properties of the lysozyme molecule. Kok et al. studied the effect of charge of the carrier protein on the renal accumulation of a lysozyme conjugate using fluorescein isothiocyanate (FITC) as a model drug (45). They showed that  $45 \pm 4\%$  of a single dose of  $0.33 \text{ mg} \cdot \text{kg}^{-1}$  negatively charged FITC–lysozyme was excreted intactly in the urine, versus  $29 \pm 4\%$  of non-derivatized FITC–lysozyme ( $P < 0.05$ ). After introduction of extra positive charge in the FITC–lysozyme preparation, the conjugate seemed to be completely reabsorbed, since it was not excreted into the urine intactly. However, an organ distribution study with the latter  $^{125}\text{I}$ -radioiodinated conjugate showed that only  $12.0 \pm 0.1\%$  of the dose accumulated in the kidney. Apparently, the distribution was no longer selective for the kidney and indeed significant amounts were found in the liver ( $53 \pm 1\%$ ) and the spleen ( $5 \pm 2\%$ ). Consequently, a proper balance of positive and negative charges has to be found for optimal renal delivery.

Drug therapy with LMWP conjugates may require the administration of relatively large amounts of lysozyme for a longer period of time. It should be noted, however, that Cojocel et al. showed that infusion of relatively high dosages of lysozyme might lead to a dose dependent and time dependent decrease of tubular reabsorption, as well as to adverse effects on systemic blood pressure and renal function (46,47). Therefore we have recently investigated the maximal amount of lysozyme that can be administered with an efficient tubular reabsorption and minimal effect on blood pressure and renal function. We compared continuous infusion of different dosages of lysozyme with single-dose injections in unrestrained rats. These studies showed that continuous low-dose infusion of lysozyme is prefera-

ble over single high-dose injections, since infusion did not affect systemic blood pressure in dosages up to  $1000 \text{ mg} \cdot \text{kg}^{-1} \cdot 6\text{h}^{-1}$ . Additionally, total urinary lysozyme excretion was sixfold lower after infusion of lysozyme. However, infusion of the LMWP could not entirely prevent the loss of intact lysozyme into the urine. About 8% of the dose was renally excreted after  $100 \text{ mg lysozyme} \cdot \text{kg}^{-1} \cdot 6\text{h}^{-1}$ , while up to 33% of the dose was lost in the urine following  $1000 \text{ mg lysozyme} \cdot \text{kg}^{-1} \cdot 6\text{h}^{-1}$ . Dosages exceeding  $100 \text{ mg} \cdot \text{kg}^{-1}$  also produced a decrease of renal blood flow and glomerular filtration rate. Therefore the amount of lysozyme that can be safely administered is limited. Using drugs with a high intrinsic activity (low  $EC_{50}$ ) may therefore limit the required dose of lysozyme and may prevent the occurrence of unwanted side effects on renal hemodynamics (R. F. G. Haverdings et al., manuscript in preparation).

Obvious disadvantages of the LMWP strategy for the treatment of chronic renal disease are the requirement of parenteral administration and the possible immunogenicity of the drug conjugate. With respect to alternative administration routes, it is encouraging that technologies for parenteral administration are being developed. This includes pulmonary spray technology and programmable wearable infusion pumps. Also it should be realized that parenteral dosing of proteins is not uncommon, since insulin dependent diabetic patients perform daily administration via subcutaneous administration for extensive periods. If immunogenicity is a serious limitation, in particular for chronic treatment, alternatively a synthetic polymer may be used as a “reabsorptive” carrier. For short-term clinical interventions, aiming to protect the kidney during acute reperfusion or preventing allograft rejection after transplantation, the prerequisite of parenteral administration does not constitute a serious limitation anyway.

#### D. How Chemically to Link an ACE Inhibitor to a Low-Molecular-Weight Protein

The characteristics of the bond between drug and protein are very important for the stability of the conjugate, but also for a proper release of the parent drug after the conjugate has accumulated in the target organ. Ideally, the bond between drug and protein should be stable while the conjugate distributes throughout the body, but at the same time it should be easily degradable after the drug has reached its target site. Drug–protein conjugates, like those that have been designed for renal drug delivery, are accumulated in the target organ by adsorptive endocytosis and followed by transport to the lysosomes (48). This cellular compartment contains a variety of proteases and esterases that can be instrumental in the enzymatic degradation of

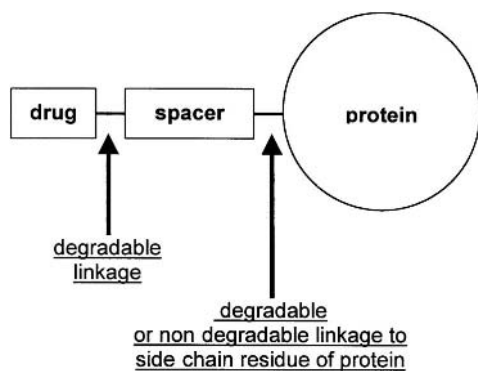

drug–protein conjugates. The regeneration of the parent drug can be ensured by the insertion of a spacer molecule between drug and protein (Fig. 4). Such a spacer moiety can provide a linkage that can be degraded either enzymatically or chemically under, for instance, influence of the acidic pH of the lysosomes (49).

In the past years, many structurally different ACE inhibitors have been developed. Figure 5 gives an overview of the chemical structures of currently available ACE inhibitors (50). Since these drugs have a similar pharmacological action, the most suitable drug for a particular conjugation strategy can be selected. Table 1 summarizes the coupling strategies that are discussed in this chapter. This table also gives examples of ACE inhibitors that can be coupled via the various strategies, and the type of bond that is formed between the drug and the linker. The strategies are based on well-known synthetic procedures that have been used for the preparation of drug–protein conjugates. They will be discussed in relation to the specific functional groups that are used for the conjugation process. Some functional groups are present in the structures of all the listed ACE inhibitors, such as the carboxylic acid group; other functional groups are unique for specific agents in this therapeutic class.

### 1. Conjugation via the Carboxylic Acid Group

The first ACE inhibitors, captopril, enalapril, and lisinopril, were designed as analogues of peptides found in the venom of a Brazilian viper (51). These drugs all contain a proline carboxylic acid group. In the more recently developed ACE inhibitors, like quinapril and cilazapril, the proline carboxyl group was replaced by conformationally restricted analogues (52). Since lysosomal proteases should

**Figure 44.4** Schematic representation of a drug–spacer–protein conjugate. The bond between drug and spacer must be biodegradable. The bond between spacer and protein might be either nondegradable or degradable.

be able to degrade bonds with a peptidic character, the ACE inhibitors with a proline carboxylic acid group can be coupled bioreversibly via a peptide spacer. We propose two types of peptide spacers that can be tailored to different classes of peptidases (Fig. 6). In both spacer concepts, the proline carboxylic acid group is coupled via a natural peptide bond to the  $\alpha$ -amino group of the spacer, thus forming a bond that should be cleavable by peptidases.

The first spacer consists of a specific sequence of amino acids that is a substrate for a lysosomal endopeptidase, for instance one of the cathepsins. The drug is coupled to the N-terminal amino group of the spacer, while the spacer itself is conjugated at its C-terminal carboxyl group to the carrier protein. The release of the parent drug can be the result from a single-step degradation of the prolyl–spacer bond (Fig. 7A) or via the formation of a drug–amino acid intermediate product, which is further degraded to the parent drug by a carboxypeptidase (Fig. 7B). Several peptide sequences have been reported as endopeptidase sensitive spacers (Table 2). Of these sequences, the spacers that have been used for the cytostatic drug methotrexate (MTX), which also has peptidic carboxyl groups, are attractive candidates for the conjugation of an ACE inhibitor to a LMWP carrier. The other peptide spacers in Table 2 have been optimized for the coupling of drug molecules that contain a primary amino group, for instance the cytostatic drug doxorubicin. Lysosomal degradation studies of those spacers with isolated lysosomal endopeptidases, like cathepsin B, D, and L, showed that these enzymes cleave the peptide spacer gly-phe-leu-gly either next to the drug moiety or between phe and leu, followed by removal of the remaining peptide fragment by an aminopeptidase (53,54). If the gly-phe-leu-gly spacer is used for the proline carboxyl drugs, the release of the parent drug is likely to result from the two-step degradation route as depicted in Fig. 7B.

The other type of peptide spacers that we propose for conjugation of an ACE inhibitor via the proline carboxyl group are the exopeptidase sensitive spacers. Figure 8 shows how the drug is coupled to the free  $\alpha$ -amino group of the spacer, which is subsequently linked to the LMWP carrier via its side chain functional group. Since the spacer has a free  $\alpha$ -carboxyl group, it should be degradable by lysosomal carboxypeptidases (Fig. 8A). We tested the carboxypeptidase sensitive spacer concept by incubating the model compound di(Z-pro)-lysine with lysosomal enzymes. This conjugate was degraded to Z-proline and Z-pro- $\epsilon$ -lysine, which proves that carboxypeptidases are indeed capable of digesting peptides in which the side chain group is modified. Interesting candidates for this spacer concept are amino acids with a reactive side chain, for instance the thiol-containing amino acid cysteine. After attachment of the drug to the amino group of this spacer, the

The bond between spacer and protein can undergo acid-catalyzed degradation. In a second degradation step, the drug is released from the spacer by exopeptidase-mediated degradation.

conjugation of the spacer to the LMWP can be performed under mild conditions by reacting the thiol group of cysteine with a LMWP that has been thiolated with N-succinimidyl 3-(2-pyryldithio) propionate (SPDP) or modified with maleimido groups with m-maleidobenzoyl-N-hydroxysuccinimide ester (MBS). A similar conjugation procedure, using cystamine as the linker, has been described for the coupling of MTX and several peptides to macromolecules (55–57).

Another amino acid that can be used as an amino acid spacer is aspartic acid, which has been reported as an acid sensitive spacer for the conjugation of doxorubicin (58). This spacer might undergo enzymatic degradation, as well as acid-catalyzed degradation of the spacer–LMWP bond followed by enzymatic degradation of the drug–spacer bond (Fig. 8B).

A major drawback of the conjugation of a proline-containing ACE inhibitor via its carboxylic acid group is the formation of undesired condensation products. We considered enalapril as the representative example of this class of ACE inhibitors, since this drug does not have functional groups that have to be protected during the conjugation reaction. However, the activated proline carboxylic acid group of enalapril can react with the secondary amino group of the ACE inhibitor structure itself, resulting in the formation of a piperazinedione internal condensation product (R. J. Kok, unpublished data) (Fig. 9). This type of condensation products has also been described as one of the few metabolic products of enalapril (59). The cyclization reaction can also occur with lisinopril, but not with captopril. However, the free thiol group of captopril can interfere with the conjugation reactions at the carboxyl group and therefore it needs to be protected during the synthesis of the conjugate. Since a conjugate with a free thiol group can induce an immunogenic response, thiol group protection is also preferable *in vivo* (60). This could be achieved by protecting the thiol group as a thioester, since such a group is metabolized *in vivo* to the free thiol group, as was shown for the ACE inhibitor prodrug alacepril (Fig. 5) (61). The preparation of a captopril-protein conjugate

**Figure 44.9** Internal condensation reaction of enalapril. The activated carboxylic acid group is attacked by the secondary amino group of the ACE inhibitor.

could be started with alacepril, in which case the prodrug moiety at the carboxylic acid group can be regarded as the first amino acid of the peptide spacer.

In order to test whether the amino acid spacer could also be useful for drugs with carboxyl groups that have nonpeptide characteristics, we synthesized the model compound cilazapril–phenylalanine. Degradation experiments with lysosomal proteases indicated that this nonpeptide conjugate could not be cleaved by proteases (R. J. Kok et al., unpublished data). Similar lysosomal degradation experiments were performed with amino acid conjugates of naproxen, an anti-inflammatory drug with a nonpeptide carboxylic acid group (62). All of the model compounds proved to be resistant to lysosomal degradation. The use of an  $\alpha$ -hydroxy acid, instead of an  $\alpha$ -amino acid, as spacer proved to be a feasible solution for obtaining a biodegradable conjugate of naproxen (62,63). Such a spacer, of which L-lactic acid is a typical example, contains a hydroxyl group that can be used for the conjugation of the drug via an ester bond, and a carboxyl group that is used for the conjugation of the spacer to the protein (Fig. 10). The naproxen–L-lactic conjugate was sufficiently stable for renal drug delivery. Lysosomal degradation experiments with this conjugate showed that the lysosomal degradation of the ester bond was even slower than the degradation of the carrier backbone itself (63).

Although ester bonds have been used frequently for the preparation of small prodrugs, they have not been frequently employed as biodegradable spacers in macromolecular drug conjugates (64). A disadvantage of the use of an ester bond is its relative instability in the circulation due to degradation by plasma esterases (65).

## 2. Conjugation via the Amino Group: Lisinopril

The ACE inhibitor lisinopril contains a free primary amino group that has similar characteristics to the lysine side chain. Lysosomal degradation experiments have demonstrated the inability of lysosomal enzymes to degrade amide bonds that are formed with such an amino group.

**Figure 44.10** Concept of an esterase sensitive spacer: L-lactic acid spacer. After conjugation of the drug to the hydroxyl group of L-lactic acid, the spacer is coupled to a lysine side chain by activation of the carboxylic acid group.

Therefore we propose the use of an acid sensitive spacer instead of aiming at enzymatic degradation for conjugated lisinopril via its amino group. Acid sensitive spacers are stable at neutral pH but undergo autocatalytic degradation at the acidic pH of the lysosomal compartment. Acid sensitive spacers that have been used for drug delivery are depicted in Fig. 11. Of these spacers, the *cis*-aconitic anhydride (*cis*-ACO) spacer has been used frequently for the conjugation of doxorubicin to different macromolecular carriers (66–70). This spacer is commonly reacted with the amino group of the drug, followed by an 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDCI) catalyzed conjugation of one of the *cis*-carboxyl groups with an amino group of the carrier. If this *cis*-ACO spacer is applied for the conjugation of lisinopril, the carboxyl groups of the drug itself should be protected beforehand, for instance by esterification with ethanol. The above-described conjugation route is depicted in Fig. 12 and has recently been carried out (R. J. Kok et al., manuscript in preparation).

The extra protection of the carboxylic acid groups of lisinopril is not necessary when one of the other *cis*-diacid spacers is used, since the conjugation reaction of those spacers to the carrier protein is aimed at functional groups that are not present in lisinopril. Another disadvantage of the *cis*-ACO linker is that the conjugation of the spacer to the LMWP will not take place exclusively at the  $\gamma$ -carboxyl group but also at one of the *cis*-carboxyl groups (66). This results in the abolishment of acid sensitivity in some of the conjugated drug molecules. Therefore we also aim at

**Figure 44.11** Acid sensitive spacers. P denotes the attachment site for the protein, D denotes the drug attachment site. (1) *cis*-ACO (66); (2) 4-(iodoacetamide)-1-cyclohexene-1,2-dicarboxylic acid (139); (3) L-aspartic acid (58); (4) *cis*-ribofuranomaleic acid (140); (5) 3-substituted 2-N-(S-acetyl-thioacetyl)amino maleic anhydride (141).

**Figure 44.12** Conjugation of lisinopril via the *cis*-ACO acid sensitive spacer. In the first reaction step, the carboxylic acid groups of lisinopril are esterified with ethanol. Following conjugation of *cis*-ACO to the primary amino group of lisinopril, the spacer is activated with EDCI and coupled to an amino group of the LMWP.

preparing a lisinopril conjugate using the acid sensitive spacer 4-(iodoacetamide)-1-cyclohexene-1,2-dicarboxylic acid (R. J. Kok et al., manuscript in preparation).

### 3. Conjugation via the Thiol Group: Captopril

The ACE inhibitor captopril contains a free sulfhydryl group that offers several possibilities for the conjugation of the drug to an LMWP. Since thiol groups are the most reactive nucleophilic groups in proteins, these groups can be reacted selectively in the presence of other amino acid side chains at neutral pH (71). Many protein cross-linking procedures that have been developed are based on the specific reactivity of thiol groups (72). These reagents form either a disulfide bond, which can be cleaved by reducing agents, or a thioether bond (73). Since the latter thioether bonds were not degradable when applied in drug targeting conjugates like immunotoxins, this type of conjugation seems not suitable for the preparation of ACE inhibitor protein conjugates (74). In contrast, disulfide bond cross-linked immunotoxins proved effective *in vivo*. Several disulfide cross-linking reagents have been applied for the preparation of immunotoxins (72). Of these reagents, the heterobifunctional cross-linker SPDP was used most frequently (75). Other reagents that were developed to introduce free thiol groups into macromolecules are 2-iminothiolane (2-IT) and S-acetylmercaptosuccinic anhydride (SAMSA) (76,77). Since the unhindered disulfide bonds that are formed with these reagents can undergo premature reduction in the circulation, other cross-linkers have been

developed that contain sterically hindered disulfide bonds (74,78–84). Figure 13 shows representative examples of disulfide cross-linking reagents. The stability of the disulfide bond can be increased by the introduction of bulky substituents next to the disulfide moiety. The steric effect of the phenyl group in the ethyl S-acetyl 3-mercaptopropionthioimide (AMPT) spacer is greater than that of the methyl group, but the reduced hydrophilicity of the phenyl group decreases the reactivity of the spacer (82). Although the introduction of substituents results in an increased stability of immunotoxins both *in vitro* and *in vivo*, no major differences were found in cytotoxicity, a process for which intracellular disulfide bond degradation is a prerequisite (74,81).

Some of the disulfide spacers have a 2-pyridyl-sulfide protecting group at their thiol group. This protecting group reacts readily with free thiols to yield a disulfide bond. The other reagents contain a thioacetyl group that can be deprotected with hydroxylamine and subsequently activated with 2,2'-dipyridyl disulfide (2-DP) (72). The second coupling site of these bifunctional linkers is directed to a primary amino group of the protein. Figure 14 shows the conjugation routes of captopril with three different spacers, resulting in conjugates with a differently charged linker. Since the net charge of a protein might influence its pharmacokinetic behavior, it is interesting to compare the influence of these linkers on the drug targeting properties of these conjugates.

#### 4. Conjugation via the Phosphinate Group: Fosinopril

The ACE inhibitor fosinopril belongs to a class of ACE inhibitors that contains a phosphinate group as the Zn binding ligand (50). The prodrug fosinopril is hydrolyzed in the gastrointestinal mucosa and liver to the active metabolite

**Figure 44.13** Disulfide cross-linking reagents (72).

**Figure 44.14** Conjugation of captopril via a disulfide linkage. The three proposed conjugation routes yield conjugates with a differently charged linkage. The conjugation of captopril to the SPDP spacer can be performed directly after the reaction of SPDP with the protein. The SAMSA spacer has to be deprotected with hydroxylamine (NH<sub>2</sub>OH), and subsequently activated with 2,2'-dipyridyl disulfide (2-DP). Conjugation of captopril to the 2-IT spacer also proceeds via 2-DP activation of the spacer.

fosinoprilate (85). In this section we propose procedures for the conjugation of fosinoprilate via its phosphinate group, thus replacing the prodrug group of fosinopril by a linkage to a proteinaceous carrier. These conjugation strategies are based on the structures of prodrugs that have been developed for nucleotides that also contain phosphate or phosphonate groups (86,87). Due to the polarity of the negatively charged phosphate group, drugs with this group exert a low bioavailability and a low diffusion rate across lipid bilayers (86). Various substituents have been attached to the phosphate group to increase the lipophilicity of these drugs. Of the linkages used in these prodrugs, the phosphoramidate would be the most attractive for the preparation of a fosinoprilate–protein conjugate, since this linkage is acid sensitive (87). The phosphoramidate linkage has been applied for the lysosomotropic drug delivery of nucleotides to the liver and macrophages using neoglycoproteins or lactosaminated polylysine as drug carriers (88–90). Figure 15 shows the conjugation strategy that can be followed to prepare a fosinoprilate conjugate with a phosphoramidate linkage. To prevent the concomitant reaction of the proline-carboxyl group, this group should be esterified in a procedure similar to the one applied to lisinopril in the conjugation strategy described in Section III.D.2.

#### 5. Discussion and Conclusions

In this review multiple conjugation routes that can be applied for the conjugation of an ACE inhibitor to a protein

**Figure 44.15** Conjugation of fosinoprilate via a phosphoramidate linkage. After protection of the carboxylic acid group of fosinopril by esterification, the phosphonate group can be activated and reacted to a primary amino group of the LMWP.

are listed. The availability of structurally different but pharmacologically equivalent ACE inhibitors offers the possibility to choose between various biodegradable linkages between the drug and the carrier molecule. Although the presented strategies were designed for a specific class of drugs, the particular linkages can also be used to prepare drug-protein conjugates for other types of drugs, that is, if they contain a free carboxylic acid, amino, sulfhydryl, or phosphate group.

Of the above presented conjugates, the ones in which the proline carboxylic acid group of the drug is conjugated via a peptide spacer will be the most stable in the bloodstream. Premature liberation of the drug from the conjugate, i.e., before the conjugate is accumulated in the lysosomal compartment of the target cells, is least likely to happen with this type of linkage. However, the stability of the amide bond also limits the applicability of peptide linkages to a small subset of drugs. Another disadvantage of this conjugation route is that the first step in the synthesis route will suffer a serious loss of starting compound when the synthesis is performed with enalapril. We suggest the use of alacepril in order to avoid this problem.

For the ACE inhibitor captopril, we have suggested several strategies that are aimed at the free thiol group. The formation of such a linkage can be accomplished in a straightforward reaction with a commercially available linker. Although disulfide bonds can undergo premature degradation in the circulation, this aspect is of limited importance if the conjugate is accumulated rapidly in the target organ. Disulfide bonds as drug carrier linkers have been incorporated into many conjugates and exhibit only a moderate immunogenic response (91,92). The availability of a spectrum of coupling reagents with differently charged linkers could be instrumental in the fine-tuning of the physicochemical properties of the conjugate.

Alternative conjugation strategies are those in which either lisinopril or fosinoprilate are conjugated via an acid sensitive linkage. The degradation of this type of linkages is a nonenzymatic process and is therefore less dependent

on the physicochemical properties of the drug than enzymatic degradation. With the conjugation of lisinopril, the selective conjugation of the spacer to the protein is the critical step. Recently, we prepared such lisinopril-ACO derivatives and linked them to the LMWP lysozyme. These conjugates might show an improved stability compared to disulfide bound captopril-lysozyme conjugates.

#### IV. DRUGS FOR RENAL DRUG TARGETING AND THEIR EFFECTIVENESS AFTER CONJUGATION TO LYSOZYME

##### A. Introduction

Currently, several kinds of drugs can be used for the treatment of renal disorders. At present, angiotensin-converting enzyme (ACE) inhibitors are the first-choice drugs for the treatment of chronic kidney diseases that are characterized by loss of proteinuria and renal function. In practice, these drugs exhibit only moderate side effects. However, renal targeting of an ACE inhibitor may improve the therapy in certain cases. For example, when proteinuria is accompanied by normal blood pressure, hypotension due to ACE inhibition limits the amount of drug that can be given.

Renal inflammations like glomerulonephritis and tubulointerstitial inflammation may be treated with corticosteroids or NSAIDs. These drugs, however, can have serious side effects, and renal targeting of these drugs may allow a more aggressive treatment of the inflammation. Also, a local suppression of the immune system may be useful to prevent transplant rejection. However, it is as yet unknown whether suppression of the local immune system is sufficient or whether the systemic system should also be suppressed to prevent rejection.

Renal tumors are characterized by insensitivity to the common antitumor drugs. This is probably due to an unfavorable kinetic profile of these drugs. By renal targeting, an antitumor drug may reach the renal tumor in higher concentrations while the extrarenal side effects may be reduced.

##### B. Nonsteroidal Anti-Inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) are among the most commonly used drugs in the world. Their application ranges from the treatment of headaches to that of rheumatoid arthritis. The inhibition of cyclo-oxygenase, responsible for the synthesis of prostaglandins, causes the well-known analgesic, anti-inflammatory, and antipyretic effects of the NSAIDs. However, the inhibited prostaglandin synthesis is also responsible for frequently observed adverse effects such as gastrointestinal ulcerations and

bleedings, impairment of renal perfusion, and induction of acute airway obstruction responses. The number and severity of the adverse reactions increases with dose and time. With respect to the kidney, the inhibition of prostaglandin synthesis can have disastrous consequences, in particular when prostaglandin synthesis is required to maintain renal perfusion. This is crucial, for example, during hypovolemia or sodium restriction or in diabetic and cirrhotic patients (93–95). A significant number of people having used NSAIDs chronically now require hemodialysis.

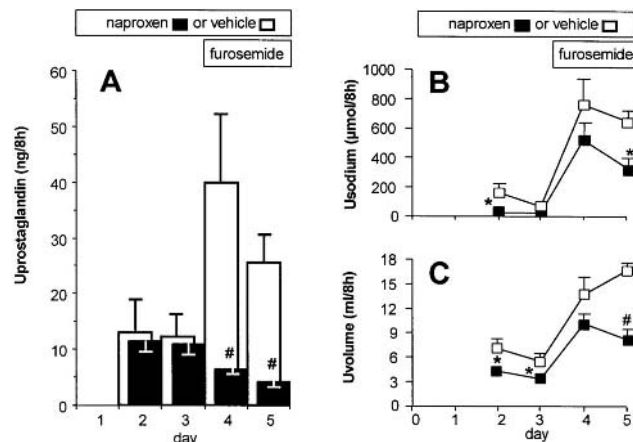

However, the application of NSAIDs in the case of several renal diseases is feasible. Before the development of ACE inhibitors, treatment with NSAIDs formed the common therapy to lower proteinuria in diabetic patients (96). Their application is still of importance when an ACE inhibitor is poorly effective or side effects hamper further treatment. In addition, the treatment of glomerulonephritis may benefit from a short-term application of NSAIDs. Finally, NSAIDs may be used for the treatment of tubular defects seen in Fanconi and Bartter's syndromes. Therefore the development of renal-selective NSAID conjugates with minimum effect on renal hemodynamics forms a challenge.

### 1. Naproxen–lysozyme

Although a conjugate with an ester spacer is favorable compared with a conjugate with a direct peptide linkage, we continued our research using a conjugate with naproxen coupled directly to lysozyme, since the synthesis of the conjugate with an ester spacer (naproxen-L-lactic acid-lysozyme) is cumbersome (Fig. 16). Fortunately, the catabolite of the conjugate with direct peptide linkage (naproxen–lysine) appeared to have an equipotent inhibitory

**Figure 44.16** Chemical structure of naproxen–lysozyme. Naproxen-N-hydroxysuccinimide was reacted with lysozyme, resulting in the naproxen–lysozyme conjugate with a peptide linkage between the free carboxylic group of naproxen and one of the free amino groups of lysozyme.

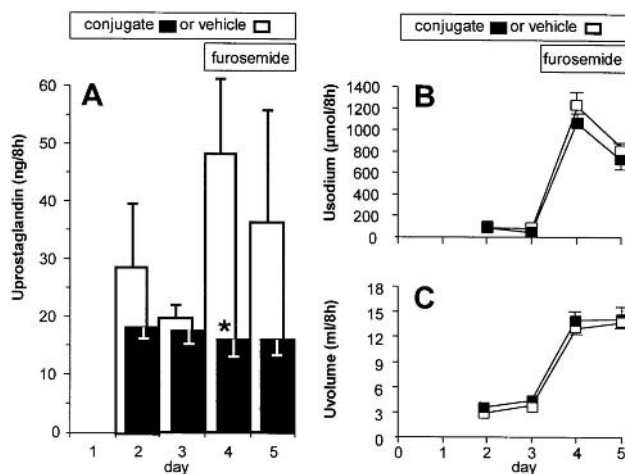

**Figure 44.17** Urinary excretion of PGE<sub>2</sub> (panel A), sodium (panel B), and water (panel C) after twice daily intravenous administration of vehicle (white bars,  $n = 6$ ) or naproxen ( $10 \text{ mg} \cdot \text{kg}^{-1} \cdot 24\text{h}^{-1}$ , black bars,  $n = 6$ ) treated rats. Furosemide  $10 \text{ mg} \cdot \text{kg}^{-1}$  was given subcutaneously on days 4 and 5 additionally to all groups of rats. Urine parameters were determined in urine collected during the daytime. Data are expressed as mean  $\pm$  SEM. Difference of naproxen versus vehicle treated rats: \*,  $p < 0.05$ ; #,  $p < 0.005$ .

effect on prostaglandin synthesis in vitro as the parent drug (63,97).

The coupling of 2 moles of naproxen to 1 mole of lysozyme did not affect the renal uptake or catabolism of the lysozyme carrier in the rat. The conjugate, like native lysozyme, rapidly accumulated in the kidney. Focusing on the drug moiety of the conjugate, it was shown that the conjugation of naproxen to lysozyme distinctly altered the kinetics of the drug. Conjugation to lysozyme resulted in a 70-fold increase in naproxen concentrations in the kidney (Fig. 17). After delivery to the kidney, naproxen was gradually released from the conjugate in the form of naproxen–lysine. This catabolite was subsequently eliminated from the kidney, and after a single injection, drug levels in the renal tissue gradually decreased with a half-life of 160 min. Since no detectable amounts of naproxen or its lysine conjugates are found in the plasma after administration of conjugate, it can be inferred that excretion into the urine is the crucial process determining the elimination half-life. The lack of diffusion to the bloodstream is favorable in relation to unwanted extrarenal effects (98).

Having obtained this promising kinetic profile, it was investigated whether naproxen–lysozyme exhibits renal effects in the rat. Naproxen, as an inhibitor of cyclo-oxygenase, blocks prostaglandin synthesis. Among others, naproxen reduces furosemide-stimulated urinary excretion of prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) as well as the natriuretic and diuretic effects of furosemide. Studies with the conjugate

**Figure 44.18** Urinary excretion of PGE<sub>2</sub> (panel A), sodium (panel B), and water (panel C) after twice daily intravenous administration of vehicle (white bars,  $n = 6$ ) or naproxen-lysosome ( $10 \text{ mg} \cdot \text{kg}^{-1} \cdot 24\text{h}^{-1}$ , black bars,  $n = 6$ ) treated rats. Furosemide  $10 \text{ mg} \cdot \text{kg}^{-1}$  was given subcutaneously on days 4 and 5 additionally to all groups of rats. Urine parameters were determined in urine collected during the daytime. Data are expressed as mean  $\pm$  SEM. Difference of naproxen versus vehicle treated rats: \*,  $p < 0.05$ ; #,  $p < 0.005$ .

showed that naproxen-lysosome treatment clearly prevents furosemide-induced excretion of PGE<sub>2</sub>. This occurred in a dose of naproxen that was not effective in the unconjugated form (Fig. 17A and 18A) (99).

Surprisingly, this effect occurred in the absence of a change in natriuretic and diuretic response to furosemide (Figs. 17B and 18B). In this respect, the pharmacological effect differed from treatment with a high dose of free naproxen. An explanation for these differences remains to be found. One possibility is that there is a difference in intrarenal kinetics of the NSAID conjugate compared with the parent drug. Free naproxen is extensively reabsorbed in the distal tubule of the kidney, via which route it may effectively inhibit prostaglandin synthesis in the medullary interstitial cells. On the other hand, naproxen-lysine is more hydrophilic and may be unable to reach these sites of prostaglandin synthesis involved in the furosemide-induced excretion of sodium and water. These data show that renal drug targeting preparations can also be used as tools to unravel the mechanisms of renal therapeutic effect.

## C. Angiotensin Converting Enzyme Inhibitors

### 1. The Renin Angiotensin System

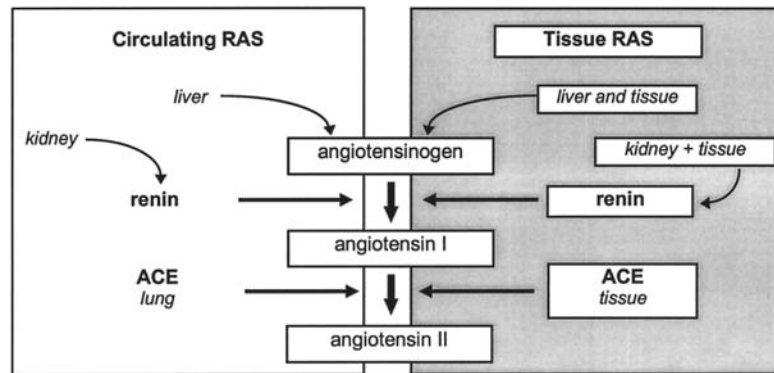

Angiotensin converting enzyme (ACE) inhibitors form a relatively new class of antihypertensive drugs acting on the renin angiotensin system (RAS). The RAS is an enzymatic

system that results in the formation of angiotensin II, via two consecutive steps. In the first step, angiotensinogen, synthesized in the liver, is cleaved by the soluble protease renin into the decapeptide angiotensin I. In the second step angiotensin I is converted to the bioactive octapeptide angiotensin II by the membrane bound protease ACE, localized at the luminal side of epithelial cells in the gastrointestinal tract, the renal proximal tubule, and at the endothelium of vascular cells (100). Finally, degradation of angiotensin II into angiotensin 1-7 and angiotensin 2-8 by ACE or other endopeptidases occurs rapidly (Fig. 19).

In the classical view, the RAS serves as a ‘‘circulating endocrine system.’’ The presence of many components of the RAS in other tissues has led to the concept of a local acting tissue RAS (101-105). Particularly, the detection of much higher concentrations of angiotensin II in the renal tubular fluid than in the plasma has focused attention on a possible physiological role for the RAS in the kidneys (106,107). However, the exact contribution of this local renal RAS has not been elucidated so far (see Section IV.C.2). In providing a renal specific ACE inhibitor, drug targeting constructs may offer a pharmacological approach to determine the effects of renal ACE inhibition.

### 2. Effects of Angiotensin II and ACE Inhibitors

Angiotensin II exerts numerous actions both systemically and intrarenally. The regulation of systemic blood pressure is among the most important roles of angiotensin II. A number of different mechanisms contribute to the blood-pressure-stimulating activity. First, angiotensin II produces sodium (and water) retention through a direct effect on the proximal tubular cells as well as the release of aldosterone from the adrenal gland (108,109). Additionally, angiotensin II regulates systemic blood pressure and renal hemodynamics resulting from its strong vasoconstrictive properties. Intrarenally, this leads to an increased glomerular capillary pressure and a reduction of the renal blood flow (105,109). Several studies have investigated the contribution of intrarenal angiotensin II production on systemic blood pressure (110), renal blood flow, and urinary sodium excretion (111-114) using intrarenal or intra-arterial administration of low dosages of ACE inhibitor to obtain a renal specific ACE inhibition. These studies made clear that local ACE inhibition is likely to have profound effects on renal physiology and pathology as well as on systemically related parameters. However, the techniques used in these investigations all required special surgical procedures. Moreover, the contribution of extrarenal ACE inhibition cannot be fully excluded in these investigations due to the administration of active ACE inhibitor. A systemically inactive renal specific ACE inhibitor-LMWP conjugate may provide a pharmacological tool to solve the problems of surgery and extrarenal effects.

**Figure 44.19** The renin-angiotensin system (RAS). In the circulating RAS, liver-derived angiotensinogen is converted by kidney-derived renin into angiotensin I in the circulation. Angiotensin I is converted into angiotensin II by angiotensin converting enzyme (ACE) in the lungs during the passage of the blood through the pulmonary circulation. ACE is a membrane bound protein, oriented with its active site at the outside of the cell. In the tissue RAS, the soluble components (renin, angiotensinogen, or angiotensin I) of the RAS are either synthesized locally or acquired from the circulation. Angiotensin II can be generated locally when both ACE and angiotensin I are present.

Besides the hemodynamic actions, angiotensin II also has trophic effects on vascular smooth muscle cells and mesangial cells (108,115). Angiotensin II has direct effects on cell growth, as well as indirect effects by stimulating the expression of other growth factors and an activation of the immune system (21,115,116). Finally, angiotensin II is probably an important mediator of cytokine release and progressive inflammation processes causing renal function loss during chronic renal disease (21).

The development of ACE inhibitors caused a breakthrough in the drug treatment of renal failure in particular. These drugs were shown to reduce proteinuria and retard the chronic progression of renal function loss in both diabetic and nondiabetic renal disease (117–120). The mechanisms by which the ACE inhibitors could show their renoprotective effect are summarized in Table 3. An important renoprotective mechanism of ACE inhibitors is their influence on the glomerular capillary pressure, caused

by vasodilation of the arterioles in the glomerulus (105,121,122). This pressure lowering results in an improved glomerular permselectivity and a marked decrease of proteinuria (120,123,124). Since proteinuria is now considered as an independent risk factor for renal function loss (125), the reduction of proteinuria may be related to the long-term renoprotective effect (120). However, ACE inhibition using standard drug dosages does not always guarantee an adequate reduction of proteinuria. Further increment of the dose is hampered by the concomitant fall of systemic blood pressure. Since intrarenal production of angiotensin II is believed to play an important role in the development and progression of renal disorders, renal specific ACE inhibitor-lysozyme conjugates may provide a way to improve renal drug therapy.

### 3. Captopril-Lysozyme

We have coupled the ACE inhibitor captopril to the LMWP lysozyme via a disulfide bond (see Section III.D.3, Fig. 20). Conjugation of captopril to lysozyme resulted in a sixfold increase of captopril accumulation in the kidney. This modest enrichment, as compared to naproxen-lysozyme, is due to the fact that free captopril is highly cleared by the kidney itself. After renal uptake, captopril was rapidly released from the conjugate as indicated by the rapid decrease of renal captopril levels in time. The difference in renal half-life of naproxen and captopril after delivery is likely to be due to an unequal rate of release from the lysozyme conjugates (126). Whereas naproxen-lysozyme requires a peptidase for cleavage, captopril is released from the conjugate enzymatically by  $\beta$ -lyase and/or nonenzy-

**Table 44.3** Postulated Renoprotective Mechanisms of ACE Inhibitors

Normalization of systemic blood pressure
Control of glomerular capillary pressure
Decreased mesangial macromolecular deposition
Decreased mesangial proliferation
Improved glomerular permselectivity
Decreased proteinuria
Decreased tubulointerstitial injury
Decreased procollagen formation
Improved serum-lipid profiles

**Figure 44.20** Chemical structure of the captopril–lysine conjugate. Captopril is coupled via a disulfide bond to the thiol group of the SMPT spacer. The amine-reactive end of the spacer is linked to a lysine residue of lyszyme.

matically by thiol-disulfide exchange with endogenous thiols. To reduce the rate of captopril–lyszyme breakdown, two different cross-linking reagents, SPDP and SMPT, were tested. Although an SMPT link between two proteins is in principle less susceptible to disulfide reduction, no difference in degradation rate was found between the SPDP and SMPT captopril–lyszyme conjugates (127).

In an *ex vivo* experiment in the rat, we measured the extent of ACE inhibition in plasma and the kidney after a single intravenous injection of the conjugate and an equimolar dosage of free captopril. Captopril–lyszyme caused a similar but more sustained renal ACE inhibition (Fig. 21B). The inhibition of plasma ACE activity was also markedly reduced but not entirely prevented (Fig. 21A). Possibly, the disulfide bond is partly degraded within the circulation. However, transportation of free captopril back into the circulation after renal degradation of the conjugate provides an alternative explanation for the observed plasma ACE inhibition. The rapid intracellular release may provide a sufficient driving force for transport across the basolateral membranes (R. F. G. Haverdings et al., manuscript in preparation).

Importantly, captopril–lyszyme did not significantly affect systemic blood pressure, whereas an equimolar dose of captopril itself largely decreased blood pressure (Fig. 22). While free captopril ( $5 \text{ mg} \cdot \text{kg}^{-1} \cdot 6\text{h}^{-1}$ ) completely prevented the angiotensin-I-induced pressor response, this response was more maintained after infusion of equimolar

amounts of captopril–lyszyme. However, in line with the direct ACE activity measurements in renal tissue and plasma, the angiotensin-I-induced pressor response was still present in captopril–lyszyme treated rats, but also less than in untreated rats, suggesting that systemic activity was not fully prevented (R. F. G. Haverdings et al., manuscript in preparation).

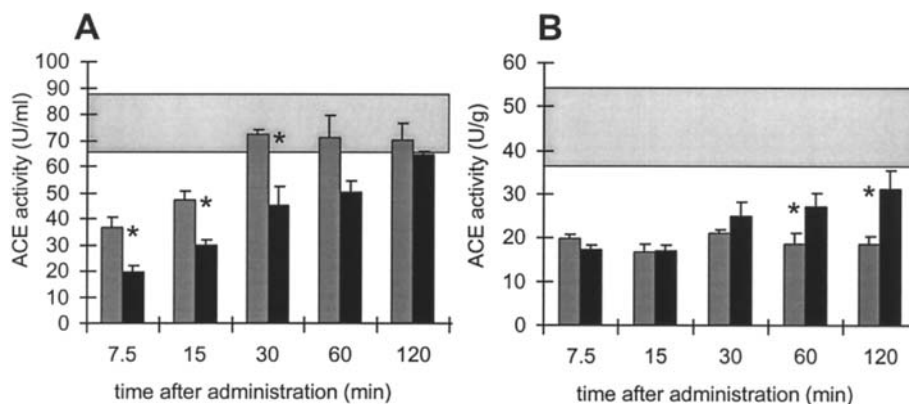

Both free and conjugated captopril did not affect glomerular filtration. Renal plasma flow increased to the same extent during treatment of free and conjugated captopril ( $1 \text{ mg} \cdot \text{kg}^{-1} \cdot 6\text{h}^{-1}$ ). Although a complete dose–effect relation was not performed, we can conclude that captopril still provides clear effects on the renal plasma flow after conjugation to lyszyme. Whether this effect is determined by intrarenal or systemic ACE inhibition remains to be studied.

At the moment, the synthesis of lyszyme conjugates with ACE inhibitors other than captopril is studied. Some of these ACE inhibitors may be advantageous for renal delivery; an example is lisinopril. The amount of conjugate required for therapy can be significantly reduced when using lisinopril, which has a higher affinity for ACE. Furthermore, the plasma stability of the conjugate may be increased by using an ACE inhibitor that is conjugated to lyszyme via a linkage that is more stable in plasma (e.g., lisinopril can in principle be coupled via an acid sensitive spacer).

#### D. Doxorubicin

The antineoplastic agent doxorubicin (adriamycin) is a standard drug in the chemotherapy of a variety of cancer diseases, including bladder carcinoma. However, although effective, the repeated administration of these drugs retrogradically via the urethra is a rather patient-unfriendly method (128,129). Unfortunately, the intravenous application is restricted due to the low urinary excretion of doxorubicin and the occurrence of cardiac toxicity, which is related to the total cumulative doxorubicin dose. Drug targeting may be able to prevent the occurrence of these side effects after intravenous administration and may form an alternative approach to bladder instillation.

During *in vivo* testing of doxorubicin conjugates it is important to realize, however, that the doxorubicin toxicity in rodents is shifted toward the kidney. The degeneration of the negatively charged glycoproteins in the glomerular basement membrane is followed by progressive loss of glomerular permselectivity. As a consequence, serum proteins are excreted in the urine (proteinuria) once the tubular protein reabsorption transport is overloaded. Moreover, the excessive amounts of reabsorbed protein congest the lysosomal compartment, causing tubular protein cast formation

**Figure 44.21** ACE activity in plasma (panel A) and kidneys (panel B) after single intravenous administration of captopril-lysozyme (lysozyme  $0.2 \text{ mg} \cdot \text{kg}^{-1}$  captopril, corresponding to  $33 \text{ mg} \cdot \text{kg}^{-1}$  lysozyme, striped bars,  $n = 6$ ) and unbound captopril-lysozyme ( $0.2 \text{ mg} \cdot \text{kg}^{-1}$  captopril plus  $33 \text{ mg} \cdot \text{kg}^{-1}$  lysozyme, black bars,  $n = 6$ ). The shaded area indicates the 95% confidence interval of the ACE activity of control rats. Data are expressed as mean  $\pm$  SEM. Difference of conjugate versus captopril treated rats: \*,  $p < 0.05$ .

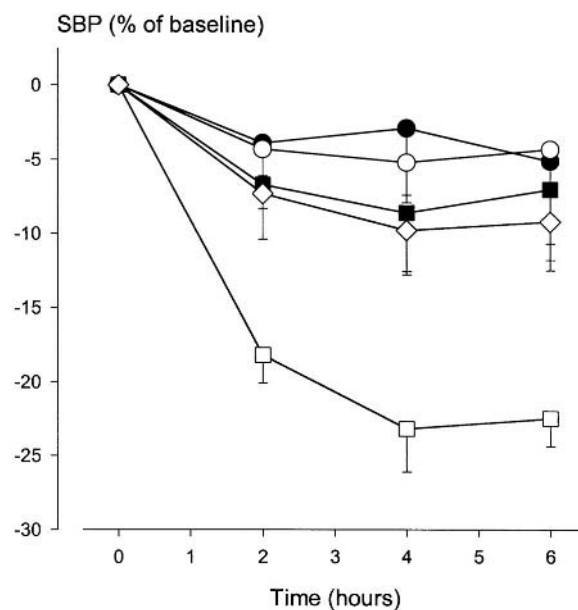

and rupture of lysosomes. Due to the release of aggressive enzymes from the lysosomes in the cytosol, cell death occurs. This vicious circle leads to a progressive loss of nephrons and a fall of renal function with time (130–134).

Since the doxorubicin-induced proteinuria in rodents resembles the nephrotic syndrome in man, this animal model is generally used to study the effectiveness of antiproteinuric drugs (135,136) such as our newly developed renal specific antiproteinuric drug conjugates.

### 1. Doxorubicin-Lysozyme

In previous sections the selective accumulation of LMWPs and drug-lysozyme conjugates in the renal proximal tubular cell has been discussed. Furthermore, in Section III.B we stressed the importance of positive charges in the lysozyme molecule for this tubular uptake. For tubular reuptake only a limited number of amino groups can be substituted to prevent loss of conjugate via the urine, and excessive drug loading may alter the favorable tissue distribution (45).

Note that tubular reabsorption should be prevented when using LMWPs for drug delivery to the distal urinary tract. We have considered the possibility of reacting all available free amino groups of the LMWP with drug molecules to prevent the tubular uptake process. Doxorubicin was coupled to lysozyme via the *cis*-aconityl acid-labile spacer, with an average coupling degree of 6.3 mol doxorubicin to 1 mol of lysozyme (Fig. 23). Since lysozyme contains seven free amino groups, an almost complete derivatization was obtained. In vitro studies showed a time dependent release of doxorubicin up to 45% after 6 hours at pH 4.5 and  $37^\circ\text{C}$  (137).

**Figure 44.22** Systemic blood pressure during 6 hour infusion of vehicle (open circles,  $n = 6$ ), lysozyme ( $100 \text{ mg} \cdot \text{kg}^{-1} \cdot 6\text{h}^{-1}$ , closed circles,  $n = 6$ ), captopril ( $1 \text{ mg} \cdot \text{kg}^{-1} \cdot 6\text{h}^{-1}$ , open diamonds,  $n = 6$ ), captopril ( $5 \text{ mg} \cdot \text{kg}^{-1} \cdot 6\text{h}^{-1}$ , open squares,  $n = 6$ ) or captopril-lysozyme ( $5 \text{ mg} \cdot \text{kg}^{-1} \cdot 6\text{h}^{-1}$ , corresponding to  $100 \text{ mg} \cdot \text{kg}^{-1} \cdot 6\text{h}^{-1}$  lysozyme, closed squares,  $n = 6$ ). Values given at  $t = 0 \text{ h}$  represent mean baseline values of 2 hour vehicle infusion in all groups. Data are expressed as mean  $\pm$  SEM.

**Figure 44.23** Chemical structure of the doxorubicin–aconityl–lysozyme conjugate.

The urinary kinetics of doxorubicin–lysozyme and free doxorubicin were studied in healthy rats. Following a single intravenous injection of  $2 \text{ mg} \cdot \text{kg}^{-1}$  free doxorubicin, only 4% of the dose was recovered in the urine 24 hours after administration. In contrast, doxorubicin–lysozyme resulted in a much higher urinary excretion of doxorubicin: 27% and 39% of the dose after injection of 2 and  $10 \text{ mg} \cdot \text{kg}^{-1}$ , respectively. In the same study, the development of proteinuria was followed. After a single injection of  $2 \text{ mg} \cdot \text{kg}^{-1}$  free doxorubicin, all rats developed a marked proteinuria and glomerulosclerosis with a maximum of approximately 450 mg protein per day. Rats treated with either 2 or  $10 \text{ mg} \cdot \text{kg}^{-1}$  doxorubicin–lysozyme did not develop proteinuria or glomerulosclerosis (Fig. 24) (137). Studies on the efficacy of this conjugate for the treatment of bladder cancer are now in progress. Rapid release of sufficient doxorubicin from the conjugate present in the bladder lumen can in principle be produced by acidification of the urine. This may provide sufficiently high concentrations in the bladder, enabling diffusion into the tumor.

## V. CONCLUDING REMARKS

In this chapter we have pointed out that the kidney is a feasible target organ for drug delivery. The kidney offers a number of characteristics including a high blood perfusion and efficient uptake mechanisms that may retain the tubular delivered drug. Since a number of renal diseases can still not be effectively treated, or serious adverse effects hamper drug treatment, selective drug delivery to the

**Figure 44.24** Time course of urinary protein excretion after single intravenous administration. Open squares:  $2 \text{ mg} \cdot \text{kg}^{-1}$  unbound doxorubicin ( $n = 5$ ); black/white squares:  $2 \text{ mg} \cdot \text{kg}^{-1}$  doxorubicin–aconityl–lysozyme ( $n = 6$ ); closed squares:  $10 \text{ mg} \cdot \text{kg}^{-1}$  doxorubicin–aconityl–lysozyme ( $n = 5$ ). Data are expressed as mean  $\pm$  SEM.

kidney, leading to local accumulation of drugs, could help to overcome some of these problems. In this chapter we have described the low-molecular-weight protein approach to target the proximal tubular cell in the kidney. Since this cell type is essential in the regulation of sodium and fluid homeostasis as well as in the induction of renal inflamma-

tory processes, it appears a suitable target for drug delivery. At present, we have investigated the effectiveness of ACE inhibitors and NSAIDs, drugs that are presently used in the drug treatment of renal disorders. Coupling of these drugs to the renal carrier resulted in a marked increase in renal selectivity as well as a change in their pharmacological profile. Additionally, we showed that charge modifications in the lysozyme molecule can be applied in the selective delivery of doxorubicin to the urinary bladder.

In future, these developments may not only improve the safety and efficacy of drug treatment, but therapy may also benefit from new pathophysiological insights provided by organ selective pharmacological tools.
